Indeed, if $\mu_0$ is an ergodic invariant measure for the transformation $T_0$, then the ergodic theorem ensures that for every $\mu$-integrable function $\varphi : M \to \mathbb{R}$ and for $\mu$-almost every point $x$ in the manifold $M$, the time average $\tilde{\varphi}(x) = \lim_{n\to+\infty} n^{-1} \sum_{j=0}^{n-1} \varphi(T_0^j(x))$ exists and equals the space average $\int \varphi \, \mathrm{d}\mu_0$. A physical measure $\mu$ is an invariant probability measure for which it is required that time averages of every continuous function $\varphi$ exist for a positive Lebesgue measure (volume) subset of the space and be equal to the space average $\mu(\varphi)$.

We note that if $\mu$ is a density, that is, absolutely continuous with respect to the volume measure, then the ergodic theorem ensures that $\mu$ is physical. However, not every physical measure is absolutely continuous. To see why in a simple example, we consider a singularity $p$ of a vector field which is an attracting fixed point (a sink), then the Dirac mass $\delta_p$ concentrated on $p$ is a physical probability measure, since every orbit in the basin of attraction of $p$ will have asymptotic time averages for any continuous observable $\varphi$ given by $\varphi(p) = \delta_p(\varphi)$.

Physical measures need not be unique or even exist in general but, when they do exist, it is desirable that the set of points whose asymptotic time averages are described by physical measures (such a set is called the basin of the physical measures) be of full Lebesgue measure – only an exceptional set of points with zero volume would not have a well-defined asymptotic behavior. This is yet far from being proved for most dynamical systems, in spite of much recent progress in this direction.

There are robust examples of systems admitting several physical measures whose basins together are of full Lebesgue measure, where "robust" means that there are whole open sets of maps of a manifold in the $C^2$ topology exhibiting these features. For typical parametrized families of one-dimensional unimodal maps (maps of the circle or of the interval with a unique critical point), it is known that the above scenario holds true for Lebesgue almost every parameter. It is known that there are systems admitting no physical measure, but the only known cases are not robust, that is, there are systems arbitrarily close which admit physical measures.

It is hoped that conclusions drawn from models admitting physical measures to be effectively observable in the physical processes being modeled. In order to lend more weight to this expectation, researchers demand stability properties from such invariant measures.

**Stochastic stability** There are two main issues concerning a mathematical model, both from theoretical and practical standpoints. The first one is to describe the asymptotic behavior of most orbits, that is, to understand what happens to orbits when time tends to infinity. The second and equally important one is to ascertain whether the asymptotic behavior is stable under small changes of the system, that is, whether the limiting behavior is still essentially the same after small changes to the law of evolution. In fact, since models are always simplifications of the real system (we cannot ever take into account the whole state of the universe in any model), the lack of stability considerably weakens the conclusions drawn from such models, because some properties might be specific to it and not in any way resembling the real system.

Random dynamical systems come into play in this setting when we need to check whether a given model is stable under small random changes to the law of evolution.

In more precise terms, we suppose that there is a dynamical system (a transformation or a flow) admitting a physical measure $\mu_0$ and we take any random dynamical system obtained from this one through the introduction of small random perturbations on the dynamics, as in Examples 1–4 or in the section on "Random perturbations of flows," with the noise level $\epsilon > 0$ close to zero.

In this setting if, for any choice $\mu_\epsilon$ of invariant measure for the random dynamical system for all $\epsilon > 0$ small enough, the set of accumulation points of

the family $(\mu_\epsilon)_{\epsilon>0}$, when $\epsilon$ tends to 0 – also known as zero-noise limits – is formed by physical measures or, more generally, by convex linear combinations of physical measures, then the original unperturbed dynamical system is stochastically stable.

This intuitively means that the asymptotic behavior measured through time averages of continuous observables for the random system is close to the behavior of the unperturbed system.

Recent progress in one-dimensional dynamics has shown that, for typical families $(f_t)_{t\in(0,1)}$ of maps of the circle or of the interval having a unique critical point, a full Lebesgue measure subset $T$ of the set of parameters is such that, for $t \in T$, the dynamics of $f_t$ admits a unique stochastically stable (under additive noise type random perturbations) physical measure $\mu_t$ whose basin has full measure in the ambient space (either the circle or the interval). Therefore, models involving one-dimensional unimodal maps typically are stochastically stable.

In many settings (e.g., low-dimensional dynamical systems), Lyapunov exponents can be given by time averages of continuous functions – for example, the time average of $\log\|DT_0\|$ gives the biggest exponent. In this case, stochastic stability directly implies stability of the Lyapunov exponents under small random perturbations of the dynamics.

**Example 6** (Stochastically stable examples). Let $T_0 : \mathbb{S}^1 \circlearrowleft$ be a map such that $\lambda$, the Lebesgue (length) measure on the circle, is $T_0$-invariant and ergodic. Then $\lambda$ is physical.

We consider the parametrized family $T_t : \mathbb{S}^1 \times \mathbb{S}^1 \to \mathbb{S}^1$, $(t, x) \mapsto x + t$ and a family of probability measures $\theta_\epsilon = (\lambda(-\epsilon, \epsilon))^{-1} \cdot (\lambda \mid (-\epsilon, \epsilon))$ given by the normalized restriction of $\lambda$ to the $\epsilon$-neighborhood of 0, where we regard $\mathbb{S}^1$ as the Lie group $\mathbb{R}/\mathbb{Z}$ and use additive notation for the group operation. Since $\lambda$ is $T_t$-invariant for every $t \in \mathbb{S}^1, \lambda$ is also an invariant measure for the measure-preserving random system

$$\mathcal{S} : (\mathbb{S}^1 \times \Omega^{\mathbb{N}}, \lambda \times \theta_\epsilon^{\mathbb{N}})\circlearrowleft$$

for every $\epsilon > 0$, where $\Omega = (\mathbb{S}^1)^{\mathbb{N}}$. Hence, $(T_0, \lambda)$ is stochastically stable under additive noise perturbations.

Concrete examples can be irrational rotations, $T_0(x) = x + \alpha$ with $\alpha \in \mathbb{R}\backslash\mathbb{Q}$, or expanding maps of the circle, $T_0(x) = b \cdot x$ for some $b \in \mathbb{N}, n \geq 2$. Analogous examples exist in higher-dimensional tori.

**Example 7** (Stochastic stability depends on the type of noise). In spite of the straightforward method for obtaining stochastic stability in Example 6, for example, an expanding circle map $T_0(x) = 2 \cdot x$, we can choose a continuous family of probability measures $\theta_\epsilon$ such that the same map $T_0$ is not stochastically stable.

It is well known that $\lambda$ is the unique absolutely continuous invariant measure for $T_0$ and also the unique physical measure. Given $\epsilon > 0$ small, let us define transition probability measures as follows:

$$p_\epsilon(\cdot \mid z) = \frac{\lambda \mid [\phi_\epsilon(z) - \epsilon, \phi_\epsilon(z) + \epsilon]}{\lambda([\phi_\epsilon(z) - \epsilon, \phi_\epsilon(z) + \epsilon])}$$

where $\phi_\epsilon \mid (-\epsilon, \epsilon) \equiv 0$, $\phi_\epsilon \mid [\mathbb{S}^1 \setminus (-2\epsilon, 2\epsilon)] \equiv T_0$, and over $(-2\epsilon, -\epsilon] \cup [\epsilon, 2\epsilon)$, we can define $\phi_\epsilon$ by interpolation in order that it be smooth.

In this setting, every random orbit starting at $(-\epsilon, \epsilon)$ never leaves this neighborhood in the future. Moreover, it is easy to see that every random orbit eventually enters $(-\epsilon, \epsilon)$. Hence, every invariant probability measure $\mu_\epsilon$ for this Markov chain model is supported in $[-\epsilon, \epsilon]$. Thus, letting $\epsilon \to 0$, we see that the only zero-noise limit is $\delta_0$, the Dirac mass concentrated at 0, which is not a physical measure for $T_0$.

This construction can be achieved in a random-maps setting, but only in the $C^0$ topology – it is not possible to realize this Markov chain by random maps that are $C^1$ close to $T_0$ for $\epsilon$ near 0.

### Characterization of Measures Satisfying the Entropy Formula

Significant effort has been put in recent years in extending important results from dynamical systems to the random setting. Among many examples are: the local conjugacy between the dynamics near a hyperbolic fixed point and the action of the derivative of the map on the tangent space, the stable/unstable manifold theorems for hyperbolic invariant sets and the notions and properties of metric and topological entropy, dimensions and equilibrium states for potentials on random (or fuzzy) sets.

The characterization of measures satisfying the entropy formula is one important result whose extension to the setting of iteration of independent and identically distributed random maps has recently had interesting new consequences back into nonrandom dynamical systems.

**Metric entropy for random perturbations** Given a probability measure $\mu$ and a partition $\xi$ of $M$, except perhaps for a subset of $\mu$-null measure, the entropy of $\mu$ with respect to $\xi$ is defined to be

$$H_\mu(\xi) = -\sum_{R\in\xi} \mu(R) \log \mu(R)$$

where the convention that $0 \log 0 = 0$ has been used. Given another finite partition $\zeta$, we write $\xi \vee \zeta$ to indicate the partition obtained through intersection of every element of $\xi$ with every element of $\zeta$, and analogously for any finite number of partitions. If $\mu$ is also a stationary measure for a random-maps model (see the section "Random maps"), then for any finite measurable partition $\xi$ of $M$,

$$h_\mu(\xi) = \inf_{n \geq 1} \frac{1}{n} \int H_\mu \left( \bigvee_{i=0}^{n-1} \left( T^i_{\underline{\omega}} \right)^{-1} (\xi) \right) \mathrm{d}p^{\mathbb{N}}(\underline{\omega})$$

is finite and is called the entropy of the random dynamical system with respect to $\xi$ and to $\mu$.

We define $h_\mu = \sup_\xi h_\mu(\xi)$ as the metric entropy of the random dynamical system, where the supremo is taken over all $\mu$-measurable partitions. An important point here is the following notion: setting $\mathcal{A}$ the Borel $\sigma$-algebra of $M$, we say that a finite partition $\xi$ of $M$ is a random generating partition for $\mathcal{A}$ if

$$\bigvee_{i=0}^{+\infty} (T^i_{\underline{\omega}})^{-1}(\xi) = \mathcal{A}$$

(except $\mu$-null sets) for $p^{\mathbb{N}}$-almost all $\omega \in \Omega = \mathcal{U}^{\mathbb{N}}$. Then a classical result from ergodic theory ensures that we can calculate the entropy using only a random generating partition $\xi$, that is, $h_\mu = h_\mu(\xi)$.

**The entropy formula** There exists a general relation ensuring that the entropy of a measure-preserving differentiable transformation $(T_0, \mu)$ on a compact Riemannian manifold is bounded from above by the sum of the positive Lyapunov exponents of $T_0$

$$h_\mu(T_0) \leq \int \sum_{\lambda_i(x) > 0} \lambda_i(x) \, \mathrm{d}\mu(x)$$

The equality (entropy formula) was first shown to hold for diffeomorphisms preserving a measure equivalent to the Riemannian volume, and then the measures satisfying the entropy formula were characterized: for $C^2$ diffeomorphisms the equality holds if and only if the disintegration of $\mu$ along the unstable manifolds is formed by measures absolutely continuous with respect to the Riemannian volume restricted to those submanifolds. The unstable manifolds are the submanifolds of $M$ everywhere tangent to the Lyapunov subspaces corresponding to all positive Lyapunov exponents, analogous to "integrating the distribution of Lyapunov subspaces corresponding to positive exponents" – this particular point is a main subject of smooth ergodic theory for nonuniformly hyperbolic dynamics.

Both the inequality and the characterization of stationary measures satisfying the entropy formula were extended to random iterations of independent and identically distributed $C^2$ maps (noninjective and admitting critical points), and the inequality reads

$$h_\mu \leq \iint \sum_{\lambda_i(x,\omega) > 0} \lambda_i(x, \omega) \, \mathrm{d}\mu(x) \, \mathrm{d}p^{\mathbb{N}}(\omega)$$

where the functions $\lambda_i$ are the random variables provided by the random multiplicative ergodic theorem.

## Construction of Physical Measures as Zero-Noise Limits

The characterization of measures which satisfy the entropy formula enables us to construct physical measures as zero-noise limits of random invariant measures in some settings, outlined in the following, obtaining in the process that the physical measures so constructed are also stochastically stable.

The physical measures obtained in this manner arguably are natural measures for the system, since they are both stable under (certain types of) random perturbations and describe the asymptotic behavior of the system for a positive-volume subset of initial conditions. This is a significant contribution to the state-of-the-art of present knowledge on dynamics from the perspective of random dynamical systems.

**Hyperbolic measures and the entropy formula** The main idea is that an ergodic invariant measure $\mu$ for a diffeomorphism $T_0$ which satisfies the entropy formula and whose Lyapunov exponents are everywhere nonzero (known as hyperbolic measure) necessarily is a physical measure for $T_0$. This follows from standard arguments of smooth nonuniformly hyperbolic ergodic theory.

Indeed $\mu$ satisfies the entropy formula if and only if $\mu$ disintegrates into densities along the unstable submanifolds of $T_0$. The unstable manifolds $W^{\mathrm{u}}(x)$ are tangent to the subspace corresponding to every positive Lyapunov exponent at $\mu$-almost every point $x$, they are an invariant family, that is, $T_0(W^{\mathrm{u}}(x)) = W^{\mathrm{u}}(x)$ for $\mu$-almost every $x$, and distances on them are uniformly contracted under iteration by $T_0^{-1}$.

If the exponents along the complementary directions are nonzero, then they must be negative and smooth ergodic theory ensures that there exist stable manifolds, which are submanifolds $W^{\mathrm{s}}(x)$ of

$M$ everywhere tangent to the subspace of negative Lyapunov exponents at $\mu$-almost every point $x$, form a $T_0$-invariant family ($T_0(W^s(x)) = W^s(x)$, $\mu$-almost everywhere), and distances on them are uniformly contracted under iteration by $T_0$.

We still need to understand that time averages are constant along both stable and unstable manifolds, and that the families of stable and unstable manifolds are absolutely continuous, in order to realize how a hyperbolic measure is a physical measure.

Given $y \in W^s(x)$, the time averages of $x$ and $y$ coincide for continuous observables simply because dist $(T_0^n(x), T_0^n(y)) \to 0$ when $n \to +\infty$. For unstable manifolds, the same holds when considering time averages for $T_0^{-1}$. Since forward and backward time averages are equal $\mu$-almost everywhere, the set of points having asymptotic time averages given by $\mu$ has positive Lebesgue measure if the set

$$B = \bigcup \{ W^s(y) \colon y \in W^u(x) \cap \mathrm{supp}(\mu) \}$$

has positive volume in $M$, for some $x$ whose time averages are well defined.

Now, stable and unstable manifolds are transverse everywhere where they are defined, but they are only defined $\mu$-almost everywhere and depend measurably on the base point, so we cannot use transversality arguments from differential topology, in spite of $W^u(x) \cap \mathrm{supp}(\mu)$ having positive volume in $W^u(x)$ by the existence of a smooth disintegration of $\mu$ along the unstable manifolds. However, it is known for smooth ($C^2$) transformations that the families of stable and unstable manifolds are absolutely continuous, meaning that projections along leaves preserve sets of zero volume. This is precisely what is needed for measure-theoretic arguments to show that $B$ has positive volume.

**Zero-noise limits satisfying the entropy formula** Using the extension of the characterization of measures satisfying the entropy formula for the random-maps setting, we can build random dynamical systems, which are small random perturbations of a map $T_0$, having invariant measures $\mu_\epsilon$ satisfying the entropy formula for all sufficiently small $\epsilon > 0$. Indeed, it is enough to construct small random perturbations of $T_0$ having absolutely continuous invariant probability measures $\mu_\epsilon$ for all small enough $\epsilon > 0$.

In order to obtain such random dynamical systems, we choose families of maps $T : \mathcal{U} \times M \to M$ and of probability measures $(\theta_\epsilon)_{\epsilon>0}$ as in Examples 3 and 4, where we assume that $o \in \mathcal{U}$, so that $T_0$ belongs to the family. Letting $T_x(u) = T(u, x)$ for all $(u, x) \in \mathcal{U} \times M$, we then have that $T_x(\theta_\epsilon)$ is absolutely continuous. This means that sets of perturbations of positive $\theta_\epsilon$-measure send points of $M$ onto positive-volume subsets of $M$. Such a perturbation can be constructed for every continuous map of any manifold.

In this setting, any invariant probability measure for the associated skew-product map $\mathcal{S} : \Omega \times M \circlearrowleft$ of the form $\theta_\epsilon^{\mathbb{N}} \times \mu_\epsilon$ is such that $\mu_\epsilon$ is absolutely continuous with respect to volume on $M$. Then the entropy formula holds:

$$h_{\mu_\epsilon} = \iint \sum_{\lambda_i(x,\omega)>0} \lambda_i(x, \omega) \, \mathrm{d}\mu_\epsilon(x) \, \mathrm{d}\theta_\epsilon^{\mathbb{N}}(\omega)$$

Having this and knowing the characterization of measures satisfying the entropy formula, it is natural to look for conditions under which we can guarantee that the above inequality extends to any zero-noise limit $\mu_0$ of $\mu_\epsilon$ when $\epsilon \to 0$. In this case, $\mu_0$ satisfies the entropy formula for $T_0$.

If, in addition, we are able to show that $\mu_0$ is a hyperbolic measure, then we obtain a physical measure for $T_0$ which is stochastically stable by construction.

These ideas can be carried out completely for hyperbolic diffeomorphisms, that is, maps admitting a continuous invariant splitting of the tangent space into two sub-bundles $E \oplus F$ defined everywhere with bounded angles, whose Lyapunov exponents are negative along $E$ and positive along $F$. Recently, maps satisfying weaker conditions were shown to admit stochastically stable physical measures following the same ideas.

These ideas also have applications to the construction and stochastic stability of physical measure for strange attractors and for all mathematical models involving ordinary differential equations or iterations of maps.

# Random Matrix Theory in Physics

**T Guhr**, Lunds Universitet, Lund, Sweden

## Introduction

We wish to study energy correlations of quantum spectra. Suppose the spectrum of a quantum system has been measured or calculated. All levels in the total spectrum having the same quantum numbers form one particular *subspectrum*. Its energy levels are at positions $x_n$, $n = 1, 2, \ldots, N$, say. We assume that $N$, the number of levels in this subspectrum, is large. With a proper *smoothing* procedure, we obtain the level density $R_1(x)$, that is, the probability density of finding a level at the energy $x$. As indicated in the top part of Figure 1, the level density $R_1(x)$ increases with $x$ for most physics systems. In the present context, however, we are not so interested in the level density. We want to measure the spectral correlations independently of it. Hence, we have to remove the level density from the subspectrum. This is referred to as *unfolding*. We introduce a new dimensionless energy scale $\xi$ such that $\mathrm{d}\xi = R_1(x)\,\mathrm{d}x$. By construction, the resulting subspectrum in $\xi$ has level density unity, as shown schematically in the bottom part of Figure 1. It is always understood that the energy correlations are analyzed in the *unfolded subspectra*.

Surprisingly, a remarkable *universality* is found in the spectral correlations of a large class of systems, including nuclei, atoms, molecules, quantum chaotic and disordered systems, and even quantum chromodynamics on the lattice. Consider the *nearest-neighbor spacing distribution* $p(s)$. It is the probability density of finding two adjacent levels in the distance $s$. If the positions of the levels are uncorrelated, the nearest-neighbor spacing distribution can be shown to follow the *Poisson law*

$$p^{(\mathrm{P})}(s) = \exp(-s) \qquad [1]$$

While this is occasionally found, many more systems show a rather different nearest-neighbor spacing distribution, the *Wigner surmise*

$$p^{(\mathrm{W})}(s) = \frac{\pi}{2} s \exp\left(-\frac{\pi}{4} s^2\right) \qquad [2]$$

As shown in Figure 2, the Wigner surmise excludes degeneracies, $p^{(\mathrm{W})}(0) = 0$, the levels repel each other. This is only possible if they are correlated. Thus, the Poisson law and the Wigner surmise reflect the absence or the presence of energy correlations, respectively.

Now, the question arises: if these correlation patterns are so frequently found in physics, is there some simple, phenomenological model? – Yes, random matrix theory (RMT) is precisely this. To describe the absence of correlations, we choose, in view of what has been said above, a diagonal Hamiltonian

$$H = \mathrm{diag}(x_1, \ldots, x_N) \qquad [3]$$

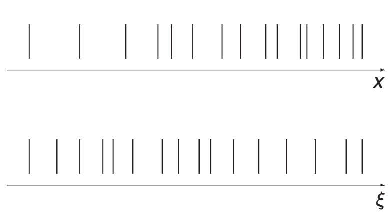

**Figure 1** Original (top) and unfolded (bottom) spectrum.

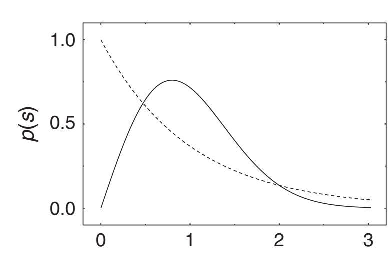

**Figure 2** Wigner surmise (solid) and Poisson law (dashed).

whose elements, the eigenvalues $x_n$, are uncorrelated random numbers. To model the presence of correlations, we insert off-diagonal matrix elements,

$$H = \begin{bmatrix} H_{11} & \cdots & H_{1N} \\ \vdots & & \vdots \\ H_{N1} & \cdots & H_{NN} \end{bmatrix} \quad [4]$$

We require that H is real symmetric, $H^{\mathrm{T}} = H$. The independent elements $H_{nm}$ are random numbers. The random matrix $H$ is diagonalized to obtain the energy levels $x_n, n = 1, 2, \ldots, N$. Indeed, a numerical simulation shows that these two models yield, after unfolding, the Poisson law and the Wigner surmise for large $N$, that is, the absence or presence of correlations. This is the most important insight into the phenomenology of RMT.

In this article, we set up RMT in a more formal way; we discuss analytical calculations of correlation functions, demonstrate how this relates to supersymmetry and stochastic field theory and show the connection to chaos, and we briefly sketch the numerous applications in many-body physics, in disordered and mesoscopic systems, in models for interacting fermions, and in quantum chromodynamics. We also mention applications in other fields, even beyond physics.

## Random Matrix Theory

### Classical Gaussian Ensembles

For now, we consider a system whose energy levels are correlated. The $N \times N$ matrix $H$ modeling it has no fixed zeros but random entries everywhere. There are three possible *symmetry classes* of random matrices in standard Schrödinger quantum mechanics. They are labeled by the Dyson index $\beta$. If the system is not time-reversal invariant, $H$ has to be Hermitian and the random entries $H_{nm}$ are complex ($\beta = 2$). If time-reversal invariance holds, two possibilities must be distinguished: if either the system is rotational symmetric, or it has integer spin and rotational symmetry is broken, the Hamilton matrix $H$ can be chosen to be real symmetric ($\beta = 1$). This is the case in eqn [4]. If, on the other hand, the system has half-integer spin and rotational symmetry is broken, $H$ is self-dual ($\beta = 4$) and the random entries $H_{nm}$ are $2 \times 2$ quaternionic. The Dyson index $\beta$ is the dimension of the number field over which $H$ is constructed.

As we are interested in the eigenvalue correlations, we diagonalize the random matrix, $H = U^{-1}xU$. Here, $x = \mathrm{diag}(x_1, \ldots, x_N)$ is the diagonal matrix of the $N$ eigenvalues. For $\beta = 4$, every eigenvalue is doubly degenerate. This is *Kramers' degeneracy*. The diagonalizing matrix $U$ is in the orthogonal group $\mathrm{O}(N)$ for $\beta = 1$, in the unitary group $\mathrm{U}(N)$ for $\beta = 2$ and in the unitary–symplectic group $\mathrm{USp}(2N)$ for $\beta = 4$. Accordingly, the three symmetry classes are referred to as *orthogonal, unitary*, and *symplectic*.

We have not yet chosen the probability densities for the random entries $H_{nm}$. To keep our assumptions about the system at a minimum, we treat all entries on equal footing. This is achieved by *rotational invariance* of the probability density $P_N^{(\beta)}(H)$, not to be confused with the rotational symmetry employed above to define the symmetry classes. No basis for the matrices is preferred in any way if we construct $P_N^{(\beta)}(H)$ from matrix invariants, that is, from traces and determinants, such that it depends only on the eigenvalues, $P_N^{(\beta)}(H) = P_N^{(\beta)}(x)$. A particularly convenient choice is the Gaussian

$$P_N^{(\beta)}(H) = C_N^{(\beta)} \exp\left(-\frac{\beta}{4v^2} \operatorname{tr} H^2\right) \quad [5]$$

where the constant $v$ sets the energy scale and the constant $C_N^{(\beta)}$ ensures normalization. The three symmetry classes together with the probability densities [5] define the *Gaussian ensembles*: the Gaussian orthogonal (GOE), unitary (GUE) and symplectic (GSE) ensemble for $\beta = 1, 2, 4$.

The phenomenology of the three Gaussian ensembles differs considerably. The higher $\beta$, the stronger the level repulsion between the eigenvalues $x_n$. Numerical simulation quickly shows that the nearest-neighbor spacing distribution behaves like $p^{(\beta)}(s) \sim s^\beta$ for small spacings $s$. This also becomes obvious by working out the differential probability $P_N^{(\beta)}(H)\mathrm{d}[H]$ of the random matrices $H$ in eigenvalue–angle coordinates $x$ and $U$. Here, $\mathrm{d}[H]$ is the invariant measure or volume element in the matrix space. When writing $\mathrm{d}[\cdot]$, we always mean the product of all differentials of independent variables for the quantity in the square brackets. Up to constants, we have

$$\mathrm{d}[H] = |\Delta_N(x)|^\beta\, \mathrm{d}[x]\, \mathrm{d}\mu(U) \quad [6]$$

where $\mathrm{d}\mu(U)$ is, apart from certain phase contributions, the invariant or Haar measure on $\mathrm{O}(N)$, $\mathrm{U}(N)$, or $\mathrm{USp}(2N)$, respectively. The Jacobian of the transformation is the modulus of the Vandermonde determinant

$$\Delta_N(x) = \prod_{n<m} (x_n - x_m) \quad [7]$$

raised to the power $\beta$. Thus, the differential probability $P_N^{(\beta)}(H)\,\mathrm{d}[H]$ vanishes whenever any two eigenvalues $x_n$ degenerate. This is the level

repulsion. It immediately explains the behavior of the nearest-neighbor spacing distribution for small spacings.

Additional symmetry constraints lead to new random matrix ensembles relevant in physics, the *Andreev* and the *chiral Gaussian ensembles*. If one refers to the classical Gaussian ensembles, one usually means the three ensembles introduced above.

## Correlation Functions

The probability density to find $k$ energy levels at positions $x_1, \ldots, x_k$ is the $k$-level correlation function $R_k^{(\beta)}(x_1, \ldots, x_k)$. We find it by integrating out $N-k$ levels in the $N$-level differential probability $P_N^{(\beta)}(H)\,\mathrm{d}[H]$. We also have to average over the bases, that is, over the diagonalizing matrices $U$. Due to rotational invariance, this simply yields the group volume. Thus, we have

$$R_k^{(\beta)}(x_1, \ldots, x_k) = \frac{N!}{(N-k)!}\int_{-\infty}^{+\infty} \mathrm{d}x_{k+1} \cdots \int_{-\infty}^{+\infty} \mathrm{d}x_N |\Delta_N(x)|^{\beta} P_N^{(\beta)}(x) \quad [8]$$

Once more, we used rotational invariance which implies that $P_N^{(\beta)}(x)$ is invariant under permutation of the levels $x_n$. Since the same then also holds for the correlation functions [8], it is convenient to normalize them to the combinatorial factor in front of the integrals. A constant ensuring this has been absorbed into $P_N^{(\beta)}(x)$.

Remarkably, the integrals in eqn [8] can be done in closed form. The GUE case ($\beta=2$) is mathematically the simplest, and one finds the determinant structure

$$R_k^{(2)}(x_1, \ldots, x_k) = \det[K_N^{(2)}(x_p, x_q)]_{p,q=1,\ldots,k} \quad [9]$$

All entries of the determinant can be expressed in terms of the kernel $K_N^{(2)}(x_p, x_q)$, which depends on two energy arguments $(x_p, x_q)$. Analogous but more complicated formulae are valid for the GOE ($\beta=1$) and the GSE ($\beta=4$), involving quaternion determinants and integrals and derivatives of the kernel.

As argued in the Introduction, we are interested in the energy correlations on the unfolded energy scale. The level density is formally the one-level correlation function. For the three Gaussian ensembles it is, to leading order in the level number $N$, the *Wigner semicircle*

$$R_1^{(\beta)}(x_1) = \frac{1}{2\pi v^2}\sqrt{4\,Nv^2 - x_1^2} \quad [10]$$

for $|x_1| \leq 2\sqrt{N}v$ and zero for $|x_1| > 2\sqrt{N}v$. None of the common systems in physics has such a level density. When unfolding, we also want to take the limit of infinitely many levels $N \to \infty$ to remove cutoff effects due to the finite dimension of the random matrices. It suffices to stay in the center of the semicircle where the mean level spacing is $D = 1/R_1^{(\beta)}(0) = \pi v/\sqrt{N}$. We introduce the dimensionless energies $\xi_p = x_p/D, p = 1, \ldots, k$, which have to be held fixed when taking the limit $N \to \infty$. The *unfolded correlation functions* are given by

$$X_k^{(\beta)}(\xi_1, \ldots, \xi_k) = \lim_{N\to\infty} D^k R_k^{(\beta)}(D\xi_1, \ldots, D\xi_k) \quad [11]$$

As we are dealing with probability densities, the Jacobians $\mathrm{d}x_p/\mathrm{d}\xi_p$ enter the reformulation in the new energy variables. This explains the factor $D^k$. Unfolding makes the correlation functions *translation invariant*; they depend only on the differences $\xi_p - \xi_q$. The unfolded correlation functions can be written in a rather compact form. For the GUE ($\beta=2$), they read

$$X_k^{(2)}(\xi_1, \ldots, \xi_k) = \det\left[\frac{\sin \pi(\xi_p - \xi_q)}{\pi(\xi_p - \xi_q)}\right]_{p,q=1,\ldots,k} \quad [12]$$

There are similar, but more complicated, formulae for the GOE ($\beta=1$) and the GSE ($\beta=4$). By construction, one has $X_1^{(\beta)}(\xi_1) = 1$.

It is useful to formulate the case where correlations are absent, that is, the *Poisson case*, accordingly. The level density $R_1^{(\mathrm{P})}(x_1)$ is simply $N$ times the (smooth) probability density chosen for the entries in the diagonal matrix [4]. Lack of correlations means that the $k$-level correlation function only involves one-level correlations,

$$R_k^{(\mathrm{P})}(x_1, \ldots, x_k) = \frac{N!}{(N-k)!N^k}\prod_{p=1}^{k} R_1^{(\mathrm{P})}(x_p) \quad [13]$$

The combinatorial factor is important, since we always normalize to $N!/(N-k)!$. Hence, one finds

$$X_k^{(\mathrm{P})}(\xi_1, \ldots, \xi_k) = 1 \quad [14]$$

for all unfolded correlation functions.

## Statistical Observables

The unfolded correlation functions yield all statistical observables. The two-level correlation function $X_2(r)$ with $r = \xi_1 - \xi_2$ is of particular interest in applications. If we do not write the superscript ($\beta$) or (P), we mean either of the functions. For the Gaussian ensembles, $X_2^{(\beta)}(r)$ is shown in Figure 3. One often writes $X_2(r) = 1 - Y_2(r)$. The two-level *cluster function* $Y_2(r)$ nicely measures the deviation from the uncorrelated Poisson case, where one has $X_2^{(\mathrm{P})}(r) = 1$ and $Y_2^{(\mathrm{P})}(r) = 0$.

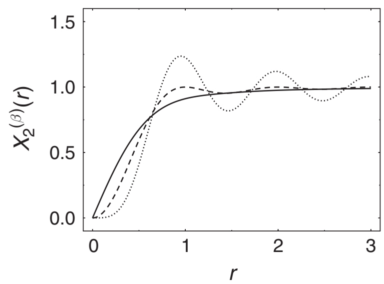

**Figure 3** Two-level correlation function $X_2^{(\beta)}(r)$ for GOE (solid), GUE (dashed) and GSE (dotted).

By construction, the average level number in an interval of length $L$ in the unfolded spectrum is $L$. The level *number variance* $\Sigma^2(L)$ is shown to be an average over the two-level cluster function,

$$\Sigma^2(L) = L - 2\int_0^L (L-r)Y_2(r)\mathrm{d}r \qquad [15]$$

We find $L \pm \sqrt{\Sigma^2(L)}$ levels in an interval of length $L$. In the uncorrelated Poisson case, one has $\Sigma^{2(\mathrm{P})}(L) = L$. This is just *Poisson's error law*. For the Gaussian ensembles $\Sigma^{2(\beta)}(L)$ behaves logarithmically for large $L$. The spectrum is said to be more *rigid* than in the Poisson case. As Figure 4 shows, the level number variance probes longer distances in the spectrum, in contrast to the nearest-neighbor spacing distribution.

Many more observables, also sensitive to higher order, $k > 2$ correlations, have been defined. In practice, however, one is often restricted to analyzing two-level correlations. An exception is, to some extent, the nearest-neighbor spacing distribution $p(s)$. It is the two-level correlation function with the *additional* requirement that the two levels in question are adjacent, that is, that there are no levels between them. Thus, *all* correlation functions are needed if one wishes to calculate the exact nearest-neighbor spacing distribution $p^{(\beta)}(s)$ for the Gaussian ensembles. These considerations explain that we have $X_2^{(\beta)}(s) \simeq p^{(\beta)}(s)$ for small $s$. But while $X_2^{(\beta)}(s)$ saturates for large $s$, $p^{(\beta)}(s)$ quickly goes to zero in a Gaussian fashion. Thus, although the nearest-neighbor spacing distribution mathematically involves all correlations, it makes in practice only a meaningful statement about the two-level correlations. Luckily, $p^{(\beta)}(s)$ differs only very slightly from the heuristic Wigner surmise [2] (corresponding to $\beta = 1$), respectively from its extensions (corresponding to $\beta = 2$ and $\beta = 4$).

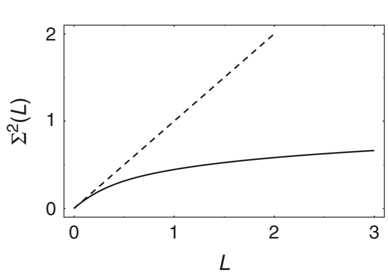

**Figure 4** Level number variance $\Sigma^2(L)$ for GOE (solid) and Poisson case (dashed).

## Ergodicity and Universality

We constructed the correlation functions as averages over an ensemble of random matrices. But this is not how we proceeded in the data analysis sketched in the Introduction. There, we started from *one single* spectrum with very many levels and obtained the statistical observable just by sampling and, if necessary, smoothing. Do these two averages, the *ensemble average* and the *spectral average*, yield the same? Indeed, one can show that the answer is affirmative, if the level number $N$ goes to infinity. This is referred to as *ergodicity* in RMT.

Moreover, as already briefly indicated in the Introduction, very many systems from different areas of physics are well described by RMT. This seems to be at odds with the Gaussian assumption [5]. There is hardly any system whose Hamilton matrix elements follow a Gaussian probability density. The solution for this puzzle lies in the unfolding. Indeed, it has been shown that almost all functional forms of the probability density $P_N^{(\beta)}(H)$ yield the same unfolded correlation functions, if no new scale comparable to the mean level spacing is present in $P_N^{(\beta)}(H)$. This is the mathematical side of the empirically found *universality*.

Ergodicity and universality are of crucial importance for the applicability of RMT in data analysis.

## Wave Functions

By modeling the Hamiltonian of a system with a random matrix $H$, we do not only make an assumption about the statistics of the energies, but also about those of the wave functions. Because of the eigenvalue equation $Hu_n = x_n u_n, n = 1, \ldots, N$, the wave function belonging to the eigenenergy $x_n$ is modeled by the eigenvector $u_n$. The columns of the diagonalizing matrix $U = [u_1\, u_2 \cdots u_N]$ are these eigenvectors. The probability density of the components $u_{nm}$ of the eigenvector $u_n$ can be calculated rather easily. For large $N$ it approaches a Gaussian. This is equivalent to the *Porter–Thomas distribution*. While wave functions are often not accessible in an experiment, one can measure transition amplitudes and widths, giving information about the matrix elements of a transition operator and a

projection of the wave functions onto a certain state in Hilbert space. If the latter are represented by a fixed matrix $A$ or a fixed vector $a$, respectively, one can calculate the RMT prediction for the probability densities of the matrix elements $u_n^\dagger A u_m$ or the widths $a^\dagger u_n$ from the probability density of the eigenvectors.

### Scattering Systems

It is important that RMT can be used as a powerful tool in scattering theory, because the major part of the experimental information about quantum systems comes from scattering experiments. Consider an example from compound nucleus scattering. In an accelerator, a proton is shot on a nucleus, with which it forms a compound nucleus. This then decays by emitting a neutron. More generally, the ingoing *channel* $\nu$ (the proton in our example) connects to the *interaction region* (the nucleus), which also connects to an outgoing channel $\mu$ (the neutron). There are $\Lambda$ channels with channel wave functions which are labeled $\nu = 1, \ldots, \Lambda$. The interaction region is described by an $N \times N$ Hamiltonian matrix $H$ whose eigenvalues $x_n$ are bound-state energies labeled $n = 1, \ldots, N$. The dimension $N$ is a cutoff which has to be taken to infinity at the end of a calculation. The $\Lambda \times \Lambda$ *scattering matrix* $S$ contains the information about how the ingoing channels are transformed into the outgoing channels. The scattering matrix $S$ is unitary. Under certain and often justified assumptions, a scattering matrix element can be cast into the form

$$S_{\nu\mu} = \delta_{\nu\mu} - \mathrm{i}2\pi W_\nu^\dagger G^{-1} W_\mu \qquad [16]$$

The couplings $W_{n\nu}$ between the bound states $n$ and the channels $\nu$ are collected in the $N \times \Lambda$ matrix $W$, $W_\nu$ is its $\nu$th column. The propagator $G^{-1}$ is the inverse of

$$G = z1_N - H + \mathrm{i}\pi \sum_{\nu \text{ open}} W_\nu W_\nu^\dagger \qquad [17]$$

Here, $z$ is the scattering energy and the summation is only over channels which are open, that is, accessible. Formula [16] has a clear intuitive interpretation. The scattering region is entered through channel $\nu$, the bound states of $H$ become *resonances* in the scattering process according to eqn [17], the interaction region is left through channel $\mu$. This formulation applies in many areas of physics. All observables such as transmission coefficients, cross sections, and others can be calculated from the scattering matrix $S$.

We have not made any statistical assumptions yet. Often, one can understand generic features of a scattering system by assuming that the Hamiltonian $H$ is a random matrix, taken from one of the three classical ensembles. This is one RMT approach used in scattering theory.

Another RMT approach is based on the scattering matrix itself, $S$ is modeled by a $\Lambda \times \Lambda$ unitary random matrix. Taking into account additional symmetries, one arrives at the *three circular ensembles*, circular orthogonal (COE), unitary (CUE) and symplectic (CSE). They correspond to the three classical Gaussian ensembles and are also labeled with the Dyson index $\beta = 1, 2, 4$. The eigenphases of the random scattering matrix correspond to the eigenvalues of the random Hamiltonian matrix. The unfolded correlation functions of the circular ensembles are identical to those of the Gaussian ensembles.

### Supersymmetry

Apart from the symmetries, random matrices contain nothing but random numbers. Thus, a certain type of redundancy is present in RMT. Remarkably, this redundancy can be removed, without losing any piece of information by using *supersymmetry*, that is, by a reformulation of the random matrix model involving commuting and anticommuting variables. For the sake of simplicity, we sketch the main ideas for the GUE, but they apply to the GOE and the GSE accordingly.

One defines the $k$-level correlation functions by using the resolvent of the Schrödinger equation,

$$\widehat{R}_k^{(2)}(x_1, \ldots, x_k) = \frac{1}{\pi^k} \int P_N^{(2)}(H) \prod_{p=1}^{k} \mathrm{tr} \frac{1}{x_p^\pm - H} \mathrm{d}[H] \qquad [18]$$

The energies carry an imaginary increment $x_p^\pm = x_p \pm \mathrm{i}\varepsilon$ and the limit $\varepsilon \to 0$ has to be taken at the end of the calculation. The $k$-level correlation functions $R_k^{(2)}(x_1, \ldots, x_k)$ as defined in eqn [8] can always be obtained from the functions [18] by constructing a linear combination of the $\widehat{R}_k^{(2)}(x_1, \ldots, x_k)$ in which the signs of the imaginary increments are chosen such that only the imaginary parts of the traces contribute. Some trivial $\delta$-distributions have to be removed. The $k$-level correlation functions [18] can be written as the $k$-fold derivative

$$\widehat{R}_k^{(2)}(x_1, \ldots, x_k) = \frac{1}{(2\pi)^k} \frac{\partial^k}{\prod_{p=1}^{k} \partial J_p} Z_k^{(2)}(x + J) \bigg|_{J=0} \qquad [19]$$

of the generating function

$$Z_k^{(2)}(x+J) = \int P_N^{(2)}(H) \prod_{p=1}^{k} \frac{\det\left(x_p^{\pm} + J_p - H\right)}{\det\left(x_p^{\pm} - J_p - H\right)} \mathrm{d}[H] \qquad [20]$$

which depends on the energies and $k$ new source variables $J_p, p = 1, \ldots, k$, ordered in $2k \times 2k$ diagonal matrices

$$\begin{aligned} x &= \mathrm{diag}(x_1, x_1, \ldots, x_k, x_k) \\ J &= \mathrm{diag}(+J_1, -J_1, \ldots, +J_k, -J_k) \end{aligned} \qquad [21]$$

We notice the normalization $Z_k^{(2)}(x) = 1$ at $J = 0$. The generating function [20] is an integral over an ordinary $N \times N$ matrix $H$. It can be exactly rewritten as an integral over a $2k \times 2k$ *supermatrix* $\sigma$ containing commuting and anticommuting variables,

$$Z_k^{(2)}(x+J) = \int Q_k^{(2)}(\sigma) \mathrm{sdet}^{-N}(x^{\pm} + J - \sigma) \mathrm{d}[\sigma] \qquad [22]$$

The integrals over the commuting variables are of the ordinary *Riemann–Stiltjes* type, while those over the anticommuting variables are *Berezin* integrals. The Gaussian probability density [5] is mapped onto its counterpart in superspace

$$Q_k^{(2)}(\sigma) = c_k^{(2)} \exp\left(-\frac{1}{2v^2} \mathrm{str}\, \sigma^2\right) \qquad [23]$$

where $c_k^{(2)}$ is a normalization constant. The supertrace str and the superdeterminant sdet generalize the corresponding invariants for ordinary matrices. The total number of integrations in eqn [22] is drastically reduced as compared to eqn [20]. Importantly, it is independent of the level number $N$ which now only appears as the negative power of the superdeterminant in eqn [22], that is, as an explicit parameter. This most convenient feature makes it possible to take the limit of infinitely many levels by means of a saddle point approximation to the generating function.

Loosely speaking, the supersymmetric formulation can be viewed as an irreducible representation of RMT which yields a clearer insight into the mathematical structures. The same is true for applications in scattering theory and in models for crossover transitions to be discussed below. This explains why supersymmetry is so often used in RMT calculations.

It should be emphasized that the rôle of supersymmetry in RMT is quite different from the one in high-energy physics, where the commuting and anticommuting variables represent physical particles, bosons and fermions, respectively. This is not so in the RMT context. The commuting and anticommuting variables have no direct physics interpretation; they appear simply as helpful mathematical devices to cast the RMT model into an often much more convenient form.

### Crossover Transitions

The RMT models discussed up to now describe four extreme situations, the absence of correlations in the Poisson case and the presence of correlations as in the three fully rotational invariant models GOE, GUE, and GSE. A real physics system, however, is often between these extreme situations. The corresponding RMT models can vary considerably, depending on the specific situation. Nevertheless, those models in which the random matrices for two extreme situations are simply added with some weight are useful in so many applications that they acquired a rather generic standing. One writes

$$H(\alpha) = H^{(0)} + \alpha H^{(\beta)} \qquad [24]$$

where $H^{(0)}$ is a random matrix drawn from an ensemble with a completely arbitrary probability density $P_N^{(0)}(H^{(0)})$. The case of a fixed matrix is included, because one may choose a product of $\delta$-distributions for the probability density. The matrix $H^{(\beta)}$ is random and drawn from the classical Gaussian ensembles with probability density $P_N^{(\beta)}(H^{(\beta)})$ for $\beta = 1, 2, 4$. One requires that the group diagonalizing $H^{(0)}$ is a subgroup of the one diagonalizing $H^{(\beta)}$. The model [24] describes a *crossover transition*. The weight $\alpha$ is referred to as *transition parameter*. It is useful to choose the spectral support of $H^{(0)}$ and $H^{(\beta)}$ equal. One can then view $\alpha$ as the root-mean-square matrix element of $H^{(\beta)}$. At $\alpha = 0$, one has the arbitrary ensemble. The Gaussian ensembles are formally recovered in the limit $\alpha \to \infty$, to be taken in a proper way such that the energies remain finite.

We are always interested in the unfolded correlation functions. Thus, $\alpha$ has to be measured in units of the mean level spacing $D$ such that $\lambda = \alpha / D$ is the physically relevant transition parameter. It means that, depending on the numerical value of $D$, even a small effect on the original energy scale can have sizeable impact on the spectral statistics. This is referred to as *statistical enhancement*. The nearest-neighbor spacing distribution is already very close to $p^{(\beta)}(s)$ for the Gaussian ensembles if $\lambda$ is larger than 0.5 or so. In the long-range observables such as the level number variance $\Sigma^2(L)$, the deviation from the Gaussian ensemble statistics becomes visible at interval lengths $L$ comparable to $\lambda$.

Crossover transitions can be interpreted as *diffusion processes*. With the fictitious time $t = \alpha^2/2$, the probability density $P_N(x,t)$ of the eigenvalues $x$ of the total Hamilton matrix $H = H(t) = H(\alpha)$ satisfies the diffusion equation

$$\Delta_x P_N(x,t) = \frac{4}{\beta}\frac{\partial}{\partial t} P_N(x,t) \qquad [25]$$

where the probability density for the arbitrary ensemble is the initial condition $P_N(x,0) = P_N^{(0)}(x)$. The Laplacian

$$\Delta_x = \sum_{n=1}^{N} \frac{\partial^2}{\partial x_n^2} + \sum_{n<m} \frac{\beta}{x_n - x_m}\left(\frac{\partial}{\partial x_n} - \frac{\partial}{\partial x_m}\right) \qquad [26]$$

lives in the curved space of the eigenvalues $x$. This diffusion process is *Dyson's Brownian motion* in slightly simplified form. It has a rather general meaning for *harmonic analysis on symmetric spaces*, connecting to the spherical functions of Gelfand and Harish-Chandra, Itzykson–Zuber integrals, and to *Calogero–Sutherland models of interacting particles*. All this generalizes to superspace. In the supersymmetric version of Dyson's Brownian motion the generating function of the correlation functions is propagated,

$$\Delta_s Z_k(s,t) = \frac{4}{\beta}\frac{\partial}{\partial t} Z_k(s,t) \qquad [27]$$

where the initial condition $Z_k(s,0) = Z_k^{(0)}(s)$ is the generating function of the correlation functions for the arbitrary ensemble. Here, $s$ denotes the eigenvalues of some supermatrices, not to be confused with the spacing between adjacent levels. Since the Laplacian $\Delta_s$ lives in this curved eigenvalue space, this diffusion process establishes an intimate connection to harmonic analysis on superspaces. Advantageously, the diffusion [27] is the same on the original and on the unfolded energy scales.

## Fields of Application

### Many-Body Systems

Numerous studies apply RMT to nuclear physics which is also the field of its origin. If the total number of nucleons, that is, protons and neutrons, is not too small, nuclei show *single-particle* and *collective* motion. Roughly speaking, the former is decoherent out-of-phase motion of the nucleons confined in the nucleus, while the latter is coherent in-phase motion of all nucleons or of large groups of them such that any additional individual motion of the nucleons becomes largely irrelevant. It has been shown empirically that the single-particle excitations lead to GOE statistics, while collective excitations produce different statistics, often of the Poisson type. Mixed statistics as described by crossover transitions are then of particular interest to investigate the character of excitations. For example, one applies the model [24] with $H^{(0)}$ drawn from a Poisson ensemble and $H^{(\beta)}$ from a GOE. Another application of crossover transitions is breaking of *time-reversal invariance* in nuclei. Here, $H^{(0)}$ is from a GOE and $H^{(\beta)}$ from a GUE. Indeed, a fit of spectral data to this model yields an upper bound for the *time-reversal invariance* violating root-mean-square matrix element in nuclei. Yet another application is breaking of symmetries such as parity or isospin. In the case of two quantum numbers, positive and negative parity, say, one chooses $H^{(0)} = \mathrm{diag}(H^{(+)}, H^{(-)})$ block-diagonal with $H^{(+)}$ and $H^{(-)}$ drawn from two uncorrelated GOE and $H^{(\beta)}$ from a third uncorrelated GOE which breaks the block structure. Again, root-mean-square matrix elements for symmetry breaking have been derived from the data.

Nuclear excitation spectra are extracted from scattering experiments. An analysis as described above is only possible if the resonances are isolated. Often, this is not the case and the resonance widths are comparable to or even much larger than the mean level spacing, making it impossible to obtain the excitation energies directly from the cross sections. One then analyzes the latter and their fluctuations as measured and applies the concepts sketched above for scattering systems. This approach has also been successful for crossover transitions.

Due to the complexity of the nuclear many-body problem, one has to use effective or phenomenological interactions when calculating spectra. Hence, one often studies whether the statistical features found in the experimental data are also present in the calculated spectra which result from the various models for nuclei.

Other many-body systems, such as complex atoms and molecules, have also been studied with RMT concepts, but the main focus has always been on nuclei.

### Quantum Chaos

Originally, RMT was intended for modeling systems with many degrees of freedom such as nuclei. Surprisingly, RMT proved useful for systems with few degrees of freedom as well. Most of these studies aim at establishing a link between RMT and *classical chaos*. Consider as an example the classical motion of a point-like particle in a rectangle billiard. Ideal reflection at the boundaries and absence of friction are assumed, implying that the particle is reflected infinitely many times. A second billiard is built by taking a rectangle and replacing one corner with a quarter circle as shown in **Figure 5**. The motion of the particle in this *Sinai*

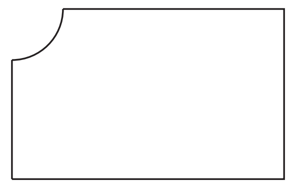

**Figure 5** The Sinai billiard.

*billiard* is very different from the one in the rectangle. The quarter circle acts like a convex mirror which spreads out the rays of light upon reflection. This effect accumulates, because the vast majority of the possible trajectories hit the quarter circle infinitely many times under different angles. This makes the motion in the Sinai billiard *classically chaotic*, while the one in the rectangle is *classically regular*. The rectangle is *separable* and *integrable*, while this feature is destroyed in the Sinai billiard. One now quantizes these billiard systems, calculates the spectra, and analyzes their statistics. Up to certain scales, the rectangle (for irrational squared ratio of the side lengths) shows Poisson behavior, the Sinai billiard yields GOE statistics.

A wealth of such empirical studies led to the Bohigas–Giannoni–Schmit conjecture. We state it here not in its original, but in a frequently used form: *spectra of systems whose classical analogues are fully chaotic show correlation properties as modeled by the Gaussian ensembles*. The Berry–Tabor conjecture is complementary: *spectra of systems whose classical analogs are fully regular show correlation properties which are often those of the Poisson type*. As far as concrete physics applications are concerned, these conjectures are well-posed. From a strict mathematical viewpoint, they have to be supplemented with certain conditions to exclude exceptions such as Artin's billiard. Due to the defnition of this system on the hyperbolic plane, its quantum version shows Poisson-like statistics, although the classical dynamics is chaotic. Up to now, no general and mathematically rigorous proofs could be given. However, *semiclassical* reasoning involving periodic orbit theory and, in particular, the *Gutzwiller trace formula*, yields at least a heuristic understanding.

Quantum chaos has been studied in numerous systems. An especially prominent example is the Hydrogen atom put in a strong magnetic field, which breaks the integrability and drives the correlations towards the GOE limit.

### Disordered and Mesoscopic Systems

An electron moving in a probe, a piece of wire, say, is scattered many times at impurities in the material. This renders the motion diffusive. In a statistical model, one writes the Hamilton operator as a sum of the kinetic part, that is, the Laplacian, and a white-noise disorder potential $V(\boldsymbol{r})$ with second moment

$$\langle V(\boldsymbol{r})V(\boldsymbol{r}')\rangle = c_V\delta^{(d)}(\boldsymbol{r}-\boldsymbol{r}') \qquad [28]$$

Here, $\boldsymbol{r}$ is the position vector in $d$ dimensions. The constant $c_V$ determines the mean free time between two scattering processes in relation to the density of states. It is assumed that phase coherence is present such that quantum effects are still significant. This defines the *mesoscopic regime*. The average over the disorder potential can be done with supersymmetry. In fact, this is the context in which supersymmetric techniques in statistical physics were developed, before they were applied to RMT models. In the case of weak disorder, the resulting field theory in superspace for two-level correlations acquires the form

$$\int d\mu(Q) f(Q)\exp(-S(Q)) \qquad [29]$$

where $f(Q)$ projects out the observable under consideration and where $S(Q)$ is the *effective Lagrangian*

$$S(Q) = -\int \mathrm{str}\Big(\mathcal{D}(\nabla Q(\boldsymbol{r}))^2 + i2rMQ(\boldsymbol{r})\Big)d^d r \qquad [30]$$

This is the *supersymmetric nonlinear $\sigma$ model*. It is used to study level correlations, but also to obtain information about the conductance and conductance fluctuations when the probe is coupled to external leads. The supermatrix field $Q(\boldsymbol{r})$ is the remainder of the disorder average, its matrix dimension is four or eight, depending on the symmetry class. This field is a Goldstone mode. It does not directly represent a particle as often the case in high-energy physics. The matrix $Q(\boldsymbol{r})$ lives in a coset space of certain supergroups. A tensor $M$ appears in the calculation, and $r$ is the energy difference on the unfolded scale, not to be confused with the position vector $\boldsymbol{r}$.

The first term in the effective Lagrangian involving a gradient squared is the *kinetic term*, it stems from the Laplacian in the Hamiltonian. The constant $\mathcal{D}$ is the classical diffusion constant for the motion of the electron through the probe. The second term is the ergodic term. In the limit of zero dimensions, $d \to 0$, the kinetic term vanishes and the remaining ergodic term yields precisely the unfolded two-level correlations of the Gaussian ensembles. Thus, RMT can be viewed as the zero-dimensional limit of field theory for disordered systems. For $d > 0$, there is a competition between the two terms. The diffusion constant $\mathcal{D}$ and the system size determine an energy scale, the *Thouless*

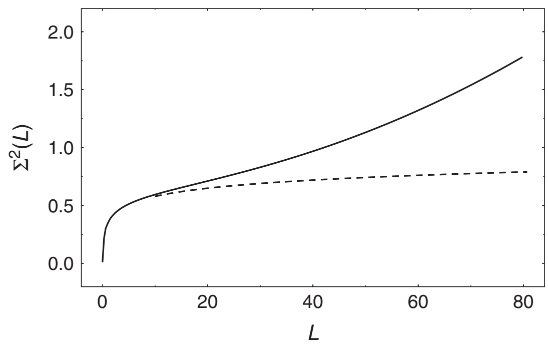

**Figure 6** Level number variance $\Sigma^2(L)$. In this example, the Thouless energy is $E_c \approx 10$ on the unfolded scale. The Gaussian ensemble behavior is dashed.

*energy* $E_c$, within which the spectral statistics is of the Gaussian ensemble type and beyond which it approaches the Poisson limit. In Figure 6, this is schematically shown for the level number variance $\Sigma^2(L)$, which bends from Gaussian ensemble to Poisson behavior when $L > E_c$. This relates to the crossover transitions in RMT. Gaussian ensemble statistics means that the electron states extend over the probe, while Poisson statistics implies their spatial localization. Hence, the Thouless energy is directly the dimensionless conductance.

A large number of issues in disordered and mesoscopic systems have been studied with the supersymmetric nonlinear $\sigma$ model. Most results have been derived for *quasi-one-dimensional* systems. Through a proper discretization, a link is established to models involving chains of random matrices. As the conductance can be formulated in terms of the scattering matrix, the experience with RMT for scattering systems can be applied and indeed leads to numerous new results.

### Quantum Chromodynamics

Quarks interact by exchanging gluons. In quantum chromodynamics, the gluons are described by gauge fields. Relativistic quantum mechanics has to be used. Analytical calculations are only possible after some drastic assumptions and one must resort to *lattice gauge theory*, that is, to demanding numerics, to study the full problem.

The massless Dirac operator has *chiral symmetry*, implying that all nonzero eigenvalues come in pairs $(-\lambda_n, +\lambda_n)$ symmetrically around zero. In chiral RMT, the Dirac operator is replaced with block off-diagonal matrices

$$W = \begin{bmatrix} 0 & W_b \\ W_b^\dagger & 0 \end{bmatrix} \qquad [31]$$

where $W_b$ is a random matrix without further symmetries. By construction, $W$ has chiral symmetry. The assumption underlying chiral RMT is that the gauge fields effectively randomize the motion of the quark. Indeed, this simple schematic model correctly reproduces low-energy sum rules and spectral statistics of lattice gauge calculations. Near the center of the spectrum, there is a direct connection to the partition function of quantum chromodynamics. Furthermore, a similarity to disordered systems exists and an analog of the Thouless energy could be found.

### Other Fields

Of the wealth of further investigations, we can mention but a few. RMT is in general useful for wave phenomena of all kinds, including classical ones. This has been shown for *elastomechanical* and *electromagnetic* resonances.

An important field of application is *quantum gravity* and matrix model aspects of *string theory*. We decided not to go into this, because the reason for the emergence of RMT concepts there is very different from everything else discussed above.

RMT is also successful beyond physics. Not surprisingly, it always received interest in mathematical statistics, but, as already said, it also relates to harmonic analysis. A connection to number theory exists as well. The high-lying zeros of the Riemann $\zeta$ function follow the GUE predictions over certain interval lengths. Unfortunately, a deeper understanding is still lacking.

As the interest in statistical concepts grows, RMT keeps finding new applications. Recently, one even started using RMT for risk management in finance.

# Random Partitions

**A Okounkov**, Princeton University, Princeton, NJ, USA

## Partitions

A partition of $n$ is a monotone sequence of nonnegative integers,

$$\lambda = (\lambda_1 \geq \lambda_2 \geq \lambda_3 \geq \cdots \geq 0)$$

with sum $n$. The number $n$ is also denoted by $|\lambda|$ and is called the size of $n$. The number of nonzero terms in $\lambda$ is called the length of $\lambda$ and often denoted by $\ell(\lambda)$. It is convenient to make the sequence $\lambda$ infinite by adding a string of zeros at the end.

A geometric object associated to partition is its diagram. The diagram of $\lambda = (4, 2, 2, 1)$ is shown in Figure 1. A larger diagram, flipped and rotated by 135°, can be seen in Figure 2. Flipping the diagram introduces an involution on the set of partitions of $n$ known as transposition. The transposed partition is denoted by $\lambda'$.

Partitions serve as natural combinatorial labels for many basic objects in mathematics and physics. For example, partitions of $n$ index both conjugacy classes and irreducible representations of the symmetric group $S(n)$. Partitions $\lambda$ with $\ell(\lambda) \leq n$ index irreducible polynomial representations of the general linear group $GL(n)$. More generally, the highest weight of a rational representation of $GL(n)$ can be naturally viewed as two partitions of total length $\leq n$.

For an even more basic example, partitions $\lambda$ with $\lambda_1 \leq m$ and $\ell(\lambda) \leq n$ are the same as upright lattice paths making $n$ steps up and $m$ steps to the right (just follow the boundary of $\lambda$). In particular, there are $\binom{n+m}{n}$ of such. By a variation on this theme, partitions label the standard basis of fermionic Fock space (Miwa *et al.* 2000). They also label a standard basis of the bosonic Fock space.

In most instances, partitions naturally occur together with some weight function. For example, the dimension, $\dim \lambda$, of an irreducible representation of $S(n)$, or some power of it, is what always appears in harmonic analysis on $S(n)$. By a theorem of Burnside,

$$\mathfrak{M}_{\text{Planch}}(\lambda) = \frac{(\dim \lambda)^2}{n!} \qquad [1]$$

is a probability measure on the set of partitions of $n$; it is known as the Plancherel measure. Besides harmonic analysis, there are many other contexts in which it appears, for example, by a theorem of Schensted (see Sagan (2001) and Stanley (1999)), the distribution of the first part $\lambda_1$ of a Plancherel random partition $\lambda$ is the same as the distribution of the longest increasing subsequence in a uniformly random permutation of $\{1, 2, \ldots, n\}$.

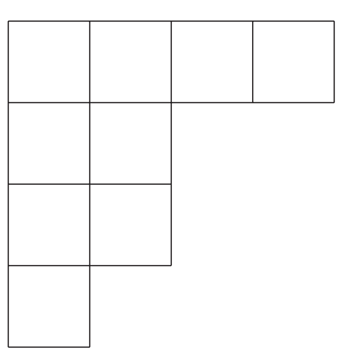

Figure 1 Diagram of a partition.

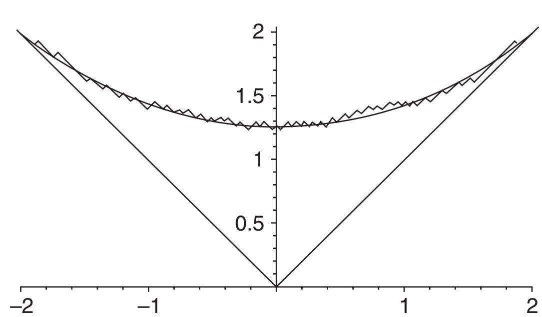

Figure 2 A Plancherel-random partition of 1000 and the limit shape.

Partitions of $n$ being just a finite set, one is often interested in letting $n \to \infty$. Even if the original problem was not of a probabilistic origin, one can still often benefit from adopting a probabilistic viewpoint because of the intuition and techniques that it brings. This is best illustrated by concrete examples, which is what we now turn to. These examples are not meant to be a panorama of random partitions. This is an old and still rapidly growing field and a simple list of all major contributions will take more space than is allowed. The books Kerov (2003), Pitman (n.d.) Sagan (2001), and Stanley (1999) offer much more information on the topics discussed below.

## Plancherel Measure

### Dimension of a Diagram

There are several formulas and interpretations for the number $\dim\lambda$ in [1]; see Sagan (2001) and Stanley (1999). The one that often appears in the context of growth processes is the following: $\dim\lambda$ is the number of ways to grow the diagram $\lambda$ from the empty diagram $\emptyset$ by adding a square at a time. That is, $\dim\lambda$ is number of chains of the form

$$\emptyset = \lambda^{(0)} \subset \lambda^{(1)} \subset \cdots \subset \lambda^{(n-1)} \subset \lambda^{(n)} = \lambda$$

where $|\lambda^{(k)}| = k$ and $\mu \subset \lambda$ means inclusion of diagrams.

From the classical formula

$$\dim\lambda = \frac{|\lambda|!}{\prod(\lambda_i + k - i)!} \prod_{i \leq j \leq k} (\lambda_i - \lambda_j + j - i) \qquad [2]$$

where $k$ is any number such that $\lambda_{k+1} = 0$, one sees that the Plancherel measure is a discrete analog of the eigenvalue density

$$\mathrm{e}^{-(1/2)\sum x_i^2} \prod_{i<j} (x_i - x_j)^2$$

of a GUE random matrix (Mehta 1991). Indeed, the first factor in [2], which looks like a multinomial coefficient, is the analog of the Gaussian weight. Kerov (2003) and Johansson were among the first to recognize the analogy between Plancherel measure and GUE. One comes across many partition sums that are discrete analogs of random matrix integrals.

The most compact formula for $\dim\lambda$ is the hook formula

$$\frac{\dim\lambda}{|\lambda|!} = \prod_{\approx \in \lambda} h(\approx)^{-1} \qquad [3]$$

Here the product is over all squares $\approx$ in the diagram of $\lambda$ and

$$h(\approx) = 1 + a(\approx) + l(\approx)$$

where $a(\approx)$ and $l(\approx)$ is the number of squares to the right of the square $\approx$ and below it, respectively. (These are known as arm-length and leg-length.)

### Limit Shape and Edge Scaling

When the diagram of $\lambda$ is very large, the logarithm of the hook product approximates a double integral. The analysis of the corresponding integral plays the central role, (see Kerov (2003), chapter 3) in the proof of the following law of large numbers for the Plancherel measure.

Take the diagram of $\lambda$, flip and rotate it as in **Figure 1** and rescale by a factor of $\sqrt{n}$ so that it has unit area. In this way one obtains a measure on continuous and, in fact, Lipschitz functions. By a result of Logan and Shepp and, independently, Vershik and Kerov these measures converge as $n \to \infty$ to the $\delta$-measure on a single function $\Omega(x)$. This limit shape for the Plancherel measure, is also plotted in **Figure 2**. Explicitly,

$$\Omega(x) = \begin{cases} \frac{2}{\pi}\left(x \arcsin(x/2) + \sqrt{4 - x^2}\right), & |x| \leq 2 \\ |x|, & |x| > 2 \end{cases}$$

This is an analog of Wigner's semicircle law (Mehta 1991) for spectra of random matrices. The Gaussian correction to the limit shape was also found by Kerov (2003).

The limit shape result can be refined to show that $\lambda_1/\sqrt{n} \to 2$ in probability. Together with Schensted's theorem, this answers the question posed by Ulam about the longest increasing subsequence in a random permutation. Further progress came in the work of Baik, Deift, and Johansson (see Deift (2000)), who conjectured (and proved for $i = 1$ and 2) that as $n \to \infty$ the joint distribution

$$\frac{\lambda_i - 2\sqrt{n}}{n^{1/6}}, \quad i = 1, 2, \ldots$$

becomes exactly the same as the distribution of largest eigenvalues of a GUE random matrix. In particular, the longest increasing subsequence, suitably scaled, is distributed exactly like the largest eigenvalue. The distribution of the latter is known as the Tracy–Widom distribution; it is given in terms of a particular solution of the Painlevé II equation. For more information about the proof of the full conjecture, see Aldous and Diaconis (1999), Deift (2000), and Okounkov (2002).

### Correlation Functions

One way to prove the full BDJ conjecture is to use the following exact formula first obtained in a more general setting by Borodin and Olshanski (see Olshanski (2003), and Okounkov (2002) for further generalizations). Look at the downsteps of the zig-zag curve in Figure 2. The $x$-coordinates of their midpoints are the numbers

$$\mathfrak{S}(\lambda) = \left\{\lambda_i - \mathrm{i} + \tfrac{1}{2}\right\} \subset \mathbb{Z} + \tfrac{1}{2} \qquad [4]$$

The map $\lambda \mapsto \mathfrak{S}(\lambda)$ makes a random partition a random subset of $\mathbb{Z} + \frac{1}{2}$, that is, a random point field on a lattice. These random points should be treated like eigenvalues of a random matrix. In particular, it is natural to consider their correlations, that is, the probability that $X \subset \mathfrak{S}(\lambda)$ for some fixed $X \subset \mathbb{Z} + \frac{1}{2}$.

Many formulas work better if we replace the Plancherel measures $\mathfrak{M}_{\mathrm{Planch},n}$ on partitions of a fixed number $n$ by their Poisson average,

$$\mathfrak{M}_{\xi} = \mathrm{e}^{-\xi} \sum_{n \geq 0} \frac{\xi^n}{n!} \mathfrak{M}_{\mathrm{Planch},n}$$

Here $\xi > 0$ is a parameter. It equals the expected size of $\lambda$. For any finite set $X$, we have

$$\mathrm{Prob}_{\xi}(X \subset \mathfrak{S}(\lambda)) = \det\left[\mathbb{K}_{\mathrm{Bessel}}(x_i, x_j; \xi)\right]_{x_i, x_j \in X} \qquad [5]$$

where $\mathbb{K}_{\mathrm{Bessel}}$ is the discrete Bessel kernel given by

$$\mathbb{K}_{\mathrm{Bessel}}(x, y; \xi) = \sqrt{\xi}\, \frac{J_{x-1/2}(2\sqrt{\xi}) J_{y+1/2}(2\sqrt{\xi}) - J_{x+1/2}(2\sqrt{\xi}) J_{y-1/2}(2\sqrt{\xi})}{x - y}$$

Note that only Bessel function of integral order enter this formula.

For large argument $\xi$, $J_n(2\sqrt{\xi})$ has sine asymptotics if $n \ll 2\sqrt{\xi}$ and Airy function asymptotics if $n \approx 2\sqrt{\xi}$. Consequently, one gets the random matrix behavior near the edge of the limit shape and discrete sine kernel asymptotics of correlations in the bulk of the limit shape.

### Permutation Enumeration

A basic combinatorial problem is to count permutations $\sigma_1, \ldots, \sigma_p \in S(n)$ of given cycle types $\mu^{(1)}, \ldots, \mu^{(p)}$ such that

$$\sigma_1 \cdots \sigma_p = 1 \qquad [6]$$

A geometric interpretation of this problem is to count covers of the sphere $S^2 = \mathbb{CP}^1$ branched over $p$ given points with monodromy $\mu^{(1)}, \ldots, \mu^{(p)}$. Elementary character theory of $S(n)$ gives (Jones 1998)

$$\#\{\sigma_i \in C_{\mu^{(i)}}, \prod \sigma_i = 1\} = \left\langle \prod f_{\mu^{(i)}} \right\rangle_{\mathrm{Planch}} \qquad [7]$$

where $C_\mu$ is the conjugacy class with cycle type $\mu$ and

$$f_\mu(\lambda) = |C_\mu| \frac{\chi^\lambda_\mu}{\dim \lambda}$$

is the central character of the irreducible representation $\lambda$. Here $\chi^\lambda_\mu$ is the character of any $\sigma \in C_\mu$ in the representation $\lambda$.

Let $\mu$ be of the form $(\bar{\mu}, 1, 1, \ldots)$ with $\bar{\mu}$ fixed. By a result of Kerov and Olshanski, $\binom{n}{|\bar{\mu}|}^{-1} f_\mu(\lambda)$, is a polynomial in $\lambda$ of degree $|\bar{\mu}|$. See [11] for the simplest example $\bar{\mu} = (2)$, that is, for the central character of a transposition. We thus recognize in [7] a discrete analog of the GUE expectation of a polynomial in traces of a random matrix. This analogy becomes even clearer in the Gromov–Witten theory of $\mathbb{CP}^1$, which can be viewed as taking into account contributions of certain degenerate covers, see Okounkov (2002).

There is a generalization, due to Burnside, of [7] to counting branched covers of surfaces of any genus $g$; see Jones (1998). The only modification required is that a representation $\lambda$ is now counted with the weight $(\dim \lambda)^{2-2g}$. For example, covers of the torus correspond to a uniform measure on partitions. In particular, the probability that two random permutation from $S(n)$ commute is $p(n)/n!$, where $p(n)$ is the number of partitions of $n$.

## Generalizations of Plancherel Measure

### Schur Functions and Cauchy Identity

Schur functions $s_\lambda(x_1, \ldots, x_n)$, where $\lambda$ is a partition with at most $n$ parts, form a distinguished linear basis of the algebra of symmetric polynomials in $x_1, \ldots, x_n$. Various definitions and many remarkable properties of these function are discussed in, for example, Sagan (2001) and Stanley (1999). One of them is that $s_\lambda(x)$ is the trace of a matrix with eigenvalues $\{x_i\}$ in an irreducible $\mathrm{GL}(n)$ module with highest weight $\lambda$. The following stability of $s_\lambda$,

$$s_\lambda(x_1, \ldots, x_n, 0) = s_\lambda(x_1, \ldots, x_n), \quad \ell(\lambda) \leq n$$

allows one to define Schur functions in infinitely many variables. The formulas

$$p_\mu = \sum_\lambda \chi^\lambda_\mu s_\lambda, \qquad s_\lambda = \sum_\mu \frac{\chi^\lambda_\mu}{\mathfrak{z}(\mu)} p_\mu$$

where

$$\mathfrak{z}(\mu) = \frac{|\mu|!}{|C_\mu|} = |\mathrm{Aut}(\mu)| \prod \mu_i$$

establish the transition between the basis of Schur function and the basis of power sum functions

$$p_\mu = \prod p_{\mu_i}, \qquad p_k = \sum_i x_i^k$$

In particular, the dimension function $\dim \lambda$ is the following specialization of the Schur function:

$$\frac{\dim \lambda}{|\lambda|!} = s_\lambda \big|_{p_1=1,\, p_2=p_3=\cdots=0}$$

We will discuss other important specializations of Schur functions later.

A typical situation in which a random matrix integral can be reduced to a sum over partition is when one uses the Cauchy identity

$$\begin{aligned} \frac{1}{\prod(1-x_i y_i)} &= \exp\left(\sum \frac{p_k(x)p_k(y)}{k}\right) \\ &= \sum_\lambda s_\lambda(x)s_\lambda(y) \end{aligned} \qquad [8]$$

to expand the integrand in Schur function and integrate term by term using, for example, the orthogonality of characters or the identity

$$\int_{\mathrm{U}(n)} s_\lambda(AgBg^{-1})\, \mathrm{d}g = \frac{1}{\dim_n \lambda} s_\lambda(A)s_\lambda(B) \qquad [9]$$

Here $s_\lambda(A)$ denotes the Schur function in eigenvalues of a matrix $A$, $\mathrm{d}g$ is the normalized Haar measure on the unitary group $\mathrm{U}(n)$, and

$$\dim_n \lambda = s_\lambda(\underbrace{1,\ldots,1}_{n \text{ times}})$$

is the dimension of irreducible $\mathrm{GL}(n)$ module $V^\lambda$ with highest weight $\lambda$. The meaning of [9] is that normalized characters are algebra homomorphisms from the center of the group algebra of $\mathrm{U}(n)$ to numbers. This method of converting a random matrix problem to a random partition problem is known as character expansion (see, e.g., Kazakov (2001)).

Inspired by the Cauchy identity, one can generalize Plancherel measure to

$$\mathfrak{M}_{\mathrm{Schur}} = \prod(1-x_i y_i)s_\lambda(x)s_\lambda(y)$$

where $x$ and $y$, or, equivalently, $p_k(x)$ and $p_k(y)$, are viewed as parameters. This is known as the Schur measure. If $p_1(x)=p_2(y)=\sqrt{\xi}$ and all other $p_k$'s vanish, we get $\mathfrak{M}_{\mathrm{Schur}} = \mathfrak{M}_\xi$. Many properties of the Plancherel measure can be generalized to Schur measure, in particular, exact formulas for correlation functions, description of the limit shape, etc. (Okounkov 2002).

### Dimension Functions

We already met the function $\dim_n \lambda$. There is a useful formula

$$\dim_n \lambda = \prod_{\square\in\lambda} \frac{n+c(\square)}{h(\square)} \qquad [10]$$

where $c((i,j)) = j - i$ is the content of the square $\square$ in $i$th row and $j$th column. From [10] it is clear that $\dim_n$ makes sense for arbitrary complex values of $n$. The corresponding specializations of the Schur measure

$$x = \underbrace{\sqrt{\xi},\ldots,\sqrt{\xi}}_{z \text{ times}}, \qquad y = \underbrace{\sqrt{\xi},\ldots,\sqrt{\xi}}_{z' \text{ times}}$$

where $\xi, z, z'$ are parameters, are related to the so-called Z-measures and their theory is much-developed (Olshanski 2003). As $z, z', \xi^{-1} \to \infty$ in such a way that $zz'\xi \to \xi_0$, we get $\mathfrak{M}_{\xi_0}$ in the limit.

The enumerative problems discussed in the section "Permutation enumeration" have analogs for the unitary groups $\mathrm{U}(n)$ and, suitably interpreted, the answers are the same with the dimension $\dim_n \lambda$ replacing $\dim \lambda$. For example, instead of counting the solutions to [6], one may be interested in the volume of the set of $p$-tuples of unitary matrices with given eigenvalues that multiply to 1. Geometrically, such data arise as the monodromy of a flat unitary connection over $S^2 \setminus \{p \text{ points}\}$, which is a $\mathrm{U}(n)$ analog of a branched cover. The analog of Burnside's formula is Witten's formula for the volumes of moduli spaces of flat connections on a genus $g$ surface with given holonomy around $p$ punctures, (see, e.g., Witten (1991) and Woodward (2004)). It involves summing normalized characters over all representations $V^\lambda$, not necessarily polynomial, with the weight $(\dim V^\lambda)^{2-2g}$. If additionally weighted by a Gaussian of the form $\exp(-A(f_2(\lambda) + (n/2)|\lambda|))$, where

$$\begin{aligned} f_2(\lambda) &= \frac{1}{2}\sum_i \left[\left(\lambda_i - i + \tfrac{1}{2}\right)^2 - \left(-i + \tfrac{1}{2}\right)^2\right] \\ &= \sum_{\square\in\lambda} c(\square) \end{aligned} \qquad [11]$$

this becomes Migdal's formula for the partition function of the 2D Yang–Mills theory, the positive constant $A$ being the area of the surface (see, e.g., Witten (1991) and Woodward (2004)).

A further generalization naturally arising in the theory of quantum groups is the quantum dimension

$$\begin{aligned} \dim_{n,q} \lambda &= s_\lambda(q^{1-n}, q^{3-n}, \ldots, q^{n-3}, q^{n-1}) \\ &= \prod_{\square\in\lambda} \frac{q^{n+c(\square)} - q^{-n-c(\square)}}{q^{h(\square)} - q^{-h(\square)}} \end{aligned}$$

where $q$ is a parameter (it is more common to use $\dim_{n,q^{1/2}}$ instead). Obviously, $\dim_{n,q} \to \dim_n$ as $q \to 1$. The function $\dim_{n,q}$ is an important building block of, for example, quantum invariants of knots and 3-folds, and various related objects (see, e.g., Bakalov and Kirillov (2001)). The Verlinde formula (Bakalov and Kirillov 2001) can be viewed as an analog of Burnside's formula with weight $\dim_{n,q}$. When $q$ is a root of unity the summation over $\lambda$ is naturally truncated to a finite sum.

The next level of generalization is obtained by deforming Schur function to Jack and, more generally, Macdonald symmetric functions (Macdonald 1995). In particular, the Jack polynomial analog of the Plancherel measure is

$$\mathfrak{M}_{\text{Jack}}(\lambda) = \prod_{\square \in \lambda} \frac{n!(t_1 t_2)^n}{((a(\square)+1)t_1 + l(\square)t_2)(a(\square)t_1 + (l(\square)+1)t_2)}$$

where $t_1, t_2$ are parameters, and $a(\square)$ and $l(\square)$ denote, as above, the arm- and leg-length of a square $\square$. This measure depends only on the ratio $t_2/t_1$ which is the usual parameter of Jack polynomials. To continue the analogy with random matrices, this should be viewed as a general $\beta$ analog of the Plancherel measure.

The measure $\mathfrak{M}_{\text{Jack}}$ naturally arises in Atiyah–Bott localization computations on the Hilbert scheme of $n$ points in $\mathbb{C}^2$. By definition, this Hilbert scheme parametrizes ideals $I \subset \mathbb{C}[x,y]$ of codimension $n$ as linear spaces. The torus $(\mathbb{C}^*)^2$ acts on it by rescaling $x$ and $y$ and the fixed points of this action are

$$I_\lambda = \text{Span of } \{x^{j-1} y^{i-1}\}_{(i,j) \notin \lambda}$$

where $\lambda$ is a partition of $n$. The weight of this fixed point in the Atiyah–Bott formula is proportional to $\mathfrak{M}_{\text{Jack}}(\lambda)$, the parameters $t_1$ and $-t_2$ being the standard torus weights. Corresponding formulas in $K$-theory involve a Macdonald polynomial analog of $\dim \lambda$.

Nekrasov defines the partition functions of $\mathcal{N}=2$ supersymmetric gauge theories by formally applying the Atiyah–Bott localization formula to (noncompact) instanton moduli spaces. The resulting expression is a sum over partitions with a weight which is a generalization of $\mathfrak{M}_{\text{Jack}}$. In this way, random partitions enter gauge theory. What is more, statistical properties of these random partitions are reflected in the dynamics of gauge theories. For example, the limit shape turns out to be precisely the Seiberg–Witten curve (see Nekrasov and Okounkov (2003), Okounkov (2002), and also Nakajima and Yoshioka (2003)).

## Harmonic Functions on Young Graph

### Definitions

Partitions form a natural directed graph $\mathbb{Y}$, known as Young graph, in which there is an edge from $\mu$ to $\lambda$ if $\lambda$ is obtained from $\mu$ by adding a square. We will denote this by $\mu \nearrow \lambda$. Let $\kappa$ be a non-negative function (called multiplicity) on edges of $\mathbb{Y}$. A function $\phi$ on the vertices of $\mathbb{Y}$ is harmonic if it satisfies

$$\phi(\mu) = \sum_{\lambda \nwarrow \mu} \kappa(\mu, \lambda) \phi(\lambda) \qquad [12]$$

for any $\mu$. For given edge multiplicities $\kappa$, non-negative harmonic functions normalized by $\phi(\emptyset) = 1$ form a convex compact (with respect to pointwise convergence) set, which we will denote by $\boldsymbol{H}(\kappa)$. The extreme points of $\boldsymbol{H}(\kappa)$ are the indecomposable or ergodic harmonic functions. They are the most important ones. One defines

$$\dim_\kappa \lambda/\mu = \sum_{\mu=\nu_0 \nearrow \nu_1 \nearrow \cdots \nearrow \nu_{|\lambda|-|\mu|}=\lambda} \prod \kappa(\nu_i, \nu_{i+1})$$

and $\dim_\kappa \lambda = \dim_\kappa \lambda/\emptyset$. For example, if $\kappa \equiv 1$ then $\dim_\kappa \lambda = \dim \lambda$. Any function $\phi \in \boldsymbol{H}(\kappa)$ defines a probability measure on partitions of fixed size $n, n = 0, 1, 2, \ldots$, by

$$\mathfrak{M}_{\phi,n}(\lambda) = \phi(\lambda) \dim_\kappa \lambda, \quad |\lambda| = n \qquad [13]$$

The mean value property [12] implies a certain coherence of these measures for different values of $n$, which, in general, does not hold for measures like $\mathfrak{M}_{\text{Schur}}$. Two multiplicity functions $\kappa$ and $\kappa'$ are gauge equivalent if

$$\kappa'(\mu, \lambda) = f(\mu) \kappa(\mu, \lambda) f(\lambda)^{-1}$$

for some function $f$. In this case, $\boldsymbol{H}(\kappa)$ and $\boldsymbol{H}(\kappa')$ are naturally isomorphic and the measures $\mathfrak{M}_\phi$ are the same.

### First Example: Thoma Theorem

Let $F$ be a central function on the infinite symmetric group $S(\infty) = \bigcup_n S(n)$, normalized by $F(1) = 1$. Restricted to $S(n)$, $F$ is a linear combination of irreducible characters

$$F|_{S(n)} = \sum_{|\lambda|=n} \phi(\lambda) \chi^\lambda$$

The branching rule $\chi^\lambda|_{S(n-1)} = \sum_{\mu \nearrow \lambda} \chi^\mu$ implies that the Fourier coefficients $\phi$ are harmonic with respect to $\kappa \equiv 1$. They are non-negative if and only if $F$ is a positive-definite function on $S(\infty)$, which means that the matrix $(F(g_i g_j^{-1}))$ is non-negative definite for any $\{g_i\} \subset S(\infty)$. The description of all indecomposable positive-definite central functions on $S(\infty)$ was first

obtained by Thoma (see Kerov (2003, 1998) and Olshanski (2003)). Rephrased in our language, it says that the functions

$$\phi(\lambda) = s_\lambda|_{p_1=1, p_k=\sum \alpha_i^k + (-1)^{k+1}\sum \beta_i^k, k>1}$$

are the extreme points of $\boldsymbol{H}(1)$. Here $\alpha_i$ and $\beta_i$ are parameters satisfying

$$\alpha_1 \geq \alpha_2 \geq \cdots \geq 0, \qquad \beta_1 \geq \beta_2 \geq \cdots \geq 0$$
$$\sum \alpha_i + \beta_i \leq 1$$

This set is known as the Thoma simplex. The origin $\alpha_i = \beta_i = 0$ corresponds to the Plancherel measure.

A general positive-definite central functions on $S(\infty)$ defines a measure on the Thoma simplex. This measure can be interpreted as a point process on the real line, for example, by placing particles at positions $\{\alpha_i\}$ and $\{-\beta_i\}$. Interesting central functions lead to interesting processes (see Olshanski (2003)).

### Second Example: Kingman Theorem

Let $\Pi$ be a partition of the naturals $\mathbb{N}$ into disjoint subsets. For any $n = 1, 2, \ldots, \Pi$ defines the induced partition $\Pi_n$ of $\{1, \ldots, n\}$ and hence a partition $\lambda(\Pi_n)$ of the number $n$. A measure $\mathcal{M}$ on partitions $\Pi$ is called exchangeable if

$$\mathcal{M}(\Pi_n) = \phi(\lambda(\Pi_n)), \quad n = 1, 2, \ldots$$

for some function $\phi$ on $\mathbb{Y}$. This implies that $\phi$ is harmonic for

$$\kappa_{\mathrm{K}}(\mu, \lambda) = \rho_k$$

where $\mu = 1^{\rho_1} 2^{\rho_2} \cdots$ and $\lambda = 1^{\rho_1} 2^{\rho_2} \cdots k^{\rho_k - 1} (k+1)^{\rho_{k+1}+1} \cdots$. The description of all exchangeable measures $\mathcal{M}$ was first obtained by Kingman. In our language, it says that the extreme points of $\boldsymbol{H}(\kappa_{\mathrm{K}})$ are

$$\phi(\lambda) = m_\lambda|_{p_1=1, p_k=\sum \alpha_i^k, k>1}$$

where $m_\lambda$ is the monomial symmetric function (sum of all monomials with exponents $\lambda$) and $\alpha_i$ are parameters as before. The corresponding measure $\mathcal{M}_\alpha$ can be described as follows. Let $X_i$ be a sequence of independent, identically distributed random variables such that $\{\alpha_i\}$ are the measures of atoms of their distribution. This defines a random partition $\Pi$ of $\mathbb{N}$ by putting $i$ and $j$ in the same block of $\Pi$ if and only if $X_i = X_j$. A general exchangeable measure $\mathcal{M}$ is then a convex linear combination of $\mathcal{M}_\alpha$, which can be viewed as making the common distribution of $X_i$ also random. See Pitman (n.d.) for a lot more about Kingman's theorem.

The multiplicities $\kappa_{\mathrm{K}}$ are gauge equivalent to multiplicities

$$\kappa_{\mathrm{VP}}(\mu, \lambda) = k\rho_k \qquad [14]$$

which arise in the study of probability measures on virtual permutations $\mathfrak{S}$ (Olshanski 2003). By definition,

$$\mathfrak{S} = \varprojlim S(n)$$

with respect to the maps $S(n) \to S(n-1)$ that delete $n$ from the disjoint cycle decomposition of a permutation $\sigma \in S(n)$. For $n \geq 5$, this is the unique map that commutes with the right and left action of $S(n-1)$. Thus, $\mathfrak{S}$ has a natural $S(\infty) \times S(\infty)$ action; however, it is not a group. A measure $\mathcal{M}$ on $\mathfrak{S}$ is central if it is invariant under the action of the diagonal subgroup in $S(\infty) \times S(\infty)$. Let the push-forward of $\mathcal{M}$ to $S(n)$ give mass $\phi(\lambda)$ to a permutation with cycle type $\lambda$. It is then easy to see that $\phi$ is harmonic with respect to [14]. Thus, Kingman's theorem gives a description of ergodic central measures on $\mathfrak{S}$. For example, $\alpha_i = 0$ corresponds to the $\delta$-measure at the identity.

### Ergodic Method

A unified approach to this type of problems was proposed and developed by Vershik and Kerov. It is based on the following ergodic theorem. Let $\phi$ be an ergodic harmonic function. Then

$$\phi(\mu) = \lim \frac{\dim_\kappa \lambda/\mu}{\dim_\kappa \lambda}, \quad |\lambda| \to \infty \qquad [15]$$

for almost all $\lambda$ with respect to the measure [13] (Kerov 2003). This is similar to approximating a Gibbs measure in infinite volume by a sequence of finite-volume Gibbs measures with appropriate boundary conditions. The ratio on the RHS of [15] is known as the Martin kernel. Its asymptotics as $|\lambda| \to \infty$ plays the essential role.

Let us call a sequence $\{\lambda(n)\}$ of partitions of $n$ regular if the limit in [15] exists for all $\mu$. For $\kappa \equiv 1$, Vershik and Kerov proved that $\{\lambda(n)\}$ is regular if and only if the following limits exist:

$$\frac{\lambda(n)_i}{n} \to \alpha_i, \qquad \frac{\lambda(n)'_i}{n} \to \beta_i \qquad [16]$$

that is, if the rows and columns of $\lambda(n)$, scaled by $n$, have a limit. In this case, the limit in [15] is the harmonic function with Thoma parameters $\alpha_i$ and $\beta_i$. This simultaneously proves Thoma classification and gives a law of large numbers for the corresponding measures [13]. It also gives a transparent geometric interpretation of Thoma parameters. Note that the behavior [16] is very different from the formation of a smooth limit shape that we saw earlier. For a common generalization of this result and Kingman's theorem see Kerov (1998).

# Random Walks in Random Environments

**L V Bogachev**, University of Leeds, Leeds, UK

## Introduction

Random walks provide a simple conventional model to describe various transport processes, for example, propagation of heat or diffusion of matter through a medium (for a general reference see, e.g., Hughes (1995)). However, in many practical cases, the medium where the system evolves is highly irregular, due to factors such as defects, impurities, fluctuations, etc. It is natural to model such irregularities as "random environment," treating the observable sample as a statistical realization of an ensemble, obtained by choosing the local characteristics of the motion (e.g., transport coefficients and driving fields) at random, according to a certain probability distribution.

In the random walks context, such models are referred to as "random walks in random environments" (RWRE). This is a relatively new chapter in applied probability and physics of disordered systems initiated in the 1970s. Early interest in RWRE models was motivated by some problems in biology, crystallography, and metal physics, but later applications have spread through numerous areas (see review papers by Alexander *et al.* (1981), Bouchaud and Georges (1990), and a comprehensive monograph by Hughes (1996)). After 30 years of extensive work, RWRE remain a very active area of research, which has been a rich source of hard and challenging questions and has already led to many surprising discoveries, such as subdiffusive behavior, trapping effects, localization, etc. It is fair to say that the RWRE paradigm has become firmly established in physics of random media, and its models, ideas, methods, results, and general effects have become an indispensable part of the standard tool kit of a mathematical physicist.

One of the central problems in random media theory is to establish conditions ensuring homogenization, whereby a given stochastic system evolving in a random medium can be adequately described, on some spatial–temporal scale, using a suitable effective system in a homogeneous (nonrandom) medium. In particular, such systems would exhibit classical diffusive behavior with effective drift and diffusion coefficient. Such an approximation, called "effective medium approximation" (EMA), may be expected to

be successful for systems exposed to a relatively small disorder of the environment. However, in certain circumstances, EMA may fail due to atypical environment configurations ("large deviations") leading to various anomalous effects. For instance, with small but positive probability a realization of the environment may create "traps" that would hold the particle for an anomalously long time, resulting in the subdiffusive behavior, with the mean square displacement growing slower than linearly in time.

RWRE models have been studied by various nonrigorous methods including Monte Carlo simulations, series expansions, and the renormalization group techniques (see more details in the above references), but only a few models have been analyzed rigorously, especially in dimensions greater than one. The situation is much more satisfactory in the one-dimensional case, where the mathematical theory has matured and the RWRE dynamics has been understood fairly well.

The goal of this article is to give a brief introduction to the beautiful area of RWRE. The principal model to be discussed is a random walk with nearest-neighbor jumps in independent and identically distributed (i.i.d.) random environment in one dimension, although we shall also comment on some generalizations. The focus is on rigorous results; however, heuristics will be used freely to motivate the ideas and explain the approaches and proofs. In a few cases, sketches of the proofs have been included, which should help appreciate the flavor of the results and methods.

## Ordinary Random Walks: A Reminder

To put our exposition in perspective, let us give a brief account of a few basic concepts and facts for ordinary random walks, that is, evolving in a nonrandom environment (see further details in Hughes (1995)). In such models, space is modeled using a suitable graph, for example, a $d$-dimensional integer lattice $\mathbb{Z}^d$, while time may be discrete or continuous. The latter distinction is not essential, and in this article we will mostly focus on the discrete-time case. The random mechanism of spatial motion is then determined by the given transition probabilities (probabilities of jumps) at each site of the graph. In the lattice case, it is usually assumed that the walk is translation invariant, so that at each step distribution of jumps is the same, with no regard to the current location of the walk.

In one dimension ($d=1$), the simple (nearest-neighbor) random walk may move one step to right or to the left at a time, with some probabilities $p$ and $q=1-p$, respectively. An important assumption is that only the current location of the walk determines the random motion mechanism, whereas the past history is not relevant. In terms of probability theory, such a process is referred to as "Markov chain." Thus, assuming that the walk starts at the origin, its position after $n$ steps can be represented as the sum of consecutive displacements, $X_n = Z_1 + \cdots + Z_n$, where $Z_i$ are independent random variables with the same distribution $P\{Z_i = 1\} = p$, $P\{Z_i = -1\} = q$.

The strong law of large numbers (LLN) states that almost surely (i.e., with probability 1)

$$\lim_{n\to\infty} \frac{X_n}{n} = EZ_1 = p - q, \quad P\text{-a.s.} \qquad [1]$$

where $E$ denotes expectation (mean value) with respect to $P$. This result shows that the random walk moves with the asymptotic average velocity close to $p-q$. It follows that if $p-q \neq 0$, then the process $X_n$, with probability 1, will ultimately drift to infinity (more precisely, $+\infty$ if $p-q>0$ and $-\infty$ if $p-q<0$). In particular, in this case, the random walk may return to the origin (and in fact visit any site on $\mathbb{Z}$) only finitely many times. Such behavior is called "transient." However, in the symmetric case (i.e., $p=q=0.5$) the average velocity vanishes, so the above argument fails. In this case, the walk behavior appears to be more complicated, as it makes increasingly large excursions both to the right and to the left, so that $\overline{\lim}_{n\to\infty} X_n = +\infty$, $\underline{\lim}_{n\to\infty} X_n = -\infty$ ($P$-a.s.). This implies that a symmetric random walk in one dimension is "recurrent," in that it visits the origin (and indeed any site on $\mathbb{Z}$) infinitely often. Moreover, it can be shown to be "null-recurrent," which means that the expected time to return to the origin is infinite. That is to say, return to the origin is guaranteed, but it takes very long until this happens.

Fluctuations of the random walk can be characterized further via the central limit theorem (CLT), which amounts to saying that the probability distribution of $X_n$ is asymptotically normal, with mean $n(p-q)$ and variance $4npq$:

$$\lim_{n\to\infty} P\left\{\frac{X_n - n(p-q)}{\sqrt{4npq}} \le x\right\} = \Phi(x) := \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{x} \mathrm{e}^{-y^2/2}\,\mathrm{d}y \qquad [2]$$

These results can be extended to more general walks in one dimension, and also to higher dimensions. For instance, the criterion of recurrence for a general one-dimensional random walk is that it is unbiased, $E(X_1 - X_0) = 0$. In the two-dimensional case, in addition one needs $E|X_1 - X_0|^2 < \infty$. In higher dimensions, any random walk (which does not reduce to lower dimension) is transient.

### Random Environments and Random Walks

The definition of an RWRE involves two ingredients: (1) the environment, which is randomly chosen but remains fixed throughout the time evolution, and (2) the random walk, whose transition probabilities are determined by the environment. The set of environments (sample space) is denoted by $\Omega=\{\omega\}$, and we use $\mathbb{P}$ to denote the probability distribution on this space. For each $\omega\in\Omega$, we define the random walk in the environment $\omega$ as the (time-homogeneous) Markov chain $\{X_t,\ t=0,1,2,\ldots\}$ on $\mathbb{Z}^d$ with certain (random) transition probabilities

$$p(x,y,\omega)=P^\omega\{X_1=y|X_0=x\} \qquad [3]$$

The probability measure $P^\omega$ that determines the distribution of the random walk in a given environment $\omega$ is referred to as the "quenched" law. We often use a subindex to indicate the initial position of the walk, so that, for example, $P_x^\omega\{X_0=x\}=1$.

By averaging the quenched probability $P_x^\omega$ further, with respect to the environment distribution, we obtain the "annealed" measure $\boldsymbol{P}_x=\mathbb{P}\times P_x^\omega$, which determines the probability law of the RWRE:

$$\boldsymbol{P}_x(A)=\int_\Omega P_x^\omega(A)\ \mathbb{P}(\mathrm{d}\omega)=\mathbb{E}P_x^\omega(A) \qquad [4]$$

Expectation with respect to the annealed measure $\boldsymbol{P_x}$ will be denoted by $\boldsymbol{E_x}$.

Equation [4] implies that if some property $A$ of the RWRE holds almost surely with respect to the quenched law $P_x^\omega$ for almost all environments (i.e., for all $\omega\in\Omega'$ such that $\mathbb{P}(\Omega')=1$), then this property is also true with probability 1 under the annealed law $\boldsymbol{P}_x$.

Note that the random walk $X_n$ is a Markov chain only conditionally on the fixed environment (i.e., with respect to $P_x^\omega$), but the Markov property fails under the annealed measure $\boldsymbol{P}_x$. This is because the past history cannot be neglected, as it tells what information about the medium must be taken into account when averaging with respect to environment. That is to say, the walk learns more about the environment by taking more steps. (This idea motivates the method of "environment viewed from the particle," see related section below.)

The simplest model is the nearest-neighbor one-dimensional walk, with transition probabilities

$$p(x,y,\omega)=\begin{cases} p_x & \text{if } y=x+1\\ q_x & \text{if } y=x-1\\ 0 & \text{otherwise}\end{cases}$$

where $p_x$ and $q_x=1-p_x$ $(x\in\mathbb{Z})$ are random variables on the probability space $(\Omega,\mathbb{P})$. That is to say, given the environment $\omega\in\Omega$, the random walk currently at point $x\in\mathbb{Z}$ will make a one-unit step to the right, with probability $p_x$, or to the left, with probability $q_x$. Here the environment is determined by the sequence of random variables $\{p_x\}$. For most of the article, we assume that the random probabilities $\{p_x, x\in\mathbb{Z}\}$ are i.i.d., which is referred to as "i.i.d. environment." Some extensions to more general environments will be mentioned briefly in the section "Some generalizations and variations." The study of RWRE is simplified under the following natural condition called "(uniform) ellipticity:"

$$0<\delta\le p_x\le 1-\delta<1,\quad x\in\mathbb{Z},\ \mathbb{P}\text{-a.s.} \qquad [5]$$

which will be frequently assumed in the sequel.

## Transience and Recurrence

In this section, we discuss a criterion for the RWRE to be transient or recurrent. The following theorem is due to Solomon (1975).

**Theorem 1** *Set $\rho_x:=q_x/p_x$, $x\in\mathbb{Z}$, and $\eta:=\mathbb{E}\ln\rho_0$.*

(i) *If $\eta\neq 0$ then $X_t$ is transient ($\boldsymbol{P}_0$-a.s.); moreover, if $\eta<0$ then $\lim_{t\to 0}X_t=+\infty$, while if $\eta>0$ then $\lim_{t\to 0}X_t=-\infty$ ($\boldsymbol{P}_0$-a.s.).*

(ii) *If $\eta=0$ then $X_t$ is recurrent ($\boldsymbol{P}_0$-a.s.); moreover,*

$$\overline{\lim_{t\to\infty}}\, X_t=+\infty,\quad \underline{\lim_{t\to\infty}}\, X_t=-\infty,\quad \boldsymbol{P}_0\text{-a.s.}$$

Let us sketch the proof. Consider the hitting times $T_x:=\min\{t\ge 0: X_t=x\}$ and denote by $f_{xy}$ the quenched first-passage probability from $x$ to $y$:

$$f_{xy}:=P_x^\omega\{1\le T_y<\infty\}$$

Starting from 0, the first step of the walk may be either to the right or to the left, hence by the Markov property the return probability $f_{00}$ can be decomposed as

$$f_{00}=p_0f_{10}+q_0f_{-1,0} \qquad [6]$$

To evaluate $f_{10}$, for $n\ge 1$ set

$$u_x\equiv u_x^{(n)}:=P_x^\omega\{T_0<T_n\},\quad 0\le x\le n$$

which is the probability to reach 0 prior to $n$, starting from $x$. Clearly,

$$f_{10}=\lim_{n\to\infty}u_1^{(n)} \qquad [7]$$

Decomposition with respect to the first step yields the difference equation

$$u_x=p_xu_{x+1}+q_xu_{x-1},\quad 0<x<n \qquad [8]$$

with the boundary conditions

$$u_0=1,\qquad u_n=0 \qquad [9]$$

Using $p_x + q_x = 1$, eqn [8] can be rewritten as

$$u_{x+1} - u_x = \rho_x(u_x - u_{x-1})$$

whence by iterations

$$u_{x+1} - u_x = (u_1 - u_0)\prod_{j=1}^{x} \rho_j \qquad [10]$$

Summing over $x$ and using the boundary conditions [9] we obtain

$$1 - u_1 = \left(\sum_{x=0}^{n-1}\prod_{j=1}^{x} \rho_j\right)^{-1} \qquad [11]$$

(if $x = 0$, the product over $j$ is interpreted as 1). In view of eqn [7] it follows that $f_{10} = 1$ if and only if the right-hand side of eqn [11] tends to 0, that is,

$$\sum_{x=1}^{\infty} \exp(Y_x) = \infty, \quad Y_x := \sum_{j=1}^{x} \ln \rho_j \qquad [12]$$

Note that the random variables $\ln \rho_j$ are i.i.d., hence by the strong LLN

$$\lim_{x\to\infty} \frac{Y_x}{x} = \mathbb{E}\ln \rho_0 \equiv \eta, \quad \mathbb{P}\text{-a.s.}$$

That is, the general term of the series [12] for large $x$ behaves like $\exp(x\eta)$; hence, for $\eta > 0$ the condition [12] holds true (and so $f_{10} = 1$), whereas for $\eta < 0$ it fails (and so $f_{10} < 1$).

By interchanging the roles of $p_x$ and $q_x$, we also have $f_{-1,0} < 1$ if $\eta > 0$ and $f_{-1,0} = 1$ if $\eta < 0$. From eqn [6], it then follows that in both cases $f_{00} < 1$, that is, the random walk is transient.

In the critical case, $\eta = 0$, by a general result from probability theory, $Y_x \geq 0$ for infinitely many $x$ ($\mathbb{P}$-a.s.), and so the series in eqn [12] diverges. Hence, $f_{10} = 1$ and, similarly, $f_{-1,0} = 1$, so by eqn [6] $f_{00} = 1$, that is, the random walk is recurrent.

It may be surprising that the critical parameter appears in the form $\eta = \mathbb{E}\ln \rho_0$, as it is probably more natural to expect, by analogy with the ordinary random walk, that the RWRE criterion would be based on the mean drift, $\mathbb{E}(p_0 - q_0)$. In the next section, we will see that the sign of $d$ may be misleading.

A canonical model of RWRE is specified by the assumption that the random variables $p_x$ take only two values, $\beta$ and $1 - \beta$, with probabilities

$$\mathbb{P}\{p_x = \beta\} = \alpha, \quad \mathbb{P}\{p_x = 1 - \beta\} = 1 - \alpha \qquad [13]$$

where $0 < \alpha < 1$, $0 < \beta < 1$. Here $\eta = (2\alpha - 1)\times \ln(1 + (1 - 2\beta)/\beta)$, and it is easy to see that, for example, $\eta < 0$ if $\alpha < 1/2$, $\beta < 1/2$ or $\alpha > 1/2$, $\beta > 1/2$. The recurrent region where $\eta = 0$ splits into two lines, $\beta = 1/2$ and $\alpha = 1/2$. Note that the first case is degenerate and amounts to the ordinary symmetric random walk, while the second one (except where $\beta = 1/2$) corresponds to Sinai's problem (see the section "Sinai's localization"). A "phase diagram" for this model, showing various limiting regimes as a function of the parameters $\alpha, \beta$, is presented in **Figure 1**.

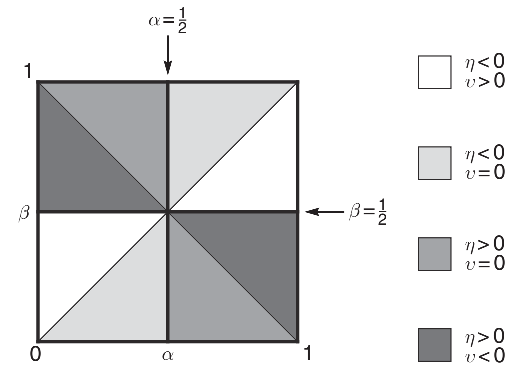

**Figure 1** Phase diagram for the canonical model, eqn [13]. In the regions where $\eta < 0$ or $\eta > 0$, the RWRE is transient to $+\infty$ or $-\infty$, respectively. The recurrent case, $\eta = 0$, arises when $\alpha = 1/2$ or $\beta = 1/2$. The asymptotic velocity $v := \lim_{t\to 0} X_t/t$ is given by eqn [14]. Adapted from Hughes BD (1996) *Random Walks and Random Environments. Volume 2: Random Environments*, Ch. 6, p. 391. Oxford: Clarendon, by permission of Oxford University Press.

## Asymptotic Velocity

In the transient case the walk escapes to infinity, and it is reasonable to ask at what speed. For a nonrandom environment, $p_x \equiv p$, the answer is given by the LLN, eqn [1]. For the simple RWRE, the asymptotic velocity was obtained by Solomon (1975). Note that by Jensen's inequality, $(\mathbb{E}\rho_0)^{-1} \leq \mathbb{E}\rho_0^{-1}$.

**Theorem 2** *The limit* $v := \lim_{t\to\infty} X_t/t$ *exists* ($\boldsymbol{P}_0$*-a.s.*) *and is given by*

$$v = \begin{cases} \dfrac{1 - \mathbb{E}\rho_0}{1 + \mathbb{E}\rho_0} & \text{if } \mathbb{E}\rho_0 < 1 \\ -\dfrac{1 - \mathbb{E}\rho_0^{-1}}{1 + \mathbb{E}\rho_0^{-1}} & \text{if } \mathbb{E}\rho_0^{-1} < 1 \\ 0 & \text{otherwise} \end{cases} \qquad [14]$$

Thus, the RWRE has a well-defined nonzero asymptotic velocity except when $(\mathbb{E}\rho_0)^{-1} \leq 1 \leq \mathbb{E}\rho_0^{-1}$. For instance, in the canonical example eqn [13] (see **Figure 1**), the criterion $\mathbb{E}\rho_0 < 1$ for the velocity $v$ to be positive amounts to the condition that both $(1 - \alpha)/\alpha$ and $(1 - \beta)/\beta$ lie on the same side of point 1.

The key idea of the proof is to analyze the hitting times $T_n$ first, deducing results for the walk $X_t$ later. More specifically, set $\tau_i = T_i - T_{i-1}$, which is the time to hit $i$ after hitting $i-1$ (providing that $i > X_0$). If $X_0 = 0$ and $n \geq 1$, then $T_n = \tau_1 + \cdots + \tau_n$. Note that in fixed environment $\omega$ the random variables $\{\tau_i\}$ are independent, since the quenched random walk "forgets" its past. Although there is no independence with respect to the annealed probability measure $\boldsymbol{P}_0$, one can show that, due to the i.i.d. property of the environment, the sequence $\{\tau_i\}$ is ergodic and therefore satisfies the LLN:

$$\frac{T_n}{n} = \frac{\tau_1 + \cdots + \tau_n}{n} \to \boldsymbol{E}_0\tau_1, \quad \boldsymbol{P}_0\text{-a.s.}$$

In turn, this implies

$$\frac{X_t}{t} \to \frac{1}{\boldsymbol{E}_0\tau_1}, \quad \boldsymbol{P}_0\text{-a.s.} \qquad [15]$$

(the clue is to note that $X_{T_n} = n$).

To compute the mean value $\boldsymbol{E}_0\tau_1$, observe that

$$\tau_1 = \mathbf{1}_{\{X_1=1\}} + \mathbf{1}_{\{X_1=-1\}}(1 + \tau_0' + \tau_1') \qquad [16]$$

where $\mathbf{1}_A$ is the indicator of event $A$ and $\tau_0', \tau_1'$ are, respectively, the times to get from $-1$ to 0 and then from 0 to 1. Taking expectations in a fixed environment $\omega$, we obtain

$$E_0^\omega\tau_1 = p_0 + q_0(1 + E_0^\omega\tau_0' + E_0^\omega\tau_1) \qquad [17]$$

and so

$$E_0^\omega\tau_1 = 1 + \rho_0 + \rho_0 E_0^\omega\tau_0' \qquad [18]$$

Note that $E_0^\omega\tau_0'$ is a function of $\{p_x, x<0\}$ and hence is independent of $\rho_0 = q_0/p_0$. Averaging eqn [18] over the environment and using $\boldsymbol{E}_0\tau_0' = \boldsymbol{E}_0\tau_1$ yields

$$\boldsymbol{E}_0\tau_1 = \begin{cases} \dfrac{1 + \mathbb{E}\rho_0}{1 - \mathbb{E}\rho_0} & \text{if } \mathbb{E}\rho_0 < 1 \\ \infty & \text{if } \mathbb{E}\rho_0 \geq 1 \end{cases} \qquad [19]$$

and by eqn [15] "half" of eqn [14] follows. The other half, in terms of $\mathbb{E}\rho_0^{-1}$, can be obtained by interchanging the roles of $p_x$ and $q_x$, whereby $\rho_0$ is replaced with $\rho_0^{-1}$.

Let us make a few remarks concerning Theorems 1 and 2. First of all, note that by Jensen's inequality $\mathbb{E}\ln\rho_0 \leq \ln\mathbb{E}\rho_0$, with a strict inequality whenever $\rho_0$ is nondegenerate. Therefore, it may be possible that, with $P_0$-probability 1, $X_t \to \infty$ but $X_t/t \to 0$ (see **Figure 1**). This is quite unusual as compared to the ordinary random walk (see the subsection "Ordinary random walks: a reminder"), and indicates some kind of slowdown in the transient case.

Furthermore, by Jensen's inequality

$$\mathbb{E}\rho_0 = \mathbb{E}p_0^{-1} - 1 \geq (\mathbb{E}p_0)^{-1} - 1$$

so eqn [14] implies that if $\mathbb{E}\rho_0 < 1$, then

$$0 < v \leq 2\,\mathbb{E}p_0 - 1 = \mathbb{E}\,(p_0 - q_0)$$

and the inequality is strict if $p_0$ is genuinely random (i.e., does not reduce to a constant). Hence, the asymptotic velocity $v$ is less than the mean drift $\mathbb{E}(p_0 - q_0)$, which is yet another evidence of slowdown. What is even more surprising is that it is possible to have $\mathbb{E}(p_0 - q_0) > 0$ but $\eta = \mathbb{E}\ln\rho_0 > 0$, so that $\mathbb{P}_0$-a.s. $X_t \to -\infty$ (although with velocity $v = 0$). Indeed, following Sznitman (2004) suppose that

$$\mathbb{P}\{p_0 = \beta\} = \alpha, \qquad \mathbb{P}\{p_0 = \gamma\} = 1 - \alpha$$

with $\alpha > 1/2$. Then $\mathbb{E}p_0 \geq \alpha\beta > 1/2$ if $1 > \beta > 1/2\alpha$, hence $\mathbb{E}(p_0 - q_0) = 2\,\mathbb{E}p_0 - 1 > 0$. On the other hand,

$$\mathbb{E}\ln\rho_0 = \alpha\ln\frac{1-\beta}{\beta} + (1-\alpha)\ln\frac{1-\gamma}{\gamma} > 0$$

if $\gamma$ is sufficiently small.

## Critical Exponent, Excursions, and Traps

Extending the previous analysis of the hitting times, one can obtain useful information about the limit distribution of $T_n$ (and hence $X_t$). To appreciate this, note that from the recursion eqn [16] it follows

$$\tau_1^s = \mathbf{1}_{\{X_1=1\}} + \mathbf{1}_{\{X_1=-1\}}(1 + \tau_0' + \tau_1')^s$$

and, similarly to [17],

$$E_0^\omega\tau_1^s = p_0 + q_0 E_0^\omega(1 + \tau_0' + \tau_1')^s$$

Taking here expectation $\mathbb{E}$, one can deduce that $\boldsymbol{E}_0\tau_1^s < \infty$ if and only if $\mathbb{E}\rho_0^s < 1$. Therefore, it is natural to expect that the root $\kappa$ of the equation

$$\mathbb{E}\rho_0^\kappa = 1 \qquad [20]$$

plays the role of a critical exponent responsible for the growth rate (and hence, for the type of the limit distribution) of the sum $T_n = \tau_1 + \cdots + \tau_n$. In particular, by analogy with sums of i.i.d. random variables one can expect that if $\kappa > 2$, then $T_n$ is asymptotically normal, with the standard scaling $\sqrt{n}$, while for $\kappa < 2$ the limit law of $T_n$ is stable (with index $\kappa$) under scaling $\approx n^{1/\kappa}$.

Alternatively, eqn [20] can be obtained from consideration of excursions of the random walk. Let $T_{11}^L$ be the left-excursion time from site 1, that is the time to return to 1 after moving to the left at the first step. If $\eta = \mathbb{E}\ln\rho_0 < 0$, then $T_{11}^L < \infty$ ($\boldsymbol{P}_0$-a.s.). Fixing an environment $\omega$, let $w_1 = E_1^\omega T_{11}^L$ be the

quenched mean duration of the excursion $T_{11}^L$ and observe that $w_1 = 1 + E_0^\omega \tau_1$, where $\tau_1$ is the time to get back to 1 after stepping to 0.

As a matter of fact, this representation and eqn [19] imply that the annealed mean duration of the left excursion, $\boldsymbol{E}_0 T_{11}^L$, is given by

$$\mathbb{E}w_1 = \begin{cases} \dfrac{2}{1 - \mathbb{E}\rho_0} & \text{if } \mathbb{E}\rho_0 < 1 \\ \infty & \text{if } \mathbb{E}\rho_0 \geq 1 \end{cases} \qquad [21]$$

Note that in the latter case (and bearing in mind $\eta < 0$), the random walk starting from 1 will eventually drift to $+\infty$, thus making only a finite number of visits to 0, but the expected number of such visits is infinite.

In fact, our goal here is to characterize the distribution of $w_1$ under the law $\mathbb{P}$. To this end, observe that the excursion $T_{11}^L$ involves at least two steps (the first and the last ones) and, possibly, several left excursions from 0, each with mean time $w_0 = E_0^\omega T_{00}^L$. Therefore,

$$w_1 = 2 + \sum_{j=1}^{\infty} q_0^j p_0 (j w_0) = 2 + \rho_0 w_0 \qquad [22]$$

By the translation invariance of the environment, the random variables $w_1$ and $w_0$ have the same distribution. Furthermore, similarly to recursion [22], we have $w_0 = 2 + \rho_{-1} w_{-1}$. This implies that $w_0$ is a function of $p_x$ with $x \leq -1$ only, and hence $w_0$ and $\rho_0$ are independent random variables. Introducing the Laplace transform $\phi(s) = \mathbb{E}\exp(-s w_1)$ and conditioning on $\rho_0$, from eqn [22] we get the equation

$$\phi(s) = \mathrm{e}^{-2s} \mathbb{E}\phi(s\rho_0) \qquad [23]$$

Suppose that

$$1 - \phi(s) \sim a s^\kappa, \quad s \to 0$$

then eqn [23] amounts to

$$1 - as^\kappa + \cdots = (1 - 2s + \cdots)(1 - as^\kappa\, \mathbb{E}\rho_0^\kappa + \cdots)$$

Expanding the product on the right, one can see that a solution with $\kappa = 1$ is possible only if $\mathbb{E}\rho_0 < 1$, in which case

$$a = \mathbb{E}w_1 = \frac{2}{1 - \mathbb{E}\rho_0}$$

We have already obtained this result in eqn [21].

The case $\kappa < 1$ is possible if $\mathbb{E}\rho_0^\kappa = 1$, which is exactly eqn [20]. Returning to $w_1$, one expects a slow decay of the distribution tail,

$$\mathbb{P}\{w_1 > t\} \sim bt^{-1/\kappa}, \quad t \to \infty$$

In particular, in this case the annealed mean duration of the left excursion appears to be infinite.

Although the above considerations point to the critical parameter $\kappa$, eqn [20], which may be expected to determine the slowdown scale, they provide little explanation of a mechanism of the slowdown phenomenon. Heuristically, it is natural to attribute the slowdown effects to the presence of "traps" in the environment, which may be thought of as regions that are easy to enter but hard to leave. In the one-dimensional case, such a trap would occur, for example, between two long series of successive sites where the probabilities $p_x$ are fairly large (on the left) and small (on the right).

Remarkably, traps can be characterized quantitatively with regard to the properties of the random environment, by linking them to certain large-deviation effects (see Sznitman (2002, 2004)). The key role in this analysis is played by the function $F(u) := \ln \mathbb{E}\rho_0^u$, $u \in \mathbb{R}$. Suppose that $\eta = \mathbb{E}\ln\rho_0 < 0$ (so that by Theorem 1 the RWRE tends to $+\infty$, $\boldsymbol{P}_0$-a.s.) and also that $\mathbb{E}\rho_0 > 1$ and $\mathbb{E}\rho_0^{-1} > 1$ (so that by Theorem 2, $v = 0$). The latter means that $F(1) > 0$ and $F(-1) > 0$, and since $F$ is a smooth strictly convex function and $F(0) = 0$, it follows that there is the second root $0 < \kappa < 1$, so that $F(\kappa) = 0$, that is, $\mathbb{E}\rho_0^\kappa = 1$ (cf. eqn [20]).

Let us estimate the probability to have a trap in $U = [-L, L]$ where the RWRE will spend anomalously long time. Using eqn [11], observe that

$$P_1^\omega\{T_0 < T_{L+1}\} \geq 1 - \exp\{-LS_L\}$$

where $S_L := L^{-1}\sum_{x=1}^{L} \ln\rho_x \to \eta < 0$ as $L \to \infty$. However, due to large deviations $S_L$ may exceed level $\epsilon > 0$ with probability

$$\mathbb{P}\{S_L > \epsilon\} \sim \exp\{-LI(\epsilon)\}, \quad L \to \infty$$

where $I(x) := \sup_u \{ux - F(u)\}$ is the Legendre transform of $F$. We can optimize this estimate by assuming that $\epsilon L \geq \ln n$ and minimizing the ratio $I(\epsilon)/\epsilon$. Note that $F(u)$ can be expressed via the inverse Legendre transform, $F(u) = \sup_x\{xu - I(x)\}$, and it is easy to see that if $\kappa := \min_{\epsilon > 0} I(\epsilon)/\epsilon$, then $F(\kappa) = 0$, so $\kappa$ is the second (positive) root of $F$.

The "left" probability $P_{-1}^\omega\{T_0 < T_{-L-1}\}$ is estimated in a similar fashion, and one can deduce that for some constants $K > 0, c > 0$, and any $\kappa' > \kappa$, for large $n$

$$\mathbb{P}\left\{P_0^\omega\left\{\max_{k \leq n} |X_k| \leq K\ln n\right\} \geq c\right\} \geq n^{-\kappa'}$$

That is to say, this is a bound on the probability to see a trap centered at 0, of size $\approx \ln n$, which will retain the RWRE for at least time $n$. It can be shown that, typically, there will be many such traps both in $[-n^{\kappa'}, 0]$ and $[0, n^{\kappa'}]$, which will essentially

prevent the RWRE from moving at distance $n^{\kappa'}$ from the origin before time $n$. In particular, it follows that $\lim_{n\to\infty} X_n/n^{\kappa'} = 0$ for any $\kappa' > \kappa$, so recalling that $0 < \kappa < 1$, we have indeed a sublinear growth of $X_n$. This result is more informative as compared to Theorem 2 (the case $v = 0$), and it clarifies the role of traps (see more details in Sznitman (2004)). The nontrivial behavior of the RWRE on the precise growth scale, $n^{\kappa}$, is characterized in the next section.

## Limit Distributions

Considerations in the previous section suggest that the exponent $\kappa$, defined as the solution of eqn [20], characterizes environments in terms of duration of left excursions. These heuristic arguments are confirmed by a limit theorem by Kesten *et al.* (1975), which specifies the slowdown scale. We state here the most striking part of their result. Denote $\ln^+ u := \max\{\ln u, 0\}$; by an arithmetic distribution one means a probability law on $\mathbb{R}$ concentrated on the set of points of the form $0, \pm c, \pm 2c, \ldots$.

**Theorem 3** *Assume that* $-\infty \le \eta = \mathbb{E} \ln \rho_0 < 0$ *and the distribution of* $\ln \rho_0$ *is nonarithmetic (excluding a possible atom at* $-\infty$*). Suppose that the root* $\kappa$ *of* eqn [20] *is such that* $0 < \kappa < 1$ *and* $\mathbb{E}\rho_0^{\kappa} \ln^+ \rho_0 < \infty$. *Then*

$$\lim_{n\to\infty} \boldsymbol{P}_0\{n^{-1/\kappa} T_n \le t\} = L_\kappa(t)$$

$$\lim_{t\to\infty} \boldsymbol{P}_0\{t^{-\kappa} X_t \le x\} = 1 - L_\kappa(x^{-1/\kappa})$$

*where* $L_\kappa(\cdot)$ *is the distribution function of a stable law with index* $\kappa$*, concentrated on* $[0, \infty)$.

General information on stable laws can be found in many probability books; we only mention here that the Laplace transform of a stable distribution on $[0, \infty)$ with index $\kappa$ has the form $\phi(s) = \exp\{-Cs^{\kappa}\}$.

Kesten *et al.* (1975) also consider the case $\kappa \ge 1$. Note that for $\kappa > 1$, we have $\mathbb{E}_{\rho_0} < (\mathbb{E}_{\rho_0^{\kappa}})^{1/\kappa} = 1$, so $v > 0$ by eqn [14]. For example, if $\kappa > 2$ then, as expected (see the previous section), there exists a nonrandom $\sigma^2 > 0$ such that

$$\lim_{n\to\infty} \boldsymbol{P}_0\left\{\frac{T_n - n/v}{\sigma\sqrt{n}} \le t\right\} = \Phi(t)$$

$$\lim_{t\to\infty} \boldsymbol{P}_0\left\{\frac{X_t - tv}{v^{3/2}\sigma\sqrt{t}} \le x\right\} = \Phi(x)$$

Let us describe an elegant idea of the proof based on a suitable renewal structure. (1) Let $U_i^n$ $(i \le n)$ be the number of left excursions starting from $i$ up to time $T_n$, and note that $T_n = n + 2\sum_i U_i^n$. Since the walk is transient to $+\infty$, the sum $\sum_{i\le 0} U_i^n$ is finite ($\boldsymbol{P}_0$-a.s.) and so does not affect the limit. (2) Observe that if the environment $\omega$ is fixed then the conditional distribution of $U_j^n$, given $U_{j+1}^n, \ldots, U_n^n = 0$, is the same as the distribution of the sum of $1 + U_{j+1}^n$ i.i.d. random variables $V_1, V_2, \ldots,$ each with geometric distribution $P_0^{\omega}\{V_i = k\} = p_j q_j^k$ $(k = 0, 1, 2, \ldots)$. Therefore, the sum $\sum_{i=1}^n U_i^n$ (read from right to left) can be represented as $\sum_{t=0}^{n-1} Z_t$, where $Z_0 = 0, Z_1, Z_2, \ldots$ is a branching process (in random environment $\{p_j\}$) with one immigrant at each step and the geometric offspring distribution with parameter $p_j$ for each particle present at time $j$. (3) Consider the successive "regeneration" times $\tau_k^*$, at which the process $Z_t$ vanishes. The partial sums $W_k := \sum_{\tau_k^* \le t < \tau_{k+1}^*} Z_t$ form an i.i.d. sequence, and the proof amounts to showing that the sum of $W_k$ has a stable limit of index $\kappa$. (4) Finally, the distribution of $W_0$ can be approximated using $M_0 := \sum_{t=1}^{\infty} \prod_{j=0}^{n-1} \rho_j$ (cf. eqn [11]), which is the quenched mean number of total progeny of the immigrant at time $t = 0$. Using Kesten's renewal theorem, it can be checked that $\mathbb{P}\{M_0 > x\} \sim Kx^{-\kappa}$ as $x \to \infty$, so $M_0$ is in the domain of attraction of a stable law with index $\kappa$, and the result follows.

Let us emphasize the significance of the regeneration times $\tau_i^*$. Returning to the original random walk, one can see that these are times at which the RWRE hits a new "record" on its way to $+\infty$, never to backtrack again. The same idea plays a crucial role in the analysis of the RWRE in higher dimensions (see the subsections "Zero–one laws and LLNs" and "Kalikow's condition and Sznitman's condition (T′)").

Finally, note that the condition $-\infty \le \eta < 0$ allows $\mathbb{P}\{p_0 = 1\} > 0$, so the distribution of $\rho_0$ may have an atom at 0 (and hence $\ln \rho_0$ at $-\infty$). In view of eqn [20], no atom is possible at $+\infty$. The restriction for the distribution of $\ln \rho_0$ to be nonarithmetic is important. This will be illustrated in the section "Diode model," where we discuss the model of random diodes.

## Sinai's Localization

The results discussed in the previous section indicate that the less transient the RWRE is (i.e., the critical exponent decreasing to zero), the slower it moves. Sinai (1982) proved a remarkable theorem showing that for the recurrent RWRE (i.e., with $\eta = \mathbb{E} \ln \rho_0 = 0$), the slowdown effect is exhibited in a striking way.

**Theorem 4** *Suppose that the environment $\{p_x\}$ is i.i.d. and elliptic, eqn [5], and assume that $\mathbb{E}\ln\rho_0 = 0$, with $\mathbb{P}\{\rho_0 = 1\} < 1$. Denote $\sigma^2 := \mathbb{E}\ln^2 \rho_0, 0 < \sigma^2 < \infty$. Then there exists a function $W_n = W_n(\omega)$ of the random environment such that for any $\varepsilon > 0$*

$$\lim_{n\to\infty} \boldsymbol{P}_0\left\{\left|\frac{\sigma^2 X_n}{\ln^2 n} - W_n\right| > \varepsilon\right\} = 0 \qquad [24]$$

*Moreover, $W_n$ has a limit distribution:*

$$\lim_{n\to\infty} \mathbb{P}\{W_n \le x\} = G(x) \qquad [25]$$

*and thus also the distribution of $\sigma^2 X_n / \ln^2 n$ under $\boldsymbol{P}_0$ converges to the same distribution $G(x)$.*

Sinai's theorem shows that in the recurrent case, the RWRE considered on the spatial scale $\ln^2 n$ becomes localized near some random point (depending on the environment only). This phenomenon, frequently referred to as "Sinai's localization," indicates an extremely strong slowdown of the motion as compared with the ordinary diffusive behavior.

Following Révész (1990), let us explain heuristically why $X_n$ is measured on the scale $\ln^2 n$. Rewrite eqn [11] as

$$P_1^\omega\{T_n < T_0\} = \left(1 + \sum_{x=1}^{n-1} \exp(Y_x)\right)^{-1} \qquad [26]$$

where $Y_x$ is defined in eqn [12]. By the CLT, the typical size of $|Y_x|$ for large $x$ is of order of $\sqrt{x}$, and so eqn [26] yields

$$P_1^\omega\{T_n < T_0\} \approx \exp\{-\sqrt{n}\}$$

This suggests that the walk started at site 1 will make about $\exp\{\sqrt{n}\}$ visits to the origin before reaching level $n$. Therefore, the first passage to site $n$ takes at least time $\approx \exp\{\sqrt{n}\}$. In other words, one may expect that a typical displacement after $n$ steps will be of order of $\ln^2 n$ (cf. eqn [24]). This argument also indicates, in the spirit of the trapping mechanism of slowdown discussed at the end of the section "Critical exponent, excursions, and traps," that there is typically a trap of size $\approx \ln^2 n$, which retains the RWRE until time $n$.

It has been shown (independently by H Kesten and A O Golosov) that the limit in [25] coincides with the distribution of a certain functional of the standard Brownian motion, with the density function

$$G'(x) = \frac{2}{\pi}\sum_{k=0}^{\infty} \frac{(-1)^k}{2k+1} \exp\left\{-\frac{(2k+1)^2\pi^2}{8}|x|\right\}$$

## Environment Viewed from the Particle

This important technique, dating back to Kozlov and Molchanov (1984), has proved to be quite efficient in the study of random motions in random media. The basic idea is to focus on the evolution of the environment viewed from the current position of the walk.

Let $\theta$ be the shift operator acting on the space of environments $\Omega = \{\omega\}$ as follows:

$$\omega = \{p_x\} \overset{\theta}{\mapsto} \bar{\omega} = \{p_{x-1}\}$$

Consider the process

$$\omega_n := \theta^{X_n}\omega, \qquad \omega_0 = \omega$$

which describes the state of the environment from the point of view of an observer moving along with the random walk $X_n$. One can show that $\omega_n$ is a Markov chain (with respect to both $P_0^\omega$ and $\boldsymbol{P}_0$), with the transition kernel

$$T(\omega, \mathrm{d}\omega') = p_0\, \delta_{\theta\omega}(\mathrm{d}\omega') + q_0\, \delta_{\theta^{-1}\omega}(\mathrm{d}\omega') \qquad [27]$$

and the respective initial law $\delta_\omega$ or $\mathbb{P}$ (here $\delta_\omega$ is the Dirac measure, i.e., unit mass at $\omega$).

This fact as it stands may not seem to be of any practical use, since the state space of this Markov chain is very complex. However, the great advantage is that one can find an explicit invariant probability $\mathbb{Q}$ for the kernel $T$ (i.e., such that $\mathbb{Q}T = \mathbb{Q}$), which is absolutely continuous with respect to $\mathbb{P}$.

More specifically, assume that $\mathbb{E}\rho_0 < 1$ and set $\mathbb{Q} = f(\omega)\mathbb{P}$, where (cf. eqn [14])

$$f = v\,(1+\rho_0)\sum_{x=0}^{\infty}\prod_{j=1}^{x}\rho_j \qquad v = \frac{1-\mathbb{E}\rho_0}{1+\mathbb{E}\rho_0} \qquad [28]$$

Using independence of $\{\rho_x\}$, we note

$$\int_\Omega \mathbb{Q}(\mathrm{d}\omega) = \mathbb{E}f = (1-\mathbb{E}\rho_0)\sum_{x=0}^{\infty}(\mathbb{E}\rho_0)^x = 1$$

hence $\mathbb{Q}$ is a probability measure on $\Omega$. Furthermore, for any bounded measurable function $g$ on $\Omega$ we have

$$\begin{aligned}\mathbb{Q}Tg &= \int_\Omega Tg(\omega)\mathbb{Q}(\mathrm{d}\omega) = \mathbb{E}f\,Tg \\ &= \mathbb{E}\{f[p_0\,(g\circ\theta) + q_0\,(g\circ\theta^{-1})]\} \\ &= \mathbb{E}\{g[(p_0 f)\circ\theta^{-1} + (q_0 f)\circ\theta]\}\end{aligned} \qquad [29]$$

By eqn [28],

$$(p_0 f)\circ\theta^{-1} = vp_{-1}(1+\rho_{-1})\sum_{x=0}^{\infty}\prod_{j=1}^{x}\rho_{j-1}$$

$$= v\left(1+\rho_0\sum_{x=0}^{\infty}\prod_{j=1}^{x}\rho_j\right) = v + \frac{\rho_0}{1+\rho_0} f$$

and similarly

$$(q_0 f)\circ\theta = -v + \frac{1}{1+\rho_0} f$$

So from eqn [29] we obtain

$$\mathbb{Q}Tg = \mathbb{E}(gf) = \int_\Omega g(\omega)\ \mathbb{Q}(\mathrm{d}\omega) = \mathbb{Q}g$$

which proves the invariance of $\mathbb{Q}$.

To illustrate the environment method, let us sketch the proof of Solomon's result on the asymptotic velocity (see Theorem 2). Set $d(x,\omega) := E_x^\omega(X_1 - X_0) = p_x - q_x$. Noting that $d(x,\omega) = d(0,\theta^x\omega)$, define

$$D_n := \sum_{i=1}^{n} d(X_{i-1},\omega) = \sum_{i=1}^{n} d(0,\theta^{X_{i-1}}\omega)$$

Due to the Markov property, the process $M_n := X_n - D_n$ is a martingale with respect to the natural filtration $\mathcal{F}_n = \sigma\{X_1,\ldots,X_n\}$ and the law $P_0^\omega$,

$$E_0^\omega[M_{n+1}\,|\,\mathcal{F}_n] = M_n, \quad P_0^\omega\text{-a.s.}$$

and it has bounded jumps, $|M_n - M_{n-1}| \le 2$. By general results, this implies $M_n/n \to 0$ ($P_0^\omega$-a.s.).

On the other hand, by Birkhoff's ergodic theorem

$$\lim_{n\to\infty}\frac{D_n}{n} = \int_\Omega d(0,\omega)\ \mathbb{Q}(\mathrm{d}\omega), \quad \boldsymbol{P}_0\text{-a.s.}$$

The last integral is easily evaluated to yield

$$\mathbb{E}(p_0 - q_0)f = v\mathbb{E}\sum_{x=0}^{\infty}\prod_{j=1}^{x}\rho_j(1-\rho_0)$$

$$= v(1-\mathbb{E}\rho_0)\sum_{x=0}^{\infty}(\mathbb{E}\rho_0)^x = v$$

and the first part of the formula [14] follows.

The case $\mathbb{E}\rho_0 \ge 1$ can be handled using a comparison argument (Sznitman 2004). Observe that if $p_x \le \tilde{p}_x$ for all $x$ then for the corresponding random walks we have $X_t \le \tilde{X}_t$ ($P_0^\omega$-a.s.). We now define a suitable dominating random medium by setting (for $\gamma > 0$)

$$\tilde{p}_x := \frac{p_x}{1+\gamma} + \frac{\gamma}{1+\gamma} \ge p_x$$

Then $\mathbb{E}\,\tilde{\rho}_0 = \mathbb{E}q_0/(p_0+\gamma) < 1$ if $\gamma$ is large enough, so by the first part of the theorem, $P_0^\omega$-a.s.,

$$\overline{\lim_{n\to\infty}}\frac{X_n}{n} \le \lim_{n\to\infty}\frac{\tilde{X}_n}{n} = \frac{1-\mathbb{E}\tilde{\rho}_0}{1+\mathbb{E}\tilde{\rho}_0} \qquad [30]$$

Note that $\mathbb{E}\tilde{\rho}_0$ is a continuous function of $\gamma$ with values in $[0,\mathbb{E}\rho_0] \ni 1$, so there exists $\gamma^*$ such that $\mathbb{E}\tilde{\rho}_0$ attains the value 1. Passing to the limit in eqn [30] as $\gamma \uparrow \gamma^*$, we obtain $\overline{\lim}_{n\to\infty}X_n/n \le 0$ ($P_0^\omega$-a.s.). Similarly, we get the reverse inequality, which proves the second part of the theorem.

A more prominent advantage of the environment method is that it naturally leads to statements of CLT type. A key step is to find a function $H(x,t,\omega) = x - vt + h(x,\omega)$ (called "harmonic coordinate") such that the process $H(X_n,n,\omega)$ is a martingale. To this end, by the Markov property it suffices to have

$$E_{X_n}^\omega H(X_{n+1},n+1,\omega) = H(X_n,n,\omega), \quad P_0^\omega\text{-a.s.}$$

For $\Delta(x,\omega) := h(x+1,\omega) - h(x,\omega)$ this condition leads to the equation

$$\Delta(x,\omega) = \rho_x\Delta(x-1,\omega) + v - 1 + (1+v)\rho_x$$

If $\mathbb{E}\rho_0 < 1$ (so that $v > 0$), there exists a bounded solution

$$\Delta(x,\omega) = v - 1 + 2v\sum_{k=0}^{\infty}\prod_{i=0}^{k}\rho_{x-i}$$

and we note that $\Delta(x,\omega) = \Delta(0,\theta^x\omega)$ is a stationary sequence with mean $\mathbb{E}\Delta(x,\omega) = 0$. Finally, setting $h(0,\omega) = 0$ we find

$$h(x,\omega) = \begin{cases} \sum_{k=0}^{x-1}\Delta(k,\omega), & x > 0 \\ -\sum_{k=1}^{-x}\Delta(-k,\omega), & x < 0 \end{cases}$$

As a result, we have the representation

$$X_n - nv = H(X_n,n,\omega) + h(X_n,\omega) \qquad [31]$$

For a fixed $\omega$, one can apply a suitable CLT for martingale differences to the martingale term in eqn [31], while using that $X_n \sim nv$ ($\boldsymbol{P}_0$-a.s.), the second term in eqn [31] is approximated by the sum $\sum_{k=0}^{nv}\Delta(k,\omega)$, which can be handled via a CLT for stationary sequences. This way, we arrive at the following result.

**Theorem 5** *Suppose that the environment is elliptic, eqn [5], and such that $\mathbb{E}\rho_0^{2+\varepsilon} < 1$ for some $\varepsilon > 0$ (which implies that $\mathbb{E}\rho_0 < 1$ and hence $v > 0$). Then there exists a nonrandom $\sigma^2 > 0$ such that*

$$\lim_{n\to\infty}\boldsymbol{P}_0\left\{\frac{X_n - nv}{\sqrt{n\sigma^2}} \le x\right\} = \Phi(x)$$

Note that this theorem is parallel to the result by Kesten *et al.* (1975) on asymptotic normality when $\kappa > 2$ (see the section "Limit distributions"). The moment assumptions in Theorem 5 are more restrictive, but they can be relaxed. On the other hand, Theorem 5 does not impose the nonarithmetic condition on the distribution of the environment (cf. Theorem 3). More importantly, the environment method proves to be quite efficient in more general situations, including non-i.i.d. environments and higher dimensions (at least in some cases, e.g., for random bonds RWRE and balanced RWRE discussed subsequently).

## Diode Model

In the preceding sections (except in the section "Limit distributions," where however we were limited to a nonarithmetic case), we assumed that $0 < p_x < 1$ and therefore excluded the situation where there are sites through which motion is permitted in one direction only. Allowing for such a possibility leads to the "diode model" (Solomon 1975). Specifically, suppose that

$$\mathbb{P}\{p_x = \beta\} = \alpha, \qquad \mathbb{P}\{p_x = 1\} = 1 - \alpha \qquad [32]$$

with $0 < \alpha < 1$, $0 < \beta < 1$, so that with probability $\alpha$ a point $x \in \mathbb{Z}$ is a usual two-way site and with probability $1 - \alpha$ it is a repelling barrier ("diode"), through which passage is only possible from left to right. This is an interesting example of statistically inhomogeneous medium, where the particle motion is strongly irreversible due to the presence of special semipenetrable nodes. The principal mathematical advantage of such a model is that the random walk can be decomposed into independent excursions from one diode to the next.

Due to diodes, the RWRE will eventually drift to $+\infty$. If $\beta > 1/2$, then on average it moves faster than in a nonrandom environment with $p_x \equiv \beta$. The situation where $\beta \le 1/2$ is potentially more interesting, as then there is a competition between the local drift of the walk to the left (in ordinary sites) and the presence of repelling diodes on its way. Note that $\mathbb{E}\rho_0 = \alpha\rho$, where $\rho := (1-\beta)/\beta$, so the condition $\mathbb{E}\rho_0 < 1$ amounts to $\beta > \alpha/(1+\alpha)$. In this case (which includes $\beta > 1/2$), formula [14] for the asymptotic velocity applies.

As explained in the section "Critical exponent, excursions, and traps," the quenched mean duration $w$ of the left excursion has Laplace transform given by eqn [23], which now reads

$$\phi(s) = \mathrm{e}^{-2s}\{1 - \alpha + \alpha\,\phi(s\rho)\}$$

This equation is easily solved by iterations:

$$\phi(s) = (1-\alpha)\sum_{k=0}^{\infty} \alpha^k \mathrm{e}^{-st_k}$$
$$t_k := 2\sum_{j=0}^{k} \rho^j \qquad [33]$$

hence the distribution of $w$ is given by

$$\mathbb{P}\{w = t_k\} = (1-\alpha)\alpha^k, \quad k = 0, 1, \ldots$$

This result has a transparent probabilistic meaning. In fact, the factor $(1-\alpha)\alpha^k$ is the probability that the nearest diode on the left of the starting point occurs at distance $k+1$, whereas $t_k$ is the corresponding mean excursion time. Note that formula [33] for $t_k$ easily follows from the recursion $t_k = 2 + \rho t_{k-1}$ (cf. eqn [22]) with the boundary condition $t_0 = 2$.

A self-similar hierarchy of timescales [33] indicates that the process will exhibit temporal oscillations. Indeed, for $\alpha\rho > 1$ the average waiting time until passing through a valley of ordinary sites of length $k$ is asymptotically proportional to $t_k \sim 2\rho^k$, so one may expect the annealed mean displacement $\boldsymbol{E}_0 X_n$ to have a local minimum at $n \approx t_k$. Passing to logarithms, we note that $\ln t_{k+1} - \ln t_k \sim \ln\rho$, which suggests the occurrence of persistent oscillations on the logarithmic timescale, with period $\ln\rho$ (see **Figure 2**). This was confirmed by Bernasconi and Schneider (1985) who showed that for $\alpha\rho > 1$

$$\boldsymbol{E}_0 X_n \sim n^{\kappa} F(\ln n), \quad n \to \infty \qquad [34]$$

where $\kappa = -\ln\alpha/\ln\rho < 1$ is the solution of eqn [20] and the function $F$ is periodic with period $\ln\rho$ (see **Figure 2**).

In contrast, for $\alpha\rho = 1$ one has

$$\boldsymbol{E}_0 X_n \sim \frac{n\ln\rho}{2\ln n}, \quad n \to \infty$$

and there are no oscillations of the above kind.

These results illuminate the earlier analysis of the diode model by Solomon (1975), which in the main has revealed the following. If $\alpha\rho = 1$, then $X_n$ satisfies the strong LLN:

$$\lim_{n\to\infty} \frac{X_n}{n/\ln n} = \frac{\ln\rho}{2}, \quad \boldsymbol{P}_0\text{-a.s.}$$

while in the case $\alpha\rho > 1$ the asymptotic behavior of $X_n$ is quite complicated and unusual: if $n_i \to \infty$ is a sequence of integers such that $\{\ln n_i\} \to \gamma$ (here $\{a\} = a - [a]$ denotes the fractional part of $a$), then the distribution of $n_i^{-\kappa} X_{n_i}$ under $\boldsymbol{P}_0$ converges to a nondegenerate distribution which depends on $\gamma$. Thus, the very existence of the limiting distribution

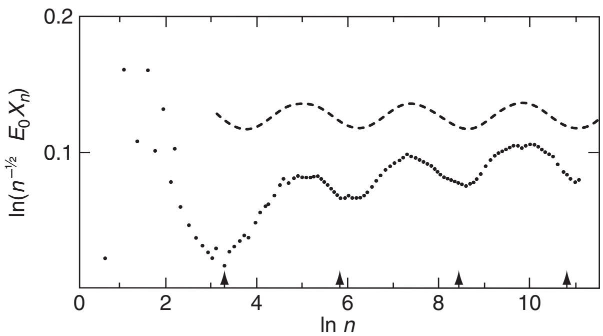

**Figure 2** Temporal oscillations for the diode model, eqn [32]. Here $\alpha=0.3$ and $\rho=1/0.09$, so that $\alpha\rho>1$ and $\kappa=1/2$. The dots represent an average of Monte Carlo simulations over 10 000 samples of the environment with a random walk of 200 000 steps in each realization. The broken curve refers to the exact asymptotic solution [34]. The arrows indicate the simulated locations of the minima $t_k$, the asymptotic spacing of which is predicted to be $\ln\rho\approx 241$. Reproduced from Bernasconi J and Schneider WR (1982). Diffusion on a one-dimensional lattice with random asymmetric transition rates. *Journal of Physics A: Mathematical and General* 15: L729–L734, by permission of IOP Publishing Ltd.

of $X_n$ and the limit itself heavily depend on the subsequence $n_i$ chosen to approach infinity.

This should be compared with a more "regular" result Theorem 3. Note that almost all the conditions of this theorem are satisfied in the diode model, except that here the distribution of $\ln\rho_0$ is arithmetic (recall that the value $\ln\rho_0=-\infty$ is permissible), so it is the discreteness of the environment distribution that does not provide enough "mixing" and hence leads to such peculiar features of the asymptotics.

## Some Generalizations and Variations

Most of the results discussed above in the simplest context of RWRE with nearest-neighbor jumps in an i.i.d. random environment have been extended to some other cases. One natural generalization is to relax the i.i.d. assumption, for example, by considering stationary ergodic environments (see details in Zeitouni (2004)). In this context, one relies on an ergodic theorem instead of the usual strong LLN. For instance, this way one readily obtains an extension of Solomon's criterion of transience versus recurrence (see Theorem 1). Other examples include an LLN (along with a formula for the asymptotic velocity, cf. Theorem 2), a CLT and stable laws for the asymptotic distribution of $X_n$ (cf. Theorem 3), and Sinai's localization result for the recurrent RWRE (cf. Theorem 4). Usually, however, ergodic theorems cannot be applied directly (like, e.g., to $X_n$, as the sequence $X_n-X_{n-1}$ is not stationary). In this case, one rather uses the hitting times which possess the desired stationarity (cf. the sections "Asymptotic velocity" and "Critical exponent, excursions, and traps"). In some situations, in addition to stationarity, one needs suitable mixing conditions in order to ensure enough decoupling (e.g., in Sinai's problem). The method of environment viewed from the particle (discussed earlier) is also suited very well to dealing with stationarity.

In the remainder of this section, we describe some other generalizations including RWRE with bounded jumps, RWRE where randomness is attached to bonds rather than sites, and continuous-time (symmetric) RWRE driven by the randomized master equation.

### RWRE with Bounded Jumps

The previous discussion was restricted to the case of RWRE with nearest-neighbor jumps. A natural extension is RWRE with bounded jumps. Let $L$, $R$ be fixed natural numbers, and suppose that from each site $x\in\mathbb{Z}$ jumps are only possible to the sites $x+i$, $i=-L,\ldots,R$, with (random) probabilities

$$p_x(i)\geq 0,\quad \sum_{i=-L}^{R} p_x(i)=1 \qquad [35]$$

We assume that the random vectors $p_x(\cdot)$ determining the environment are i.i.d. for different $x\in\mathbb{Z}$ (although many results can be extended to the stationary ergodic case).

The study of asymptotic properties of such a model is essentially more complex, as it involves products of certain random matrices and hence must use extensively the theory of Lyapunov exponents (see details and further references in Brémont (2004)). Lyapunov exponents, being natural analogs of logarithms of eigenvalues, characterize the asymptotic action of the product of random matrices along (random) principal directions, as described by Oseledec's multiplicative ergodic theorem. In most situations, however, the Lyapunov spectrum can

only be accessed implicitly, which makes the analysis rather hard.

To explain how random matrices arise here, let us first consider a particular case $R=1, L\geq 1$. Assume that $p_x(-L), p_x(1)\geq \delta>0$ for all $x\in\mathbb{Z}$ (ellipticity condition, cf. eqn [5]), and consider the hitting probabilities $u_n := P_n^{\omega}\{T_0<\infty\}$, where $T_0:=\min\{t\geq 0: X_t\leq 0\}$ (cf. the section "Transience and recurrence"). By decomposing with respect to the first step, for $n\geq 1$ we obtain the difference equation

$$u_n = p_n(1)u_{n+1} + \sum_{i=0}^{L} p_n(-i)u_{n-i} \qquad [36]$$

with the boundary conditions $u_0=\cdots=u_{-L+1}=1$. Using that $1=p_n(1)+\sum_{i=0}^{L} p_n(-i)$, we can rewrite eqn [36] as

$$p_n(1)(u_n-u_{n+1}) = \sum_{i=1}^{L} p_n(-i)(u_{n-i}-u_n)$$

or, equivalently,

$$v_n = \sum_{i=1}^{L} b_n(i)v_{n-i} \qquad [37]$$

where $v_i := u_i - u_{i+1}$ and

$$b_n(i) := \frac{p_n(-i)+\cdots+p_n(-L)}{p_n(1)} \qquad [38]$$

Recursion [37] can be written in a matrix form, $V_n = M_n V_{n-1}$, where $V_n := (v_n,\ldots,v_{n-L+1})^{\top}$,

$$M_n := \begin{pmatrix} b_n(1) & \cdots & \cdots & b_n(L) \\ 1 & \cdots & 0 & 0 \\ \vdots & \ddots & \vdots & \vdots \\ 0 & \cdots & 1 & 0 \end{pmatrix} \qquad [39]$$

and by iterations we get (cf. eqn [10])

$$V_n = M_n\cdots M_1 V_0, \qquad V_0 = (1-u_1, 0,\ldots,0)^{\top}$$

Note that $M_n$ depends only on the transition probability vector $p_n(\cdot)$, and hence $M_n\cdots M_1$ is the product of i.i.d. random (non-negative) matrices. By Furstenberg–Kesten's theorem, the limiting behavior of such a product, as $n\to\infty$, is controlled by the largest Lyapunov exponent

$$\gamma_1 := \lim_{n\to\infty} n^{-1}\ln\|M_n\ldots M_1\| \qquad [40]$$

(by Kingman's subadditive ergodic theorem, the limit exists $\mathbb{P}$-a.s. and is nonrandom). It follows that, $P_0$-a.s., the RWRE $X_n$ is transient if and only if $\gamma_1\neq 0$, and moreover, $\lim_{n\to\infty}X_n=+\infty\,(-\infty)$ when $\gamma_1<0\,(>0)$, whereas $\underline{\lim}_{n\to\infty}X_n=-\infty$, $\overline{\lim}_{n\to\infty}X_n=+\infty$ when $\gamma_1=0$.

For orientation, note that if $p_n(i)=p(i)$ are nonrandom constants, then $\gamma_1=\ln\lambda_1$, where $\lambda_1>0$ is the largest eigenvalue of $M_0$, and so $\gamma_1<0$ if and only if $\lambda_1<1$. The latter means that the characteristic polynomial $\varphi(\lambda):=\det(M_0-\lambda I)$ satisfies the condition $(-1)^L\varphi(1)>0$. To evaluate $\det(M_0-I)$, replace the first column by the sum of all columns and expand to get $\varphi(1)=(-1)^{L-1}(b_1+\cdots+b_L)$. Substituting expressions [38] it is easy to see that the above condition amounts to $p(1)-\sum_{i=1}^{L} ip\times(-i)>0$, that is, the mean drift of the random walk is positive and hence $X_n\to+\infty$ a.s.

In the general case, $L\geq 1, R\geq 1$, similar considerations lead to the following matrices of order $d:=L+R-1$ (cf. eqn [39]):

$$M_n = \begin{pmatrix} a_n(R-1) & \cdots & a_n(1) & b_n(1) & \cdots & b_n(L) \\ 1 & 0 & \cdots & \cdots & \cdots & 0 \\ 0 & 1 & 0 & \cdots & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & \cdots & \cdots & 0 & 1 & 0 \end{pmatrix}$$

where $b_n(i)$ are given by eqn [38] and

$$a_n(i) := -\frac{p_n(i)+\cdots+p_n(R)}{p_n(R)}$$

Suppose that the ellipticity condition is satisfied in the form $p_n(i)\geq\delta>0$, $i\neq 0$, $-L\leq i\leq R$, and let $\gamma_1\geq\gamma_2\geq\cdots\geq\gamma_d$ be the (nonrandom) Lyapunov exponents of $\{M_n\}$. The largest exponent $\gamma_1$ is again given by eqn [40], while other exponents are determined recursively from the equalities

$$\gamma_1+\cdots+\gamma_k = \lim_{n\to\infty} n^{-1}\ln\|\wedge^k(M_n\cdots M_1)\|$$

$(1\leq k\leq d)$. Here $\wedge$ denotes the external (antisymmetric) product: $x\wedge y=-y\wedge x$ $(x,y\in\mathbb{R}^d)$, and $\wedge^k M$ acts on the external product space $\wedge^k\mathbb{R}^d$, generated by the canonical basis $\{e_{i_1}\wedge\cdots\wedge e_{i_k}, 1\leq i_1<\cdots<i_k\leq d\}$, as follows:

$$\wedge^k M(x_1\wedge\cdots\wedge x_k) := M(x_1)\wedge\cdots\wedge M(x_k)$$

One can show that all exponents except $\gamma_R$ are sign-definite: $\gamma_{R-1}>0>\gamma_{R+1}$. Moreover, it is the sign of $\gamma_R$ that determines whether the RWRE is transient or recurrent, the dichotomy being the same as in the case $R=1$ above (with $\gamma_1$ replaced by $\gamma_R$). Let us also mention that an LLN and CLT can be proved here (see Brémont (2004)).

In conclusion, let us point out an alternative approach due to Bolthausen and Goldsheid (2000)

who studied a more general RWRE on a strip $\mathbb{Z}\times\{0,1,\dots,m-1\}$. The link between these two models is given by the representation $X_n = mY_n + Z_n$, where $m := \max\{L,R\}$, $Y_n\in\mathbb{Z}$, $Z_n\in\{0,\dots,m-1\}$. Random matrices arising here are constructed indirectly using an auxiliary stationary sequence. Even though these matrices are nonindependent, thanks to their positivity the criterion of transience can be given in terms of the sign of the largest Lyapunov exponent, which is usually much easier to deal with. An additional attractive feature of this approach is that the condition $p_x(R)>0$ ($\mathbb{P}$-a.s.), which was essential for the previous technique, can be replaced with a more natural condition $\mathbb{P}\{p_x(R)>0\}>0$.

### Random Bonds RWRE

Instead of having random probabilities of jumps at each site, one could assign random weights to bonds between the sites. For instance, the transition probabilities $p_x = p(x,x+1,\omega)$ can be defined by

$$p_x = \frac{c_{x,x+1}}{c_{x-1,x}+c_{x,x+1}} \qquad [41]$$

where $c_{x,x+1}>0$ are i.i.d. random variables on the environment space $\Omega$.

The difference between the two models may not seem very prominent, but the behavior of the walk in the modified model [41] appears to be quite different. Indeed, working as in the section "Transience and recurrence," we note that

$$\rho_x = \frac{q_x}{p_x} = \frac{c_{x-1,x}}{c_{x,x+1}}$$

hence, exploiting formulas [11] and [41], we obtain, $\mathbb{P}$-a.s.,

$$\frac{1}{1-u_1} = \sum_{x=0}^{n-1}\frac{c_{01}}{c_{x,x+1}} \sim c_{01}\, n\,\mathbb{E}c_{01}^{-1} \to \infty \qquad [42]$$

since $\mathbb{E}c_{01}^{-1}>0$. Therefore, $f_{00}=1$, that is, the random walk is recurrent ($\boldsymbol{P}_0$-a.s.).

The method of environment viewed from the particle can also be applied here (see Sznitman (2004)). Similarly to the section "Environment viewed from the particle," we define a new probability measure $\mathbb{Q}=f(\omega)\,\mathbb{P}$ using the density

$$f(\omega) = Z^{-1}\big(c_{-1,0}(\omega)+c_{01}(\omega)\big)$$

where $Z=2\mathbb{E}c_{01}$ is the normalizing constant (we assume that $\mathbb{E}c_{01}<\infty$). One can check that $\mathbb{Q}$ is invariant with respect to the transition kernel eqn [41], and by similar arguments as in that section, we obtain that $\lim_{n\to\infty}X_n/n$ exists ($P_0^\omega$-a.s.) and is given by

$$\int_\Omega d(0,\omega)\;\mathbb{Q}(\mathrm{d}\omega) = Z^{-1}\mathbb{E}\big[c_{01}-c_{-1,0}\big] = 0$$

so the asymptotic velocity vanishes.

Furthermore, under suitable technical conditions on the environment (e.g., $c_{01}$ being bounded away from 0 and $\infty$, cf. eqn [5]), one can prove the following CLT:

$$\lim_{n\to\infty}\boldsymbol{P}_0\left\{\frac{X_n}{\sqrt{n\sigma^2}}\le x\right\} = \Phi(x) \qquad [43]$$

where $\sigma^2=(\mathbb{E}c_{01}\cdot\mathbb{E}c_{01}^{-1})^{-1}$. Note that $\sigma^2\le 1$ (with a strict inequality if $c_{01}$ is not reduced to a constant), which indicates some slowdown in the spatial spread of the random bonds RWRE, as compared to the ordinary symmetric random walk.

Thus, there is a dramatic distinction between the random bonds RWRE, which is recurrent and diffusive, and the random sites RWRE, with a much more complex asymptotics including both transient and recurrent scenarios, slowdown effects, and subdiffusive behavior. This can be explained heuristically by noting that the random bonds RWRE is reversible, that is, $m(x)p(x,y)=m(y)\times p(y,x)$ for all $x,y\in\mathbb{Z}$, with $m(x):=c_{x-1,x}+c_{x,x+1}$ (this property also easily extends to multidimensional versions). Hence, it appears impossible to create extended traps which would retain the particle for a very long time. Instead, the mechanism of the diffusive slowdown in a reversible case is associated with the natural variability of the environment resulting in the occasional occurrence of isolated "screening" bonds with an anomalously small weight $c_{x,x+1}$.

Let us point out that the RWRE determined by eqn [41] can be interpreted in terms of the random conductivity model (see Hughes (1996)). Suppose that each random variable $c_{x,x+1}$ attached to the bond $(x,x+1)$ has the meaning of the conductance of this bond (the reciprocal, $c_{x,x+1}^{-1}$, being its resistance). If a voltage drop $V$ is applied across the system of $N$ successive bonds, say from 0 to $N$, then the same current $I$ flows in each of the conductors and by Ohm's law we have $I=c_{x,x+1}\;V_{x,x+1}$, where $V_{x,x+1}$ is the voltage drop across the corresponding bond. Hence

$$V=\sum_{x=0}^{N}V_{x,x+1} = I\sum_{x=0}^{N}c_{x,x+1}^{-1}$$

which amounts to saying that the total resistance of the system of consecutive elements is given by the sum of the individual resistances. The effective

conductivity of the finite system, $\bar{c}_N$, is defined as the average conductance per bond, so that

$$\bar{c}_N^{-1} = \frac{1}{N}\sum_{x=0}^{N} c_{x,x+1}^{-1}$$

and by the strong LLN, $\bar{c}_N^{-1} \to \mathbb{E}c_{01}^{-1}$ as $N \to \infty$ ($\mathbb{P}$-a.s.). Therefore, the effective conductivity of the infinite system is given by $\bar{c} = (\mathbb{E}c_{01}^{-1})^{-1}$, and we note that $\bar{c} < \mathbb{E}c_{01}$ if the random medium is nondegenerate.

Returning to the random bonds RWRE, eqn [41], it is easy to see that a site $j$ is recurrent if and only if the conductance $c_{j,\infty}$ between $x$ and $\infty$ equals zero. Using again Ohm's law, we have (cf. eqn [42])

$$c_{j,+\infty}^{-1} = \sum_{x=j}^{\infty} c_{x,x+1}^{-1} = 0, \quad \mathbb{P}\text{-a.s.}$$

and we recover the result about recurrence.

### Continuous-Time RWRE

As in the discrete-time case, a random walk on $\mathbb{Z}$ with continuous time is a homogeneous Markov chain $X_t$, $t \in [0, \infty)$, with state space $\mathbb{Z}$ and nearest-neighbor (or at least bounded) jumps. The term "Markov" as usual refers to the "lack of memory" property, which amounts to saying that from the entire history of the process development up to a given time, only the current position of the walk is important for the future evolution while all other information is irrelevant.

Since there is no smallest time unit as in the discrete-time case, it is convenient to describe transitions of $X_t$ in terms of transition rates characterizing the likelihood of various jumps during a very short time. More precisely, if $p_{xy}(t) := P\{X_t = y \mid X_0 = x\}$ are the transition probabilities over time $t$, then for $h \to 0$

$$\begin{aligned} p_{xy}(h) &= c_{xy}h + o(h) \quad (x \neq y) \\ p_{xx}(h) &= 1 - h\sum_{y\neq x} c_{xy} + o(h) \end{aligned} \qquad [44]$$

Equations for the functions $p_{xy}(t)$ can then be derived by adapting the method of decomposition commonly used for discrete-time Markov chains (cf. the section "Transience and recurrence"). Here it is more convenient to decompose with respect to the "last" step, that is, by considering all possible transitions during a small increment of time at the end of the time interval $[0, t+h]$. Using Markov property and eqn [44] we can write

$$\begin{aligned} p_{0x}(t+h) &= h\sum_{y\neq x} p_{0y}(t)\, c_{yx} \\ &\quad + p_{0x}(t)\left(1 - h\sum_{y\neq x} c_{xy}\right) + o(h) \end{aligned}$$

which in the limit $h \to 0$ yields the master equation (or Chapman–Kolmogorov's forward equation)

$$\begin{aligned} \frac{\mathrm{d}}{\mathrm{d}t} p_{0x}(t) &= \sum_{y\neq x} \{c_{yx}p_{0y}(t) - c_{xy}p_{0x}(t)\} \\ p_{0x}(0) &= \delta_0(x) \end{aligned} \qquad [45]$$

where $\delta_0(x)$ is the Kronecker symbol.

Continuous-time RWRE are therefore naturally described via the randomized master equation, that is, with random transition rates. The canonical example, originally motivated by Dyson's study of the chain of harmonic oscillators with random couplings, is a symmetric nearest-neighbor RWRE, where the random transition rates $c_{xy}$ are nonzero only for $y = x \pm 1$ and satisfy the condition $c_{x,x+1} = c_{x+1,x}$, otherwise being i.i.d. (see Alexander *et al.* (1981)). In this case, the problem [45] can be formally solved using the Laplace transform, leading to the equations

$$s + G_0^+ + G_0^- = [\hat{p}_0(s)]^{-1} \qquad [46]$$

$$s + G_x^- + G_x^+ = 0 \quad (x \neq 0) \qquad [47]$$

where $G_x^-, G_x^+$ are defined as

$$G_x^{\pm} := c_{x,x\pm1}\,\frac{\hat{p}_{0x}(s) - \hat{p}_{0,x\pm1}(s)}{\hat{p}_{0x}(s)} \qquad [48]$$

and $\hat{p}_{0x}(s) := \int_0^\infty p_{0x}(t)\, \mathrm{e}^{-st}\mathrm{d}t$. From eqns [47] and [48] one obtains the recursion

$$\begin{aligned} G_x^{\pm} &= \left(\frac{1}{c_{x,x\pm1}} + \frac{1}{s + G_{x\pm1}^{+}}\right)^{-1} \\ x &= 0, \pm1, \pm2, \ldots \end{aligned} \qquad [49]$$

The quantities $G_0^{\pm}$ are therefore expressed as infinite continued fractions depending on $s$ and the random variables $c_{x,x\pm1}$, $c_{x,x\pm2}, \ldots$. The function $\hat{p}_{00}(s)$ can then be found from eqn [46].

In its generality, the problem is far too hard, and we shall only comment on how one can evaluate the annealed mean

$$\mathbb{E}\hat{p}_{00}(s) = \mathbb{E}\big(s + G_0^+ + G_0^-\big)^{-1}$$

According to eqn [49], the random variables $G_0^+, G_0^-$ are determined by the same algebraic formula, but involve the rate coefficients from different sides of site $x$, and hence are i.i.d. Furthermore, eqn [49] implies that the random variables $G_0^+, G_1^+$ have the same distribution and, moreover, $G_1^+$ and $c_{01}$ are independent. Therefore, eqn [49] may be used as an integral equation for the unknown density function of $G_0^+$. It can be proved that the suitable solution exists and is unique, and

although an explicit solution is not available, one can obtain the asymptotics of small values of $s$, thereby rendering information about the behavior of $p_{00}(t)$ for large $t$. More specifically, one can show that if $c_* := (\mathbb{E}c_{01}^{-1})^{-1} > 0$, then

$$\mathbb{E}\hat{p}_{00}(s) \sim (4c_* s)^{-1/2}, \quad s \to 0$$

and so by a Tauberian theorem

$$\mathbb{E}p_{00}(t) \sim (4\pi c_* t)^{-1/2}, \quad t \to \infty \qquad [50]$$

Note that asymptotics [50] appears to be the same as for an ordinary symmetric random walk with constant transition rates $c_{x,x+1} = c_{x+1,x} = c_*$, suggesting that the latter provides an EMA for the RWRE considered above.

This is further confirmed by the asymptotic calculation of the annealed mean square displacement, $\boldsymbol{E}_0 X_t^2 \sim 2c_* t$ as $t \to \infty$ (Alexander *et al.* 1981). Moreover, Kawazu and Kesten (1984) proved that $X_t$ is asymptotically normal:

$$\lim_{t\to\infty} \boldsymbol{P}_0 \left\{ \frac{X_t}{\sqrt{2c_* t}} \le x \right\} = \Phi(x) \qquad [51]$$

Therefore, if $c_* > 0$, then the RWRE has the same diffusive behavior as the corresponding ordered system, with a well-defined diffusion constant $D = c_*$.

In the case where $c_* = 0$ (i.e., $\mathbb{E}c_{01}^{-1} = \infty$), one may expect that the RWRE exhibits subdiffusive behavior. For example, if the density function of the transition rates is modeled by

$$f_a(u) = (1-\alpha)\, u^{-\alpha} \mathbf{1}_{\{0<u<1\}} \quad (0 < \alpha < 1)$$

then, as shown by Alexander *et al.* (1981),

$$\mathbb{E}p_{00}(t) \sim C_\alpha t^{-(1-\alpha)/(2-\alpha)}$$
$$\boldsymbol{E}_0 X_t^2 \sim C'_\alpha t^{2(1-\alpha)/(2-\alpha)}$$

In fact, Kawazu and Kesten (1984) proved that in this case $t^{-\alpha/(1+\alpha)} X_t$ has a (non-Gaussian) limit distribution as $t \to \infty$.

To conclude the discussion of the continuous-time case, let us point out that some useful information about recurrence of $X_t$ can be obtained by considering an imbedded (discrete-time) random walk $\tilde{X}_n$, defined as the position of $X_t$ after $n$ jumps. Note that continuous-time Markov chains admit an alternative description of their evolution in terms of sojourn times and the distribution of transitions at a jump. Namely, if the environment $\omega$ is fixed, then the random sojourn time of $X_t$ in each state $x$ is exponentially distributed with mean $1/c_x$, where $c_x := \sum_{y \ne x} c_{xy}$, while the distribution of transitions from $x$ is given by the probabilities $p_{xy} = c_{xy}/c_x$.

For the symmetric nearest-neighbor RWRE considered above, the transition probabilities of the imbedded random walk are given by

$$p_x := p_{x,x+1} = \frac{c_{x,x+1}}{c_{x-1,x} + c_{x,x+1}}$$
$$q_x := p_{x,x-1} = 1 - p_x$$

and we recognize here the transition law of a random walk in the random bonds environment considered in the previous subsection (cf. eqn [41]). Recurrence and zero asymptotic velocity established there are consistent with the results discussed in the present section (e.g., note that the CLT for both $X_n$, eqn [43], and $X_t$, eqn [51], does not involve any centering). Let us point out, however, that a "naive" discretization of time using the mean sojourn time appears to be incorrect, as this would lead to the scaling $t = n\delta_1$ with $\delta_1 := \mathbb{E}(c_{-1,0} + c_{01})^{-1}$, while from comparing the limit theorems in these two cases, one can conclude that the true value of the effective discretization step is given by $\delta_* := (2c_*)^{-1} = (1/2)\mathbb{E}c_{01}^{-1}$. In fact, by the arithmetic–harmonic mean inequality we have $\delta_* > \delta_1$, which is a manifestation of the RWRE's diffusive slowdown.

## RWRE in Higher Dimensions

Multidimensional RWRE with nearest-neighbor jumps are defined in a similar fashion: from site $x \in \mathbb{Z}^d$ the random walk can jump to one of the $2d$ adjacent sites $x + e \in \mathbb{Z}^d$ (such that $|e| = 1$), with probabilities $p_x(e) \ge 0$, $\sum_{|e|=1} p_x(e) = 1$, where the random vectors $p_x(\cdot)$ are assumed to be i.i.d. for different $x \in \mathbb{Z}^d$. As usual, we will also impose the condition of uniform ellipticity:

$$p_x(e) \ge \delta > 0, \quad \mathbb{P}\text{-a.s.}$$
$$|e| = 1, \quad x \in \mathbb{Z}^d \qquad [52]$$

In contrast to the one-dimensional case, theory of RWRE in higher dimensions is far from maturity. Possible asymptotic behaviors of the RWRE for $d \ge 2$ are not understood well enough, and many basic questions remain open. For instance, no definitive classification of the RWRE is available regarding transience and recurrence. Similarly, LLN and CLT have been proved only for a limited number of specific models, while no general sharp results have been obtained. On a more positive note, there has been considerable progress in recent years in the so-called ballistic case, where powerful techniques have been developed (see Sznitman (2002, 2004) and Zeitouni (2003, 2004)). Unfortunately, not much is

known for nonballistic RWRE, apart from special cases of balanced RWRE in $d \geq 2$ (Lawler 1982), small isotropic perturbations of ordinary symmetric random walks in $d \geq 3$ (Bricmont and Kupiainen 1991), and some examples based on combining components of ordinary random walks and RWRE in $d \geq 7$ (Bolthausen *et al.* 2003). In particular, there are no examples of subdiffusive behavior in any dimension $d \geq 2$, and in fact it is largely believed that a CLT is always true in any uniformly elliptic, i.i.d. random environment in dimensions $d \geq 3$, with somewhat less certainty about $d = 2$. A heuristic explanation for such a striking difference with the case $d = 1$ is that due to a less restricted topology of space in higher dimensions, it is much harder to force the random walk to visit traps, and hence the slowdown is not so pronounced.

In what follows, we give a brief account of some of the known results and methods in this fast-developing area (for further information and specific references, see an extensive review by Zeitouni (2004)).

### Zero–One Laws and LLNs

A natural first step in a multidimensional context is to explore the behavior of the random walk $X_n$ as projected on various one-dimensional straight lines. Let us fix a test unit vector $\ell \in \mathbb{R}^d$, and consider the process $Z_n^\ell := X_n \cdot \ell$. Then for the events $A_{\pm\ell} := \{\lim_{n\to\infty} Z_n^\ell = \pm\infty\}$ one can show that

$$\boldsymbol{P}_0(A_\ell \cup A_{-\ell}) \in \{0, 1\} \qquad [53]$$

That is to say, for each $\ell$ the probability that the random walk escapes to infinity in the direction $\ell$ is either 0 or 1.

Let us sketch the proof. We say that $\tau$ is "record time" if $|Z_t^\ell| > |Z_k^\ell|$ for all $k < t$, and "regeneration time" if in addition $|Z_\tau^\ell| \leq |Z_n^\ell|$ for all $n \geq \tau$. Note that by the ellipticity condition [52], $\overline{\lim}_{n\to\infty} |Z_n^\ell| = \infty$ ($\boldsymbol{P}_0$-a.s.), hence there is an infinite sequence of record times $0 = \tau_0 < \tau_1 < \tau_2 < \cdots$. If $\boldsymbol{P}_0(A_\ell \cup A_{-\ell}) > 0$, we can pick a subsequence of record times $\tau_i'$, each of which has a positive $\boldsymbol{P}_0$-probability to be a regeneration time (because otherwise $|Z_n^\ell|$ would persistently backtrack towards the origin and the event $A_\ell \cup A_{-\ell}$ could not occur). Since the trials for different record times are independent, it follows that a regeneration time $\tau^*$ occurs $\boldsymbol{P}_0$-a.s. Repeating this argument, we conclude that there exists an infinite sequence of regeneration times $\tau_i^*$, which implies that $|Z_n^\ell| \to \infty$ ($\boldsymbol{P}_0$-a.s.), that is, $\boldsymbol{P}(A_\ell \cup A_{-\ell}) = 1$.

Regeneration structure introduced by the sequence $\{\tau_i^*\}$ plays a key role in further analysis of the RWRE and is particularly useful for proving an LLN and a CLT, due to the fact that pieces of the random walk between consecutive regeneration times (and fragments of the random environment involved thereby) are independent and identically distributed (at least starting from $\tau_1^*$). In this vein, one can prove a "directional" version of the LLN, stating that for each $\ell$ there exist deterministic $v_\ell, v_{-\ell}$ (possibly zero) such that

$$\lim_{n\to\infty} \frac{Z_n^\ell}{n} = v_\ell \mathbf{1}_{A_\ell} + v_{-\ell} \mathbf{1}_{A_{-\ell}}, \quad \boldsymbol{P}_0\text{-a.s.} \qquad [54]$$

Note that if $\boldsymbol{P}_0(A_\ell) \in \{0, 1\}$, then eqn [54] in conjunction with eqn [53] would readily imply

$$\lim_{n\to\infty} \frac{Z_n^\ell}{n} = v_\ell, \quad \boldsymbol{P}_0\text{-a.s.} \qquad [55]$$

Moreover, if $\boldsymbol{P}_0(A_\ell) \in \{0, 1\}$ for any $\ell$, then there exists a deterministic $v$ (possibly zero) such that

$$\lim_{n\to\infty} \frac{X_n}{n} = v, \quad \boldsymbol{P}_0\text{-a.s.} \qquad [56]$$

Therefore, it is natural to ask if a zero–one law [53] can be enhanced to that for the individual probabilities $\boldsymbol{P}_0(A_\ell)$. It is known that the answer is affirmative for i.i.d. environments in $d = 2$, where indeed $\boldsymbol{P}(A_\ell) \in \{0, 1\}$ for any $\ell$, with counterexamples in certain stationary ergodic (but not uniformly elliptic) environments. However, in the case $d \geq 3$ this is an open problem.

### Kalikow's Condition and Sznitman's Condition (T′)

An RWRE is called "ballistic" (ballistic in direction $\ell$) if $v \neq 0$ ($v_\ell \neq 0$), see eqns [55] and [56]. In this section, we describe conditions on the random environment which ensure that the RWRE is ballistic.

Let $U$ be a connected strict subset of $\mathbb{Z}^d$ containing the origin. For $x \in U$, denote by

$$g(x, \omega) := E_0^\omega \sum_{n=0}^{T_U} \mathbf{1}_{\{X_n = x\}}$$

the quenched mean number of visits to $x$ prior to the exit time $T_U := \min\{n \geq 0 : X_n \notin U\}$. Consider an auxiliary Markov chain $\widehat{X}_n$, which starts from 0, makes nearest-neighbor jumps while in $U$, with (nonrandom) probabilities

$$\widehat{p}_x(e) = \frac{\mathbb{E}[g(x, \omega) p_x(e)]}{\mathbb{E}[g(x, \omega)]}, \quad x \in U \qquad [57]$$

and is absorbed as soon as it first leaves $U$. Note that the expectations in eqn [57] are finite; indeed, if $\alpha_x$ is the probability to return to $x$ before leaving $U$,

then, by the Markov property, the mean number of returns is given by

$$\sum_{k=1}^{\infty} k\alpha_x^k(1-\alpha_x) = \frac{\alpha_x}{1-\alpha_x} < \infty$$

since, due to ellipticity, $\alpha_x < 1$.

An important property, highlighting the usefulness of $\widehat{X}_n$, is that if $\widehat{X}_n$ leaves $U$ with probability 1, then the same is true for the original RWRE $X_n$ (under the annealed law $\boldsymbol{P}_0$), and moreover, the exit points $\widehat{X}_{\hat{T}_U}$ and $X_{T_U}$ have the same distribution laws.

Let $\ell \in \mathbb{R}^d, |\ell| = 1$. One says that Kalikow's condition with respect to $\ell$ holds if the local drift of $\widehat{X}_n$ in the direction $\ell$ is uniformly bounded away from zero:

$$\inf_U \inf_{x\in U} \sum_{|e|=1} (e\cdot\ell)\,\widehat{p}_x(e) > 0 \qquad [58]$$

A sufficient condition for [58] is, for example, that for some $\kappa > 0$

$$\mathbb{E}\big[(d(0,\omega)\cdot\ell)_+\big] \geq \kappa\mathbb{E}\big[(d(0,\omega)\cdot\ell)_-\big]$$

where $d(0,\omega) = E_0^\omega X_1$ and $u_\pm := \max\{\pm u, 0\}$.

A natural implication of Kalikow's condition [58] is that $\boldsymbol{P}_0(A_\ell) = 1$ and $v_\ell > 0$ (see eqn [55]). Moreover, noting that eqn [58] also holds for all $\ell'$ in a vicinity of $\ell$ and applying the above result with $d$ noncollinear vectors from that vicinity, we conclude that under Kalikow's condition there exists a deterministic $v \neq 0$ such that $X_n/n \to v$ as $n \to \infty$ ($\boldsymbol{P}_0$-a.s.). Furthermore, it can be proved that $(X_n - nv)/\sqrt{n}$ converges in law to a Gaussian distribution (see Sznitman (2004)).

It is not hard to check that in dimension $d = 1$ Kalikow's condition is equivalent to $v \neq 0$ and therefore characterizes completely all ballistic walks. For $d \geq 2$, the situation is less clear; for instance, it is not known if there exist RWRE with $\boldsymbol{P}(A_\ell) > 0$ and $v_\ell = 0$ (of course, such RWRE cannot satisfy Kalikow's condition).

Sznitman (2004) has proposed a more complicated transience condition (T′) involving certain regeneration times $\tau_i^*$ similar to those described in the previous subsection. An RWRE is said to satisfy Sznitman's condition (T′) relative to direction $\ell$ if $\boldsymbol{P}_0(A_\ell) = 1$ and for some $c > 0$ and all $0 < \gamma < 1$

$$\boldsymbol{E}_0 \exp\left(c \sup_{n\leq\tau_1^*} |X_n|^\gamma\right) < \infty \qquad [59]$$

This condition provides a powerful control over $\tau_1^*$ for $d \geq 2$ and in particular ensures that $\tau_1^*$ has finite moments of any order. This is in sharp contrast with the one-dimensional case, and should be viewed as a reflection of much weaker traps in dimensions $d \geq 2$.

Condition [59] can also be reformulated in terms of the exit distribution of the RWRE from infinite thick slabs "orthonormal" to directions $\ell'$ sufficiently close to $\ell$. As it stands, the latter reformulation is difficult to check, but Sznitman (2004) has developed a remarkable "effective" criterion reducing the job to a similar condition in finite boxes, which is much more tractable and can be checked in a number of cases.

In fact, condition (T′) follows from Kalikow's condition, but not the other way around. In the one-dimensional case, condition (T′) (applied to $\ell = 1$ and $\ell = -1$) proves to be equivalent to the transient behavior of the RWRE, which, as we have seen in Theorem 2, may happen with $v = 0$, that is, in a nonballistic scenario. The situation in $d \geq 2$ is quite different, as condition (T′) implies that the RWRE is ballistic in the direction $\ell$ (with $v_\ell > 0$) and satisfies a CLT (under $\boldsymbol{P}_0$). It is not known whether the ballistic behavior for $d \geq 2$ is completely characterized by condition (T′), although this is expected to be true.

### Balanced RWRE

In this section we discuss a particular case of nonballistic RWRE, for which LLN and CLT can be proved. Following Lawler (1982), we say that an RWRE is "balanced" if $p_x(e) = p_x(-e)$ for all $x \in \mathbb{Z}^d, |e| = 1$ ($\mathbb{P}$-a.s.). In this case, the local drift vanishes, $d(x,\omega) = 0$, hence the coordinate processes $X_n^i$ $(i = 1, \ldots, d)$ are martingales with respect to the natural filtration $\mathcal{F}_n = \sigma\{X_0, \ldots, X_n\}$. The quenched covariance matrix of the increments $\Delta X_n^i := X_{n+1}^i - X_n^i$ $(i = 1, \ldots, d)$ is given by

$$E_0^\omega\big[\Delta X_n^i \Delta X_n^j | \mathcal{F}_n\big] = 2\delta_{ij} p_{X_n}(e_i) \qquad [60]$$

Since the right-hand side of eqn [60] is uniformly bounded, it follows that $X_n/n \to 0$ ($\boldsymbol{P}_0$-a.s.). Further, it can be proved that there exist deterministic positive constants $a_1, \ldots, a_d$ such that for $i = 1, \ldots, d$

$$\lim_{n\to\infty} \frac{1}{n}\sum_{k=0}^{n-1} p_{X_k}(e_i) = \frac{a_i}{2}, \quad \boldsymbol{P}_0\text{-a.s.} \qquad [61]$$

Once this is proved, a multidimensional CLT for martingale differences yields that $X_n/\sqrt{n}$ converges in law to a Gaussian distribution with zero mean and the covariances $b_{ij} = \delta_{ij} a_i$.

The proof of [61] employs the method of environment viewed from the particle. Namely, define a Markov chain $\omega_n := \theta^{X_n}\omega$ with the transition kernel

$$T(\omega, \mathrm{d}\omega') = \sum_{i=1}^{d} [p_0(e_i)\delta_{\theta\omega}(\mathrm{d}\omega') + p_0(-e_i)\delta_{\theta^{-1}\omega}(\mathrm{d}\omega')]$$

(cf. eqn [27]). The next step is to find a probability measure $\mathbb{Q}$ on $\Omega$ invariant under $T$ and absolutely continuous with respect to $\mathbb{P}$. Unlike the one-dimensional case, however, an explicit form of $\mathbb{Q}$ is not available, and $\mathbb{Q}$ is constructed indirectly as the limit of invariant measures of certain periodic modifications of the RWRE. Birkhoff's ergodic theorem then yields, $\boldsymbol{P}_0$-a.s.,

$$\frac{1}{n}\sum_{k=0}^{n-1} p_{X_k}(e_i,\omega) = \frac{1}{n}\sum_{k=0}^{n-1} p_0(e_i,\omega_k) \to \int_\Omega p_0(e_i,\omega)\ \mathbb{Q}(\mathrm{d}\omega) \geq \delta$$

by the ellipticity condition [52], and eqn [61] follows.

With regard to transience, balanced RWREs admit a complete and simple classification. Namely, it has been proved (see Zeitouni (2004)) that any balanced RWRE is transient for $d \geq 3$ and recurrent for $d = 2$ ($\boldsymbol{P}_0$-a.s.). It is interesting to note, however, that these answers may be false for certain balanced random walks in a fixed environment ($\mathbb{P}$-probability of such environments being zero, of course). Indeed, examples can be constructed of balanced random walks in $\mathbb{Z}^2$ and in $\mathbb{Z}^d$ with $d \geq 3$, which are transient and recurrent, respectively (Zeitouni 2004).

### RWRE Based on Modification of Ordinary Random Walks

A number of partial results are known for RWRE constructed on the basis of ordinary random walks via certain randomization of the environment. A natural model is obtained by a small perturbation of a simple symmetric random walk. To be more precise, suppose that: (1) $|p_x(e) - 1/2d| < \varepsilon$ for all $x \in \mathbb{Z}^d$ and any $|e| = 1$, where $\varepsilon > 0$ is small enough; (2) $\mathbb{E}p_x(e) = 1/2d$; (3) vectors $p_x(\cdot)$ are i.i.d. for different $x \in \mathbb{Z}^d$; and (4) the distribution of the vector $p_x(\cdot)$ is isotropic, that is, invariant with respect to permutations of its coordinates. Then for $d \geq 3$ Bricmont and Kupiainen (1991) have proved an LLN (with zero asymptotic velocity) and a quenched CLT (with nondegenerate covariance matrix). The proof is based on the renormalization group method, which involves decimation in time combined with a suitable spatial–temporal scaling. This transformation replaces an RWRE by another RWRE with weaker randomness, and it can be shown that iterations converge to a Gaussian fixed point.

Another class of examples is also built using small perturbations of simple symmetric random walks, but is anisotropic and exhibits ballistic behavior, providing that the annealed local drift in some direction is strong enough (see Sznitman (2004)). More precisely, suppose that $d \geq 3$ and $\eta \in (0,1)$. Then there exists $\varepsilon_0 = \varepsilon_0(d,\eta) > 0$ such that if $|p_x(e) - 1/2d| < \varepsilon$ ($x \in \mathbb{Z}^d, |e| = 1$) with $0 < \varepsilon < \varepsilon_0$, and for some $e_0$ one has $\mathbb{E}[d(x,\omega)\cdot e_0] \geq \varepsilon^{2.5-\eta}$ ($d = 3$) or $\geq \varepsilon^{3-\eta}$ ($d \geq 4$), then Sznitman's condition (T′) is satisfied with respect to $e_0$ and therefore the RWRE is ballistic in the direction $e_0$ (cf. the subsection "Kalikow's condition and Sznitman's condition (T′)").

Examples of a different type are constructed in dimensions $d \geq 6$ by letting the first $d_1 \geq 5$ coordinates of the RWRE $X_n$ behave according to an ordinary random walk, while the remaining $d_2 = d - d_1$ coordinates are exposed to a random environment (see Bolthausen *et al.* (2003)). One can show that there exists a deterministic $v$ (possibly zero) such that $X_n/n \to v$ ($\boldsymbol{P}_0$-a.s.). Moreover, if $d_1 \geq 13$, then $(X_n - nv)/\sqrt{n}$ satisfies both quenched and annealed CLT. Incidentally, such models can be used to demonstrate the surprising features of the multidimensional RWRE. For instance, for $d \geq 7$ one can construct an RWRE $X_n$ such that the annealed local drift does not vanish, $\mathbb{E}d(x,\omega) \neq 0$, but the asymptotic velocity is zero, $X_n/n \to 0$ ($\boldsymbol{P}_0$ - a.s.), and furthermore, if $d \geq 15$, then in this example $X_n/\sqrt{n}$ satisfies a quenched CLT. (In fact, one can construct such RWRE as small perturbations of a simple symmetric walk.) On the other hand, there exist examples (in high enough dimensions) where the walk is ballistic with a velocity which has an opposite direction to the annealed drift $\mathbb{E}d(x,\omega) \neq 0$. These striking examples provide "experimental" evidence of many unusual properties of the multidimensional RWRE, which, no doubt, will be discovered in the years to come.

# Recursion Operators in Classical Mechanics

**F Magri**, Università di Milano Bicocca, Milan, Italy
**M Pedroni**, Università di Bergamo, Dalmine (BG), Italy

## Introduction

One of the tasks of classical mechanics has always been to identify those Hamiltonian systems which, by their peculiar properties, are considered solvable. The integrable systems of Liouville and the separable systems of Jacobi can serve as representative examples here. The bi-Hamiltonian geometry, a branch of Poisson geometry dealing with a special kind of deformation of Poisson bracket, suggests two further classes of Hamiltonian systems – the bi-Hamiltonian systems and the cyclic systems of Levi-Civita. The purpose of this article is to investigate the second class of systems mentioned above, and to explain why they are relevant for classical mechanics. (*see* Bi-Hamiltonian Methods in Soliton Theory and Multi-Hamiltonian Systems for further details).

To define a cyclic system of Levi-Civita, one must consider a symplectic manifold $(S, \omega)$ endowed with a tensor field of type $(1, 1)$, seen as an endomorphism $N : TS \to TS$ that obeys two conditions. The first condition is that the vector-valued 2-form

$$T_N(X, Y) = [NX, NY] - N[NX, Y] - N[X, NY] + N^2[X, Y]$$

(called the Nijenhuis torsion of $N$) vanishes identically. In this case $N$ is termed a "recursion operator." The second condition is that

$$\omega'(X, Y) = \omega(NX, Y)$$

is a closed 2-form. The manifolds where these conditions are fulfilled are called $\omega N$ manifolds. On these manifolds, each Hamiltonian vector field $X_h$ is embedded into the distribution

$$D_h = \langle X_h, NX_h, N^2X_h, \ldots \rangle$$

which is the minimal invariant distribution containing $X_h$. This can be called the Levi-Civita distribution generated by $X_h$. Experience has shown that $D_h$ is seldom integrable. The cyclic systems of Levi-Civita are, by definition, the generators of the integrable Levi-Civita distributions. Even though this notion is new in classical mechanics, many interesting classical systems display this property.

The aim of this article is to show that the cyclic systems of Levi-Civita are closely related to

separable systems of Jacobi. To this end, the article is organized in four sections, of which the first three clarify the above-mentioned concepts. In the section "$\omega N$ manifolds," the idea of $\omega N$ manifolds is explained from the viewpoint of bi-Hamiltonian geometry. The section "Cotangent bundles" shows that cotangent bundles provide a large class of $\omega N$ manifolds, proving that such manifolds are not rare. Next, two basic examples of cyclic systems of Levi-Civita are presented. Finally, the relation between cyclic systems of Levi-Civita and separable systems of Jacobi is explained briefly.

## $\omega N$ Manifolds

Let us consider a symplectic manifold $(S, \omega)$ with its Hamiltonian vector fields $X_h$ defined by

$$\omega(X_h, \cdot) = -\mathrm{d}h$$

and with the Poisson bracket

$$\{f, g\} = \omega(X_f, X_g)$$

Both the Hamiltonian vector fields and the functions on $S$ form a Lie algebra, and these algebras are homomorphic, since

$$[X_f, X_g] = X_{\{f,g\}}$$

The bi-Hamiltonian geometry is the study of the deformations of the Lie algebras which preserve the above morphism.

We start from the deformations of the Poisson algebra of functions, by replacing the bracket $\{f, g\}$ with the linear pencil

$$\{f, g\}_\epsilon = \{f, g\} + \epsilon\{f, g\}', \quad \epsilon \in \mathbb{R}$$

The problem is to find $\{f, g\}'$ in such a way that the linear pencil satisfies the Jacobi identity for any value of the parameter $\epsilon$. To solve this problem it is convenient to represent the bracket $\{f, g\}'$ in the form

$$\{f, g\}' = \omega'(X_f, X_g)$$

(which is analogous to the standard representation of the Poisson bracket of $S$) and then to notice that there exists a unique (1, 1) tensor field $N: TS \to TS$ such that

$$\omega'(X_f, X_g) = \omega(NX_f, X_g)$$

Due to the skew-symmetry of $\omega'$, the tensor field $N$ must satisfy the condition

$$\omega(NX_f, X_g) = \omega(X_f, NX_g)$$

To the first order in $\epsilon$, the Jacobi identity on $\{f, g\}_\epsilon$ gives

$$\{\{f, g\}, h\}' + \{\{f, g\}', h\} + \text{cyclic permutations} = 0$$

This condition entails a constraint on $\omega'$. One can readily check that $\omega'$ must be a closed 2-form:

$$\mathrm{d}\omega' = 0$$

In turn, this constraint imposes a condition on $N$. The translation of the closure of $\omega'$ on $N$ is

$$[NX_f, X_g] + [X_f, NX_g] - N[X_f, X_g] = X_{\{f,g\}'}$$

To the second order in $\epsilon$, the Jacobi identity on $\{f, g\}_\epsilon$ gives

$$\{\{f, g\}', h\}' + \text{cyclic permutations} = 0$$

entailing the condition

$$[NX_f, NX_g] = NX_{\{f,g\}'}$$

on $N$. Thus, the Jacobi identity is satisfied at any order in $\epsilon$ if and only if $N$ is torsion free and $\omega'$ is a closed 2-form. Hence, according to the definition given in the "Introduction," the manifold $S$ is an $\omega N$ manifold.

It may be of interest to notice that the bracket

$$[X, Y]_N = [NX, Y] + [X, NY] - N[X, Y]$$

is a new (deformed) commutator on vector fields, since the torsion of $N$ vanishes. The same is also true for

$$[X, Y]_\epsilon = [X, Y] + \epsilon[X, Y]_N$$

since the torsion of $(\mathrm{Id} + \epsilon N)$ vanishes too. Therefore, one can write

$$[X_f, X_g]_\epsilon = X_{\{f,g\}_\epsilon}$$

This formula shows that this process of deformation is rigid. For each change of the Poisson bracket, there is a deformation of the commutator of vector fields such that the basic correspondence between functions and Hamiltonian vector fields, established by the symplectic form $\omega$, remains a Lie algebra morphism.

The same phenomenon can be observed in connection with the definition of Hamiltonian vector field. If one introduces the pencil of 2-forms

$$\omega_\epsilon = \omega + \epsilon\omega'$$

and the pencil of derivations

$$\mathrm{d}_\epsilon = \mathrm{d} + \epsilon \mathrm{d}_N$$

where $\mathrm{d}_N$ is the derivation of type d and degree 1 canonically associated with $N$ according to the

theory of graded derivations of Frölicher and Nijenhuis, one can prove that

$$d_\epsilon^2 = 0, \qquad d_\epsilon \omega_\epsilon = 0$$

and that

$$\omega_\epsilon(X_h, \cdot) = -d_\epsilon h$$

This means that, on an $\omega N$ manifold, the symplectic form $\omega$ and the de Rham differential d are deformed in such a way that the basic relation between functions and Hamiltonian vector fields established by $\omega$ holds true.

## Cotangent Bundles

Cotangent bundles are a source of examples of $\omega N$ manifolds. The construction begins on the base manifold $Q$. For any $(1,1)$ tensor field $L: TQ \to TQ$ with vanishing Nijenhuis torsion, one constructs the deformed Liouville 1-form

$$\theta' = \sum_{i=1}^{n} y_i L^*(dx^i)$$

and its exterior derivative

$$\omega' = d\theta'$$

It can be proved that $\omega'$ satisfies the conditions explained in the previous section, and conclude that $T^*Q$, endowed with the pencil of 2-form $\omega_\epsilon = \omega +_\epsilon \omega'$, is an $\omega N$ manifold.

A subclass of these structures merits attention. It is related to the polynomials

$$s(\lambda) = \lambda^n - \left(s_1\lambda^{n-1} + s_2\lambda^{n-2} + \cdots + s_n\right)$$

the coefficients of which are functions on $Q$ satisfying the condition

$$ds_1 \wedge ds_2 \wedge \cdots \wedge ds_n \neq 0$$

(almost) everywhere on $Q$. Moreover, it is convenient to assume that the roots $(\lambda_1, \lambda_2, \ldots, \lambda_n)$ of $s(\lambda)$ are distinct and real, so that they are functionally independent and can be used as coordinates on $Q$. Therefore, the choice of $s(\lambda)$ is equivalent to fix a special system of coordinates on $Q$, as it happens in $\mathbb{R}^3$ when one introduces the elliptical coordinates as the roots of the polynomial

$$s(\lambda) = (\lambda - a)(\lambda - b)(\lambda - c) \times \left(1 + \frac{x^2}{\lambda - a} + \frac{y^2}{\lambda - b} + \frac{z^2}{\lambda - c}\right)$$

The peculiarity of this situation is that there exists a unique recursion operator $L: TQ \to TQ$ whose characteristic polynomial is $s(\lambda)$. Thus, the choice of $s(\lambda)$ also determines an $\omega N$ structure on $T^*Q$ according to the previous prescription. The conclusion is that there is a relation between pencils of Poisson brackets on $T^*Q$ and coordinate systems on $Q$. This relation is the clue to understand the geometry of separable systems of Jacobi.

## Cyclic Systems of Levi-Civita

The systems of coupled harmonic oscillators are the first example of cyclic systems of Levi-Civita. Let us consider, for simplicity, a system formed by only two particles, with masses $m_1$ and $m_2$, moving on a line under the action of an internal elastic force. The Lagrangian of the system is

$$L = \tfrac{1}{2}\left(m_1\dot{x}_1^2 + m_2\dot{x}_2^2\right) - \tfrac{1}{2}k(x_1 - x_2)^2$$

and the equations of motion are

$$M\ddot{x} + Kx = 0, \quad x = \begin{pmatrix} x_1 \\ x_2 \end{pmatrix}$$

where

$$M = \begin{pmatrix} m_1 & 0 \\ 0 & m_2 \end{pmatrix}, \qquad K = \begin{pmatrix} k & -k \\ -k & k \end{pmatrix}$$

Under a change of coordinates, the entries of the matrices $M$ and $K$ obey the transformation law of the components of a second-order covariant tensor. Therefore, the entries of the matrix $L = M^{-1}K$ are the components of a tensor field of type $(1,1)$ on $\mathbb{R}^2$. The defining equations of the associated endomorphism $L: T\mathbb{R}^2 \to \mathbb{R}^2$ are

$$L^*(dx_1) = \omega_1^2(dx_2 - dx_1)$$
$$L^*(dx_2) = \omega_2^2(dx_1 - dx_2)$$

if $\omega_1^2 = k/m_1$ and $\omega_2^2 = k/m_2$, and these equations clearly show that $L$ is torsion free. The same argument holds for any system of coupled harmonic oscillators. Therefore, the cotangent bundle associated with any system of coupled harmonic oscillators is an $\omega N$ manifold.

To compute the tensor field $N$ in our example, one has to follow the prescription, passing from

$$\theta' = \left(\omega_1^2 y_1 - \omega_2^2 y_2\right)(dx_2 - dx_1)$$

to

$$\omega' = \left(\omega_1^2\, dy_1 - \omega_2^2\, dy_2\right) \wedge (dx_2 - dx_1)$$

and to

$$N\left(\frac{\partial}{\partial x_1}\right) = \omega_1^2 \frac{\partial}{\partial x_1} - \omega_2^2 \frac{\partial}{\partial x_2}$$
$$N\left(\frac{\partial}{\partial x_2}\right) = -\omega_1^2 \frac{\partial}{\partial x_1} + \omega_2^2 \frac{\partial}{\partial x_2}$$
$$N\left(\frac{\partial}{\partial y_1}\right) = \omega_1^2 \left(\frac{\partial}{\partial y_1} - \frac{\partial}{\partial y_2}\right)$$
$$N\left(\frac{\partial}{\partial y_2}\right) = \omega_2^2 \left(-\frac{\partial}{\partial y_1} + \frac{\partial}{\partial y_2}\right)$$

The Levi-Civita distribution $D_h$ is therefore spanned by the vector fields

$$X_h = k\left[\frac{y_1}{\omega_1^2}\frac{\partial}{\partial x_1} + \frac{y_2}{\omega_2^2}\frac{\partial}{\partial x_2} + (x_2 - x_1)\left(\frac{\partial}{\partial y_1} - \frac{\partial}{\partial y_2}\right)\right]$$
$$NX_h = k\left[\left(y_1 - \frac{\omega_1^2}{\omega_2^2}y_2\right)\frac{\partial}{\partial x_1} + \left(y_2 - \frac{\omega_2^2}{\omega_1^2}y_1\right)\frac{\partial}{\partial x_2} + (\omega_1^2 + \omega_2^2)(x_2 - x_1)\left(\frac{\partial}{\partial y_1} - \frac{\partial}{\partial y_2}\right)\right]$$

related to the Hamiltonian

$$h = \frac{y_1^2}{2m_1} + \frac{y_2^2}{2m_2} + \frac{1}{2}k(x_1 - x_2)^2$$

of the system of coupled oscillators. Since $[X_h, NX_h] = 0$, the distribution is integrable; therefore, the system is a cyclic system of Levi-Civita. This property holds for any system of coupled harmonic oscillators. It will be apparent at the end of this article that this result is due to the eigenvectors of $L$ defining the separation coordinates of the coupled oscillators.

The second and final example of cyclic systems of Levi-Civita is the Neumann system, that is, the anisotropic harmonic oscillator on the sphere $S^2$, whose Lagrangian is

$$L = \tfrac{1}{2}m\left(\dot{x}_1^2 + \dot{x}_2^2 + \dot{x}_3^2\right) - \tfrac{1}{2}\left(a_1x_1^2 + a_2x_2^2 + a_3x_3^2\right)$$

with the constraint

$$x_1^2 + x_2^2 + x_3^2 = 1$$

This constraint can be avoided by using the first two Cartesian coordinates $(x_1, x_2)$ as local coordinates on $S^2$. The Hamiltonian of the system can then be written in the form

$$h = \tfrac{1}{2}\left(1 + x_1^2\right)y_1^2 - x_1x_2y_1y_2 + \tfrac{1}{2}\left(1 + x_2^2\right)y_2^2 + \tfrac{1}{2}(a_1 - a_3)x_1^2 + \tfrac{1}{2}(a_2 - a_3)x_2^2$$

where, for simplicity, $m = 1$. Formally one is back in $\mathbb{R}^2$ as in the previous example, but the nonlinearity of the equations of motion hinders us to readily see the appropriate recursion operator $L : T\mathbb{R}^2 \to T\mathbb{R}^2$ to be used to construct the $\omega N$ structure on $T^*\mathbb{R}^2$. Let us however recall that according to Neumann, the system is separable in elliptical spherical (also called spheroconical) coordinates, defined as the roots of the restriction to $S^2$ of the polynomial

$$s(\lambda) = (\lambda - a)(\lambda - b)(\lambda - c)\left(\frac{x_1^2}{\lambda - a} + \frac{x_2^2}{\lambda - b} + \frac{x_3^2}{\lambda - c}\right) = \lambda^2 - (s_1\lambda + s_2)$$

Let us, therefore, use this polynomial to construct the unique recursion operator $L$ having $s(\lambda)$ as its characteristic polynomial. It is given by

$$L^*(\mathrm{d}s_1) = \mathrm{d}s_2 + s_1\,\mathrm{d}s_1$$
$$L^*(\mathrm{d}s_2) = s_2\,\mathrm{d}s_1$$

or, after a brief computation, by

$$L^*(\mathrm{d}x_1) = a_1\,\mathrm{d}x_1 - x_1\,\mathrm{d}\left[\tfrac{1}{2}(a_1 - a_3)x_1^2 + \tfrac{1}{2}(a_2 - a_3)x_2^2\right]$$
$$L^*(\mathrm{d}x_2) = a_2\,\mathrm{d}x_2 - x_2\,\mathrm{d}\left[\tfrac{1}{2}(a_1 - a_3)x_1^2 + \tfrac{1}{2}(a_2 - a_3)x_2^2\right]$$

The situation stays the same as in the previous example. Accordingly, the recursion operator $N$ on $T^*\mathbb{R}^2$ is now given by

$$N^*\,\mathrm{d}x_1 = a_1\,\mathrm{d}x_1 - x_1\,\mathrm{d}f$$
$$N^*\,\mathrm{d}x_2 = a_2\,\mathrm{d}x_2 - x_2\,\mathrm{d}f$$
$$N^*\,\mathrm{d}y_1 = a_1\,\mathrm{d}y_1 - (a_1 - a_3)x_1\,\mathrm{d}g + y_1\,\mathrm{d}f$$
$$N^*\,\mathrm{d}y_2 = a_2\,\mathrm{d}y_2 - (a_2 - a_3)x_2\,\mathrm{d}g + y_2\,\mathrm{d}f$$

where the shorthand notations

$$f = \tfrac{1}{2}(a_1 - a_3)x_1^2 + \tfrac{1}{2}(a_2 - a_3)x_2^2$$
$$g = x_1y_1 + x_2y_2$$

have been used. The derivation $\mathrm{d}_N$, associated with $N$, is accordingly defined by

$$\mathrm{d}_Nx_1 = N^*\,\mathrm{d}x_1 = \left[a_1 + (a_3 - a_1)x_1^2\right]\mathrm{d}x_1 + (a_3 - a_2)x_1x_2\,\mathrm{d}x_2$$
$$\mathrm{d}_Nx_2 = N^*\,\mathrm{d}x_2 = (a_3 - a_1)x_1x_2\,\mathrm{d}x_1 + \left[a_2 + (a_3 - a_2)x_2^2\right]\mathrm{d}x_2$$
$$\mathrm{d}_Ny_1 = N^*\,\mathrm{d}y_1 = \left[(a_3 - a_1)x_1y_2 - (a_3 - a_2)x_2y_1\right]\mathrm{d}x_2 + \left[a_1 + (a_3 - a_1)x_1^2\right]\mathrm{d}y_1 + (a_3 - a_1)x_1x_2\,\mathrm{d}y_2$$
$$\mathrm{d}_Ny_2 = N^*\,\mathrm{d}y_2 = \left[(a_3 - a_2)x_2y_1 - (a_3 - a_1)x_1y_2\right]\mathrm{d}x_1 + (a_3 - a_2)x_1x_2\,\mathrm{d}y_1 + \left[a_2 + (a_3 - a_2)x_2^2\right]\mathrm{d}y_2$$

on the coordinate functions. Recalling that $\mathrm{d}_N$ anticommutes with d, one can then easily check the condition

$$\mathrm{d}\mathrm{d}_Nh = \mathrm{d}s_1 \wedge \mathrm{d}h$$

where $s_1$ is the first coefficient of the polynomial defining the elliptical spherical coordinates, and $h$ is the Hamiltonian of the Neumann system. By the Frobenius theorem, this equation alone entails the integrability of the distribution $D_h$, without the need of computing $X_h, NX_h$, and their commutator $[X_h, NX_h]$. Thus, it can be concluded that the Neumann system too is a cyclic system of Levi-Civita, and that the recursion operator $N$, generating the distribution $D_h$, is closely related to the polynomial defining the separation coordinates of the Neumann system.

## Separable System of Jacobi

In 1838, Jacobi noticed that the Hamilton–Jacobi equation

$$h\left(x_1, x_2, \ldots, x_n, \frac{\partial W}{\partial x_1}, \ldots, \frac{\partial W}{\partial x_n}\right) = e$$

of many Hamiltonian systems splits owing to an appropriate choice of coordinates in a set of ordinary differential equations. On account of this property, these systems have been called separable. In 1904, Levi-Civita gave a first partial characterization of separable Hamiltonians by means of his separability conditions. In a letter addressed to Stäckel, he proved that $h$ is separable in a preassigned system of canonical coordinates if and only if the conditions

$$\frac{\partial^2 h}{\partial x_j \partial x_k}\frac{\partial h}{\partial y_j}\frac{\partial h}{\partial y_k} - \frac{\partial^2 h}{\partial x_j \partial y_k}\frac{\partial h}{\partial y_j}\frac{\partial h}{\partial x_k} - \frac{\partial^2 h}{\partial y_j \partial x_k}\frac{\partial h}{\partial x_j}\frac{\partial h}{\partial y_k} + \frac{\partial^2 h}{\partial y_j \partial y_k}\frac{\partial h}{\partial x_j}\frac{\partial h}{\partial x_k} = 0$$

are satisfied by $h$. One must notice the nontensorial character of these conditions; they hold only in a specific coordinate system, and if the coordinates are changed, it is not possible to reconstruct the form of the separability conditions in the new coordinates. The nontensorial character is the major drawback of the separability conditions of Levi-Civita, making them practically useless in the search of separation coordinates.

The contact between the theory of separable system of Jacobi and the theory of cyclic systems of Levi-Civita rests on two occurrences. The first is the form of the integrability conditions of the distribution $D_h$ generated by any vector field $X_h$ on an $\omega N$ manifold. Exploiting the Frobenius integrability conditions and the properties of the differential operator $d_N$ associated with the recursion operator $N$, it can be proved that $D_h$ is integrable if and only if the 2-form $dd_N h$ vanishes on $D_h$:

$$dd_N h = 0 \quad \text{on} \quad D_h$$

Suppose now that the dimension of $D_h$ is maximal, that is, equal to $n = (1/2)\dim S$. Then $D_h$ is spanned by the $n$ vector fields $(X_h, NX_h, \ldots, N^{n-1}X_h)$, and the vanishing condition of $dd_N h$ on $D_h$ turns out to be equivalent to

$$dd_N h(N^j X_h, N^k X_h) = 0$$

for any value of $j$ and $k$ from 0 to $n-1$. Thus, the number of separability conditions of $h$ and the number of integrability conditions of $D_h$ are equal. This circumstance strongly suggests that the two sets of conditions are related. The nontensorial character of the Levi-Civita conditions, compared with the tensorial character of the integrability conditions of $D_h$, further suggests that the former should be the evaluation of the latter in a specific system of coordinates. These coordinates are the "normal coordinates" of an $\omega N$ manifold, that will be introduced in the following.

Assume that the minimal polynomial of $N$ has real and distinct roots $(l_1, \ldots, l_n)$. In this case, the $\omega N$ manifold is said to be semisimple. A two-dimensional eigenspace is associated with each root $l_k$. Let us consider the distribution $E_k$ spanned by all the eigenvectors of $N$, except those associated with $l_k$. Since $N$ is torsion free, each distribution $E_k$ is integrable. Let us fix the attention on one of these distributions. It turns out that its leaves are symplectic submanifolds of codimension 2. So they are the level surfaces of a pair of (local) functions which are not in involution. By collecting together the pairs of functions associated with the $n$ distributions $(E_1, \ldots, E_n)$, one obtains, at the end, a coordinate system $(\lambda_1, \mu_1, \lambda_2, \mu_2, \ldots, \lambda_n, \mu_n)$ on $S$. Moreover, these functions can be chosen in such a way to form a system of canonical coordinates. The final result is that, on a semisimple $\omega N$ manifold, one can construct a coordinate system such that

$$\omega = \sum_{j=1}^{n} d\mu_j \wedge d\lambda_j$$

and

$$N^*(d\lambda_j) = l_j d\lambda_j$$
$$N^*(d\mu_j) = l_j d\mu_j$$

These coordinates are called the normal coordinates (or sometimes, the Darboux–Nijenhuis coordinates) of the $\omega N$ manifold. One can prove that the separability conditions of Levi-Civita are the integrability

conditions of $D_h$, written in normal coordinates. This result allows us to claim that the cyclic systems of Levi-Civita on semisimple $\omega N$ manifolds are all separable.

The reverse is also true. As has already been shown in the example of the Neumann system, a given separable system of Jacobi can be associated with a recursion operator $N$ in such a way that its phase space (with the possible exclusion of a singular locus) becomes an $\omega N$ manifold, and the Hamiltonian vector field $X_h$ becomes a cyclic system of Levi-Civita. A new interpretation of the process of separation of variables follows from this result. Indeed, to find separation coordinates for a given system on a symplectic manifold $S$ is equivalent to deforming the Poisson bracket of $S$ into a pencil

$$\{f,g\}_\epsilon = \{f,g\} + \epsilon\{f,g\}'$$

in such a way that the recursion operator $N$ defining the pencil $\{f,g\}_\epsilon$ generates, with $X_h$, an integrable distribution $D_h$. Therefore, classical mechanics is deeply entangled with the theory of recursion operators, even if the insistence on the use of separation coordinates has hidden this factor for a long time.

## Phase Transitions in Lattice Systems

### Introduction

Phase transitions are among the main objects of equilibrium statistical mechanics, both classical and quantum. There exist several approaches to the description of these phenomena. Their common point is that the macroscopic behavior of a statistical mechanical model can be different at the same values of the model parameters. This corresponds to the multiplicity of equilibrium phases, each of which has its own properties. In the mathematical formulation, models are defined by interaction potentials and equilibrium phases appear as states – positive linear functionals on algebras of observables. In the classical case the states are defined by means of the probability measures which satisfy equilibrium conditions, formulated in terms of the interaction potentials. Such measures are called Gibbs measures and the corresponding states are called Gibbs states. The observables are then integrable functions. In the quantum case the states mostly are introduced by means of the Kubo–Martin–Schwinger condition – a quantum analog of the equilibrium conditions used for classical models. The quantum observables constitute noncommutative von Neumann algebras.

Infinite systems of particles studied in statistical mechanics fall into two main groups. These are continuous systems and lattice systems. In the latter case, particles are attached to the points of various crystalline lattices. In view of the specifics of our subject, in this article we will deal with lattice systems only.

One of the main problems of the mathematical theory of phase transitions is to prove that the Gibbs states of a given model can be multiple, that is, that this model undergoes a phase transition. To solve this problem one has to elaborate corresponding mathematical tools. Typically, at high temperatures (equivalently, for weak interactions), a model, which undergoes a phase transition, has only one Gibbs state. This state inherits all the symmetries possessed by the interaction potentials. At low temperatures this model has multiple Gibbs states, which may lose the symmetries. In this case the phase transition is accompanied by a symmetry breaking. Among the symmetries important in the theory of lattice systems, there is the invariance with respect to the lattice translations. If the Gibbs state of a translation invariant lattice model is unique, it ought to be ergodic with respect to the group of lattice translations. This means in particular that the spacial correlations in this state decay to zero at long distances. Therefore, the lack of the latter property may indicate a phase transition. In a number of lattice models, phase transitions can be established by means of their special property – reflection positivity. The most important consequence of reflection positivity are chessboard (another name checkerboard) estimates, being extended versions of Hölder's inequalities. The proof of a phase transition is then performed either by means of a combination of such estimates and contour methods, or by means of infrared estimates obtained from the chessboard estimates.

In this article we show how to prove phase transitions by means of the infrared estimates for some simple reflection positive models, both classical and quantum. The details on the reflection positivity method in all its versions may be found in the literature listed at the end of the article. There we also provide short bibliographic comments.

#### Nonergodicity and Infrared Estimates

The following heuristic arguments should give an idea how to establish the nonergodicity of a Gibbs state by means of infrared estimates. Let us consider a classical ferromagnetic translation-invariant model. (Of course, we assume that it possesses Gibbs states, which for models with unbounded spins is a nontrivial property. A particular case of this model is described in more detail in the subsection "Gaussian domination.") This model describes the system of interacting $N$-dimensional spins $x_\ell \in \mathbb{R}^N$, indexed by the elements $\ell \in \mathbb{Z}^d$ of the $d$-dimensional simple cubic lattice. The interaction is pairwise, attractive, nearest-neighbor, and invariant with respect to the rotations in $\mathbb{R}^N$. Consider a translation-invariant Gibbs state of this model, which always exists. Let $K(\ell, \ell'), \ell, \ell' \in \mathbb{Z}^d$, be the expectation of the scalar product $(x_\ell, x_{\ell'})$ of spins in this state. Then $K(\ell, \ell')$ is also translation invariant and hence may be written as

$$K(\ell, \ell') = \frac{1}{(2\pi)^d} \int_{(-\pi,\pi]^d} \widehat{K}(p) e^{i(p, \ell - \ell')} dp, \quad i = \sqrt{-1} \qquad [1]$$

where the generalized function $\widehat{K}$ is defined by the Fourier series

$$\widehat{K}(p) = \sum_{\ell' \in \mathbb{Z}^d} K(\ell, \ell') e^{-i(p, \ell - \ell')}, \quad p \in (-\pi, \pi]^d \qquad [2]$$

As the model is ferromagnetic, $K(\ell, \ell') \geq 0$. The Gibbs state is nonergodic if $K(\ell, \ell')$ does not tend to zero as $|\ell - \ell'| \to \infty$. In this case $\widehat{K}$ should be singular at $p = 0$. Set

$$\widehat{K}(p) = (2\pi)^d \lambda \delta(p) + g(p) \qquad [3]$$

where $\delta(p)$ is the Dirac $\delta$-function and $g(p)$ is regular at $p = 0$. Then the Gibbs state is nonergodic if $\lambda \neq 0$. Suppose we know that $g(p) \geq 0$ and that the following two estimates hold. The first one is

$$g(p) \leq \gamma / J |p|^2, \quad p \neq 0 \qquad [4]$$

where $\gamma > 0$ is a constant and $J > 0$ is the interaction intensity multiplied by the inverse temperature $\beta$. This is the infrared estimate. The second estimate is

$$K(\ell, \ell) \geq \varkappa > 0 \qquad [5]$$

where $\varkappa$ is independent of $J$. By these estimates and [1], [2], we get

$$\lambda \geq \varkappa - \frac{\gamma}{(2\pi)^d J} \int_{(-\pi,\pi]^d} \frac{dp}{|p|^2} \qquad [6]$$

For $d \geq 3$, the latter integral exists; hence, $\lambda > 0$ for $J$ large enough, which means that the state we consider is nonergodic.

The quantum case is more involved. The infrared bounds are obtained not for functions like $\widehat{K}(p)$ but for the so-called Duhamel two-point functions. Then one has to prove a number of additional statements, which finally lead to the proof of the result desired. In the section on reflection positivity in quantum systems we indicate how to do this for a simple quantum spin model.

### Reflection Positivity and Phase Transitions in Classical Systems

We begin by studying reflection positive (RP) functionals. Gibbs states of RP models are such functionals.

### Reflection Positive Functionals

Let $\Lambda$ be a finite set of indices consisting of an even number $|\Lambda|$ of elements, which label real variables $x_\ell, \ell \in \Lambda$. For $\Lambda' \subseteq \Lambda$, we write $x_{\Lambda'} = (x_\ell)_{\ell \in \Lambda'} \in \mathbb{R}^{|\Lambda'|}$. Suppose we are given a bijection $\rho : \Lambda \to \Lambda, \rho \circ \rho = \mathrm{id}$, such that the set $\Lambda$ falls into two disjoint parts $\Lambda_\pm$ with the property $\rho : \Lambda_+ \to \Lambda_-$. Therefore, $|\Lambda_+| = |\Lambda_-|$, and the map $\rho$ may be regarded as a reflection. For $x_\Lambda \in \mathbb{R}^{|\Lambda|}$, we set $\rho(x_\Lambda) = (x_{\rho(\ell)})_{\ell \in \Lambda}$. Now let $\mathcal{A}$ be an algebra of functions $A : \mathbb{R}^{|\Lambda|} \to \mathbb{R}$. Then we define the map $\vartheta : \mathcal{A} \to \mathcal{A}$ by setting

$$\vartheta(A)(x_\Lambda) = A(\rho(x_\Lambda)) \qquad [7]$$

Clearly, for all $A, B \in \mathcal{A}$ and $\xi, \eta \in \mathbb{R}$,

$$\begin{aligned} \vartheta(\xi A + \eta B) &= \xi\vartheta(A) + \eta\vartheta(B) \\ \vartheta(A \cdot B) &= \vartheta(A) \cdot \vartheta(B) \end{aligned} \qquad [8]$$

By $\mathcal{A}^+$ (respectively, $\mathcal{A}^-$), we denote the subalgebra of $\mathcal{A}$ consisting of functions dependent on $x_{\Lambda_+}$ (respectively, $x_{\Lambda_-}$). Then $\vartheta(\mathcal{A}^+) = \mathcal{A}^-$ and $\vartheta \circ \vartheta = \mathrm{id}$.

**Definition 1** A linear functional $\phi : \mathcal{A} \to \mathbb{R}$ is called RP with respect to the maps $\rho$ and $\vartheta$, if

$$\forall A \in \mathcal{A}^+ : \ \phi[A\vartheta(A)] \geq 0 \qquad [9]$$

**Example 2** Let $\chi$ be a Borel measure on the real line (not necessarily positive), with respect to which all real polynomials are integrable. Let also $\mathcal{A}$ be the algebra of all real-valued polynomials on $\mathbb{R}^{|\Lambda|}$, $|\Lambda|$ being even. Finally, let $\rho$ and $\vartheta$ be any of the maps with the properties described above. Then the functional

$$\begin{aligned} \phi(A) &= \int_{\mathbb{R}^{|\Lambda|}} A(x_\Lambda)\, \mathrm{d}\chi_\Lambda(x_\Lambda) \\ \mathrm{d}\chi_\Lambda(x_\Lambda) &= \prod_{\ell \in \Lambda} \mathrm{d}\chi(x_\ell) \end{aligned} \qquad [10]$$

is RP. Indeed, let $F : \mathbb{R}^{|\Lambda|/2} \to \mathbb{R}$ be such that $A(x_\Lambda) = F(x_{\Lambda_+})$. Then

$$\begin{aligned} \phi[A\vartheta(A)] &= \int F(x_{\Lambda_+}) \prod_{\ell \in \Lambda_+} \mathrm{d}\chi(x_\ell) \cdot \int F(x_{\Lambda_-}) \prod_{\ell \in \Lambda_-} \mathrm{d}\chi(x_\ell) \\ &= \left[ \int F(x_{\Lambda_+}) \prod_{\ell \in \Lambda_+} \mathrm{d}\chi(x_\ell) \right]^2 \geq 0 \end{aligned}$$

In the above example the multiplicative structure of the measure $\chi_\Lambda$ is crucial. It results in the positivity of $\phi$ with respect to all reflections. If one has just one such reflection, the measure which defines $\phi$ may be decomposable onto two measures only. Let $\Lambda, \mathcal{A}, \rho$, and $\vartheta$ be as above. Consider a Borel measure $\nu$ on $\mathbb{R}^{|\Lambda|/2}$ such that every real-valued polynomial on $\mathbb{R}^{|\Lambda|/2}$ is $\nu$-integrable.

**Proposition 3** *The functional*

$$\phi(A) = \int_{\mathbb{R}^{|\Lambda|}} A(x_\Lambda)\, \mathrm{d}\nu(x_{\Lambda_+})\, \mathrm{d}\nu(x_{\Lambda_-}) \qquad [11]$$

*is RP.*

In both these examples the states are symmetric, that is,

$$\phi[A\vartheta(B)] = \phi[B\vartheta(A)], \quad \text{for all } A, B \in \mathcal{A}^+ \qquad [12]$$

In the sequel we shall suppose that all RP functionals possess this property. Therefore, RP functionals obey a Cauchy–Schwarz type inequality.

**Lemma 4** *If $\phi$ is RP, then for any $A, B \in \mathcal{A}^+$,*

$$\{\phi[A\vartheta(B)]\}^2 \leq \phi[A\vartheta(A)] \cdot \phi[B\vartheta(B)] \qquad [13]$$

**Proof** For $\xi \in \mathbb{R}$, by [8] we have

$$\begin{aligned} &\phi[(A + \xi B)\vartheta(A + \xi B)] \\ &\quad = \phi[(A + \xi B)(\vartheta(A) + \xi\vartheta(B))] \geq 0 \end{aligned}$$

Since $\phi$ is linear, the latter can be written as a 3-nomial, whose positivity for all $\xi \in \mathbb{R}$ is equivalent to [13]. □

Now let an RP functional $\phi$ be such that for

$$A, B, C_1, \ldots, C_m, D_1, \ldots, D_m \in \mathcal{A}^+$$

there exists

$$\phi\left[\exp\left(A + \vartheta(B) + \sum_{i=1}^m C_i\vartheta(D_i)\right)\right]$$

and that the series

$$\begin{aligned} &\sum_{n_1, \ldots, n_m = 0}^{\infty} \frac{1}{n_1! \cdots n_m!} \cdot \phi\{[C_1\vartheta(C_1)]^{n_1} \cdots [C_m\vartheta(C_m)]^{n_m} \\ &\quad \times \exp[A + \vartheta(B)]\} \end{aligned} \qquad [14]$$

as well as the one with all $C_i$s replaced by $D_i$s converge absolutely.

**Lemma 5** *Let the functional $\phi$ and the functions $A, B, C_i, D_i, i = 1, \ldots, m$, be as above. Then*

$$\begin{aligned} &\left\{\phi\left[\exp\left(A + \vartheta(B) + \sum_{i=1}^m C_i\vartheta(D_i)\right)\right]\right\}^2 \\ &\quad \leq \phi\left[\exp\left(A + \vartheta(A) + \sum_{i=1}^m C_i\vartheta(C_i)\right)\right] \\ &\quad \times \phi\left[\exp\left(B + \vartheta(B) + \sum_{i=1}^m D_i\vartheta(D_i)\right)\right] \end{aligned} \qquad [15]$$

**Proof** By the above assumptions

$$\phi\left[\exp\left(A+\vartheta(B)+\sum_{i=1}^{m}C_i\vartheta(D_i)\right)\right]$$
$$=\phi\left[F\vartheta(G)\exp\left(\sum_{i=1}^{m}C_i\vartheta(D_i)\right)\right]$$
$$=\sum_{n_1,\dots,n_m=0}^{\infty}\frac{1}{n_1!\cdots n_m!}\cdot\phi[F\vartheta(G)[C_1\vartheta(D_1)]^{n_1}\cdots\times[C_m\vartheta(D_m)]^{n_m}] \qquad [16]$$

where $F=\mathrm{e}^A, G=\mathrm{e}^B$. Then by [13] and the Cauchy–Schwarz inequality for sums we get

$$\begin{aligned}\text{RHS}[16] &\le \sum_{n_1,\dots,n_m=0}^{\infty}\left\{\frac{1}{n_1!\cdots n_m!}\cdot\phi[F\vartheta(F)[C_1\vartheta(C_1)]^{n_1}\cdots[C_m\vartheta(C_m)]^{n_m}]\right\}^{1/2}\\ &\quad\times\left\{\frac{1}{n_1!\cdots n_m!}\cdot\phi[G\vartheta(G)[D_1\vartheta(D_1)]^{n_1}\cdots[D_m\vartheta(D_m)]^{n_m}]\right\}^{1/2}\\ &\le\left\{\sum_{n_1,\dots,n_m=0}^{\infty}\frac{1}{n_1!\cdots n_m!}\cdot\phi[F\vartheta(F)[C_1\vartheta(C_1)]^{n_1}\cdots[C_m\vartheta(C_m)]^{n_m}]\right\}^{1/2}\\ &\quad\times\left\{\sum_{n_1,\dots,n_m=0}^{\infty}\frac{1}{n_1!\cdots n_m!}\cdot\phi[G\vartheta(G)[D_1\vartheta(D_1)]^{n_1}\cdots[D_m\vartheta(D_m)]^{n_m}]\right\}^{1/2}\\ &=\left\{\phi\left[\exp\left(A+\vartheta(A)+\sum_{i=1}^{m}C_i\vartheta(C_i)\right)\right]\right\}^{1/2}\\ &\quad\times\left\{\phi\left[\exp\left(B+\vartheta(B)+\sum_{i=1}^{m}D_i\vartheta(D_i)\right)\right]\right\}^{1/2}\end{aligned}$$

which yields [15]. □

### Main Estimate

Let $\Delta$ be a finite set and $\Delta'$ be its nonempty subset. Let also $\mu$ and $\nu$ be finite Borel measures on $\mathbb{R}^{N|\Delta|}, N\in\mathbb{N}$. For vectors $b,c\in\mathbb{R}^N$, by $(b,c)$ and $|b|,|c|$ we denote their scalar product $\sum_{k=1}^{N}b^{(k)}c^{(k)}$ and the corresponding norms, respectively. By $x_\Delta$ we denote $(x_\ell)_{\ell\in\Delta}, x_\ell\in\mathbb{R}^N$; hence, $x_\Delta\in\mathbb{R}^{N|\Delta|}$.

**Lemma 6** *Let the sets $\Delta,\Delta'$ and the measures $\mu,\nu$ be as above. Then for every $(a_\ell)_{\ell\in\Delta'}\in\mathbb{R}^{N|\Delta'|}$ and $J\ge 0$,*

$$\left[\int_{\mathbb{R}^{2N|\Delta|}}\exp\left(-\frac{J}{2}\sum_{\ell\in\Delta'}|x_\ell-y_\ell-a_\ell|^2\right)\mathrm{d}\mu(x_\Delta)\mathrm{d}\nu(y_\Delta)\right]^2$$
$$\le\int_{\mathbb{R}^{2N|\Delta|}}\exp\left(-\frac{J}{2}\sum_{\ell\in\Delta'}|x_\ell-y_\ell|^2\right)\mathrm{d}\mu(x_\Delta)\,\mathrm{d}\mu(y_\Delta)$$
$$\times\int_{\mathbb{R}^{2N|\Delta|}}\exp\left(-\frac{J}{2}\sum_{\ell\in\Delta'}|x_\ell-y_\ell|^2\right)\mathrm{d}\nu(x_\Delta)\,\mathrm{d}\nu(y_\Delta) \qquad [17]$$

**Proof** Take two copies of $\Delta$ and denote them by $\Lambda_\pm$. Furthermore, by $\Lambda'_\pm\subset\Lambda_\pm$ we denote the subsets consisting of the elements of $\Delta'\subset\Delta$. For an $\ell\in\Lambda_+$, by $\rho(\ell)$ we denote its counterpart in $\Lambda_-$. Then $\rho$ is a reflection and $\rho(\Lambda'_+)=\Lambda'_-$. Let $\Lambda=\Lambda_+\cup\Lambda_-, \Lambda'=\Lambda'_+\cup\Lambda'_-$, and $\mathcal{A}$ be the algebra of all polynomials of $(x_{\Lambda'},y_{\Lambda'})\in\mathbb{R}^{2N|\Lambda'|}$. Note that $x_{\Lambda'}$ may be regarded as the pair $(x_{\Lambda'_+},x_{\Lambda'_-})$. Let $\mathcal{A}^+$ (respectively, $\mathcal{A}^-$) be the subalgebra of $\mathcal{A}$ consisting of the polynomials which depend on $x_{\Lambda'_+},y_{\Lambda'_+}$ (respectively, $x_{\Lambda'_-},y_{\Lambda'_-}$) only. Introduce the measures

$$\mathrm{d}\tilde{\mu}(x_\Delta)=\exp\left(-\frac{J}{2}\sum_{\ell\in\Delta'}|x_\ell|^2\right)\mathrm{d}\mu(x_\Delta)$$
$$\mathrm{d}\tilde{\nu}(x_\Delta)=\exp\left(-\frac{J}{2}\sum_{\ell\in\Delta'}|x|_\ell^2\right)\mathrm{d}\nu(x_\Delta)$$

and define the following functional on $\mathcal{A}$:

$$\phi(F)=\int_{\mathbb{R}^{2N|\Lambda|}}F(x_{\Lambda'},y_{\Lambda'})\,\mathrm{d}\tilde{\mu}(x_{\Lambda_+})\times\mathrm{d}\tilde{\nu}(y_{\Lambda_+})\,\mathrm{d}\tilde{\mu}(x_{\Lambda_-})\,\mathrm{d}\tilde{\nu}(y_{\Lambda_-}) \qquad [18]$$

It has the same structure as the one described by Proposition 3, hence is RP with respect to the map $\vartheta$ defined by the reflection $\rho$. Set

$$\Upsilon_\mu=\int_{\mathbb{R}^{N|\Delta|}}\mathrm{d}\tilde{\mu}(x_\Delta),\qquad\Upsilon_\nu=\int_{\mathbb{R}^{N|\Delta|}}\mathrm{d}\tilde{\nu}(y_\Delta) \qquad [19]$$

and

$$\begin{aligned}&A\equiv 0,\qquad B=-J\sum_{\ell\in\Lambda'_+}\left[\frac{1}{2}|a_\ell|^2+(a_\ell,y_\ell)\right]\\ &C_\ell^{(k)}=\sqrt{J}x_\ell^{(k)},\qquad D_\ell^{(k)}=\sqrt{J}\left(y_\ell^{(k)}+a_\ell^{(k)}\right)\\ &\ell\in\Lambda'_+,\quad k=1,\dots,N\end{aligned} \qquad [20]$$

Then the left-hand side of [17] is

$$\text{LHS }[17]=\frac{1}{(\Upsilon_\mu\Upsilon_\nu)^2}\left|\phi\left[\exp\left(A+\vartheta(B)+\sum_{\ell\in\Lambda'_+}\sum_{k=1}^{N}C_\ell^{(k)}\vartheta\left(D_\ell^{(k)}\right)\right)\right]\right|^2 \qquad [21]$$

with $\phi$ given by [18]. Applying [15] and taking into account [19], we arrive at

$$\begin{aligned}\text{LHS }[17]&\le\frac{1}{(\Upsilon_\mu\Upsilon_\nu)^2}\int_{\mathbb{R}^{2N|\Lambda|}}\exp\left(J\sum_{\ell\in\Lambda'_+}x_\ell x_{\rho(\ell)}\right)\\ &\quad\times\mathrm{d}\tilde{\mu}(x_{\Lambda_+})\,\mathrm{d}\tilde{\mu}(x_{\Lambda_-})\,\mathrm{d}\tilde{\nu}(y_{\Lambda_+})\,\mathrm{d}\tilde{\nu}(y_{\Lambda_-})\\ &\quad\times\int_{\mathbb{R}^{2N|\Lambda|}}\exp\left(J\sum_{\ell\in\Lambda'_+}y_\ell y_{\rho(\ell)}\right)\\ &\quad\times\mathrm{d}\tilde{\mu}(x_{\Lambda_+})\,\mathrm{d}\tilde{\mu}(x_{\Lambda_-})\,\mathrm{d}\tilde{\nu}(y_{\Lambda_+})\,\mathrm{d}\tilde{\nu}(y_{\Lambda_-})=\text{RHS }[17]\end{aligned}$$

which completes the proof. □

### Gaussian Domination

Let $\Lambda$ be a finite set, $|\Lambda|$ even, and $E$ be a set of unordered pairs of elements of $\Lambda$, such that the graph $(\Lambda, E)$ is connected. If $e \in E$ connects given $\ell, \ell' \in \Lambda$, we write $e = \langle \ell, \ell' \rangle$. We suppose that $E$ contains no loops $\langle \ell, \ell \rangle$. With each $\ell \in \Lambda$ we associate a random $N$-component vector $x_\ell$, called spin. The joint probability distribution of the spins $(x_\ell)_{\ell \in \Lambda}$ is defined by means of the local Gibbs measure

$$d\mu_\Lambda(x_\Lambda) = \frac{1}{Z_\Lambda} \exp\left( -\frac{J}{2} \sum_{\langle \ell, \ell' \rangle \in E} |x_\ell - x_{\ell'}|^2 \right) d\chi_\Lambda(x_\Lambda), \quad x_\Lambda \in \mathbb{R}^{N|\Lambda|} \qquad [22]$$

Here the measure

$$d\chi_\Lambda(x_\Lambda) = \prod_{\ell \in \Lambda} d\chi(x_\ell) \qquad [23]$$

describes the system if the interaction intensity $J$ equals zero. In general, $J \geq 0$, that is, the model [22], [23] is ferromagnetic. The single-spin measure $\chi$ is a probability measure on $\mathbb{R}^N$ and

$$Z_\Lambda = \int_{\mathbb{R}^{N|\Lambda|}} \exp\left( -\frac{J}{2} \sum_{\langle \ell, \ell' \rangle \in E} |x_\ell - x_{\ell'}|^2 \right) d\chi_\Lambda(x_\Lambda) \qquad [24]$$

is the partition function. Set

$$Z_\Lambda(h) = \int_{\mathbb{R}^{N|\Lambda|}} \exp\left( -\frac{J}{2} \sum_{\langle \ell, \ell' \rangle \in E} |x_\ell - x_{\ell'} - h_{\ell\ell'}|^2 \right) \times d\chi_\Lambda(x_\Lambda) \qquad [25]$$

where $h_{\ell\ell'} = h_{\ell'\ell} \in \mathbb{R}^N$, $\langle \ell, \ell' \rangle \in E$.

**Definition 7** The model [22]–[23] admits Gaussian domination if for all $h = (h_{\ell\ell'})_{\langle \ell, \ell' \rangle \in E}$,

$$Z_\Lambda(h) \leq Z_\Lambda(0) \qquad [26]$$

We prove that our model admits Gaussian domination if the graph satisfies the following:

**Assumption 8** The set of edges $E$ can be decomposed

$$E = \bigcup_{n=1}^{m} E_n, \qquad E_n \bigcap E_{n'} = \emptyset, \quad \text{if } n \neq n' \qquad [27]$$

in such a way that for every $n = 1, \ldots, m$, the graph $(\Lambda, E \backslash E_n)$ is disconnected and falls into two connected components, $(\Lambda_+^{(n)}, E_+^{(n)})$ and $(\Lambda_-^{(n)}, E_-^{(n)})$, which are isomorphic. This means that there exists a bijection $\rho_n : \Lambda \to \Lambda, \rho_n \circ \rho_n = \text{id}$, such that $\rho_n(\Lambda_+^{(n)}) = \Lambda_-^{(n)}$ and $\langle \rho_n(\ell), \rho_n(\ell') \rangle \in E_-^{(n)}$ whenever $\langle \ell, \ell' \rangle \in E_+^{(n)}$. Finally, we assume that if $\langle \ell, \ell' \rangle \in E_n$ and $\ell \in \Lambda_+^{(n)}$, then $\rho_n(\ell) = \ell'$.

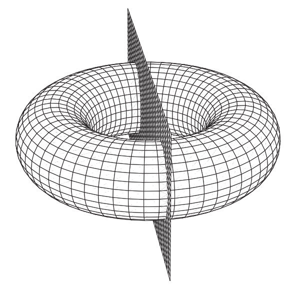

**Figure 1** The torus.

By this assumption if $\langle \ell, \ell' \rangle \in E_n$, then no other elements of $E_n$ can be of the form $\langle \ell, \ell'' \rangle$ or $\langle \ell'', \ell' \rangle$. The basic example here is the torus which one obtains from a rectangular box $\Lambda \subset \mathbb{Z}^d$, $|\Lambda|$ even, by imposing periodic conditions on its boundaries. The set of edges is $E = \{\langle \ell, \ell' \rangle \,|\, |\ell - \ell'|_\Lambda = 1\}$, where $|\ell - \ell'|_\Lambda$ is the periodic distance on $\Lambda$ (see the next subsection). Then every plane which contains the center of the torus and its axis cuts it out along a family of edges onto two subgraphs with the property desired (see Figure 1).

**Theorem 9** *The model* [22]–[23] *defined on the graph obeying* Assumption 8 *admits Gaussian domination.*

**Proof** For $\sigma = \pm 1, h = (h_{\ell\ell'})_{\langle \ell, \ell' \rangle \in E}$, and $n = 1, \ldots, m$, we define the map

$$(T_n^\sigma h)_{\ell\ell'} = \begin{cases} h_{\ell\ell'}, & \text{if } \langle \ell, \ell' \rangle \in E_\sigma^{(n)} \\ h_{\rho_n(\ell)\rho_n(\ell')}, & \text{if } \langle \ell, \ell' \rangle \in E_{-\sigma}^{(n)} \\ 0, & \text{if } \langle \ell, \ell' \rangle \in E_n \end{cases} \qquad [28]$$

According to Assumption 8

$$Z_\Lambda(h) = \int_{\mathbb{R}^{N|\Lambda|}} \exp\left( -\frac{J}{2} \sum_{\langle \ell, \ell' \rangle \in E_1} |x_\ell - x_{\ell'} - h_{\ell\ell'}|^2 \right) \times d\nu^+_{\Lambda_+^{(1)}}\left(x_{\Lambda_+^{(1)}}\right) d\nu^-_{\Lambda_-^{(1)}}\left(x_{\Lambda_-^{(1)}}\right) \qquad [29]$$

where

$$d\nu^\sigma_{\Lambda_\sigma^{(1)}}\left(x_{\Lambda_\sigma^{(1)}}\right) = \exp\left( -\frac{J}{2} \sum_{\langle \ell, \ell' \rangle \in E_\sigma^{(1)}} |x_\ell - x_{\ell'} - h_{\ell\ell'}|^2 \right) d\chi_{\Lambda_\sigma^{(1)}}\left(x_{\Lambda_\sigma^{(1)}}\right), \quad \sigma = \pm 1$$

Set

$$\mathrm{d}\nu^-_{\Lambda^{(1)}_+}(x_{\Lambda^{(1)}_+}) = \exp\left(-\frac{J}{2}\sum_{\langle \ell,\ell'\rangle\in E^{(1)}_+} |x_\ell - x_{\ell'} - h_{\rho(\ell)\rho(\ell')}|^2\right) \times \mathrm{d}\chi_{\Lambda^{(1)}_+}(x_{\Lambda^{(1)}_+})$$

$$\mathrm{d}\nu^+_{\Lambda^{(1)}_-}\left(x_{\Lambda^{(1)}_-}\right) = \exp\left(-\frac{J}{2}\sum_{\langle \ell,\ell'\rangle\in E^{(1)}_+} |x_{\rho(\ell)} - x_{\rho(\ell')} - h_{\ell\ell'}|^2\right) \times \mathrm{d}\chi_{\Lambda^{(1)}_-}(x_{\Lambda^{(1)}_-})$$

Then we apply here Lemma 6, with $\Lambda'_+ = \{\ell \in \Lambda^{(1)}_+ | \langle \ell,\ell'\rangle \in E_1\}$, and obtain

$$\begin{aligned}[Z_\Lambda(h)]^2 \le & \int_{\mathbb{R}^{N|\Lambda|}} \exp\left(-\frac{J}{2}\sum_{\langle \ell,\ell'\rangle\in E_1} |x_\ell - x_{\ell'}|^2\right) \\ & \times \mathrm{d}\nu^+_{\Lambda^{(1)}_+}\left(x_{\Lambda^{(1)}_+}\right)\mathrm{d}\nu^+_{\Lambda^{(1)}_-}\left(x_{\Lambda^{(1)}_-}\right) \\ & \times \int_{\mathbb{R}^{N|\Lambda|}} \exp\left(-\frac{J}{2}\sum_{\langle \ell,\ell'\rangle\in E_1} |x_\ell - x_{\ell'}|^2\right) \\ & \times \mathrm{d}\nu^-_{\Lambda^{(1)}_-}\left(x_{\Lambda^{(1)}_-}\right)\mathrm{d}\nu^-_{\Lambda^{(1)}_+}\left(x_{\Lambda^{(1)}_+}\right) \\ = & Z_\Lambda(T_1^+h)Z_\Lambda(T_1^-h)\end{aligned}$$

Next we estimate both $Z_\Lambda(T_1^\pm h)$ employing $E_2$ and $T_2^\sigma$. Repeating this procedure due times we finally get

$$[Z_\Lambda(h)]^{2^m} \le \prod_{\sigma_1,\ldots,\sigma_m=\pm 1} Z_\Lambda(T_m^{\sigma_m}\cdots T_1^{\sigma_1}h) = [Z_\Lambda(0)]^{2^m} \quad [30]$$

Note that $T_m^{\sigma_m}\cdots T_1^{\sigma_1}h = 0$ for any $h\in\mathbb{R}^{N|E|}$ and any sequence $\sigma_1,\ldots,\sigma_m = \pm 1$, which follows from [27] and [28]. □

As might be clear from the proof given above, the local Gibbs state

$$\phi_\Lambda(A) = \int_{\mathbb{R}^{N|\Lambda|}} A(x_\Lambda)\,\mathrm{d}\mu_\Lambda(x_\Lambda) \quad [31]$$

defined by means of the measure [22], is RP with respect to all reflections $\rho_n, n = 1,\ldots,m$. Indeed, the functional defined by the product measure

$$\mathrm{d}\tilde{\chi}_\Lambda(x_\Lambda) \stackrel{\text{def}}{=} \exp\left(-\frac{J}{2}\sum_{\ell\in\Lambda}|x_\ell|^2\right)\mathrm{d}\chi_\Lambda(x_\Lambda) \quad [32]$$

is RP (see Example 2). The Gibbs measure [22] can be written as

$$\mathrm{d}\mu_\Lambda(x_\Lambda) = \frac{1}{Z_\Lambda(0)}\exp\left(\sum_{n=1}^m\sum_{k=1}^N\sum_{\ell\in\Lambda'_{+,n}} C_\ell^{(k)}\vartheta_n\left(C_\ell^{(k)}\right)\right) \times \mathrm{d}\tilde{\chi}_\Lambda(x_\Lambda) \quad [33]$$

where $C_\ell^{(k)}, k = 1,\ldots,N$, are the same as in [20] and $\Lambda'_{+,n} \stackrel{\text{def}}{=} \{\ell\in\Lambda_+^{(n)} | \langle\ell,\ell'\rangle\in E_n\}$. Then the reflection positivity of the Gibbs state [31] can be obtained along the line of arguments used for proving Lemma 6. It appears that this is the only possible way to construct an RP functional from another RP functional.

Repeated application of the estimate [15] also yields

$$\phi_\Lambda\left(\prod_{\ell\in\Lambda}F_\ell(x_\ell)\right) \le \prod_{\ell\in\Lambda}\left[\phi_\Lambda\left(\prod_{\ell'\in\Lambda}F_\ell(x_{\ell'})\right)\right]^{1/|\Lambda|} \quad [34]$$

which holds for any family of functions $\{F_\ell : \mathbb{R}^N \to [0,+\infty)\}_{\ell\in\Lambda}$, for which the above expressions make sense. The estimate [34] is a chessboard estimate, which is a very important element of the theory of phase transitions in RP models. The estimate [26] may be obtained from [34].

### Infrared Bound

Let us show now how to derive the infrared estimates from the Gaussian domination [26]. Consider the system of $N$-dimensional spins indexed by the elements of $\mathbb{Z}^d$ with the nearest-neighbor ferromagnetic interaction and the single-spin measure $\chi$. To construct the periodic local Gibbs measure of this system, we take the box

$$\Lambda = (-L, L]^d \bigcap \mathbb{Z}^d, \quad L\in\mathbb{N} \quad [35]$$

and impose periodic conditions on its boundaries. This defines the periodic distance

$$\begin{aligned}|\ell-\ell'|_\Lambda &= \left[\sum_{j=1}^d |\ell_j - \ell'_j|_L^2\right]^{1/2}, \quad \ell,\ell'\in\Lambda \\ |\ell_j-\ell'_j|_L &= \min\{|\ell_j-\ell'_j|;\ L - |\ell_j - \ell'_j|\}\end{aligned} \quad [36]$$

and hence the set of edges $E$, being unordered pairs $\langle\ell,\ell'\rangle$ such that $|\ell-\ell'|_\Lambda = 1$. Thus, we have the graph $(\Lambda, E)$ and the measure [22]. This is the periodic local Gibbs measure of our model. By [31] it defines the periodic local Gibbs state $\phi_\Lambda$. We have included the inverse temperature $\beta$ into $J$

and assumed that the single-spin measure $\chi$ is rotation invariant. Let us introduce the Fourier transformation

$$\hat{x}(p) = \frac{1}{\sqrt{|\Lambda|}} \sum_{\ell \in \Lambda} x_\ell e^{i(\ell, p)}$$
$$x_\ell = \frac{1}{\sqrt{|\Lambda|}} \sum_{p \in \Lambda_*} \hat{x}(p) e^{-i(\ell, p)} \quad [37]$$

$$\Lambda_* = \left\{ p = (p_1, \ldots, p_d) | \, p_j = -\pi + \frac{\pi}{L}\kappa_j, \right.$$
$$\left. \kappa_j = 1, \ldots, 2L, \; j = 1, \ldots, d \right\} \quad [38]$$

Then we can set

$$\widehat{K}_\Lambda^{(k)}(p) = \phi_\Lambda \left[ \hat{x}^{(k)}(p) \hat{x}^{(k)}(-p) \right]$$
$$\widehat{K}_\Lambda(p) = \sum_{k=1}^{N} \widehat{K}_\Lambda^{(k)}(p) \quad [39]$$

Thereby, cf. [1], [2],

$$K_\Lambda(\ell, \ell') \stackrel{\text{def}}{=} \phi_\Lambda[(x_\ell, x_{\ell'})] = \frac{1}{|\Lambda|} \sum_{p \in \Lambda_*} \widehat{K}_\Lambda(p) e^{i(p, \ell - \ell')} \quad [40]$$

By construction, for any $\ell_0 \in \Lambda$,

$$K_\Lambda(\ell, \ell') = K_\Lambda(\ell + \ell_0, \ell' + \ell_0) \quad [41]$$

where addition is componentwise modulo $2L$. This means that $K_\Lambda(\ell, \ell')$ is invariant with respect to the translations on the corresponding torus. One can show that $K_\Lambda(\ell, \ell')$ converges, as $L \to +\infty$, to $K(\ell, \ell')$ discussed in the Introduction. The corresponding Gibbs state of the whole model is called the periodic Gibbs state. By construction, it is translation invariant. Set

$$\mathcal{E}(p) = \sum_{j=1}^{d} [1 - \cos p_j], \quad p \in (-\pi, \pi]^d \quad [42]$$

**Theorem 10** *For all* $p \in \Lambda_* \setminus \{0\}$,

$$\widehat{K}_\Lambda(p) \le \frac{N}{2J\mathcal{E}(p)} \quad [43]$$

**Proof** Consider the function $f(\xi) = Z_\Lambda(\xi h), \xi \in \mathbb{R}$, where $Z_\Lambda(h)$ is defined by [25]. By Theorem 9 it has a maximum at $\xi = 0$; hence,

$$f''(0) \le 0 \quad [44]$$

Obviously, $f''(0)$ depends on $h = (h_{\ell\ell'})_{\langle \ell, \ell' \rangle \in E}$, $h_{\ell\ell'} \in \mathbb{R}^N$. Let us choose $h$ such that only the first components $h_{\ell\ell'}^{(1)}$ are nonzero. Then [44] holds if

$$J \sum_{\langle \ell_1, \ell_1' \rangle \in E} \sum_{\langle \ell_2, \ell_2' \rangle \in E} \phi_\Lambda \left[ \left( x_{\ell_1}^{(1)} - x_{\ell_1'}^{(1)} \right) \left( x_{\ell_2}^{(1)} - x_{\ell_2'}^{(1)} \right) \right] h_{\ell_1 \ell_1'}^{(1)} h_{\ell_2 \ell_2'}^{(1)}$$
$$\le \sum_{\langle \ell, \ell' \rangle \in E} \left[ h_{\ell\ell'}^{(1)} \right]^2 \quad [45]$$

This means that the eigenvalues of the matrix of the real quadratic form (with respect to $h$) defined by the left-hand side of [45] do not exceed one. The same ought to be true for the extension of this form to the complex case. Let us show that the complex eigenvectors $h_{\ell\ell'}^{(1)}(p)$ of this matrix and the corresponding eigenvalues $\lambda(p)$ are

$$h_{\ell\ell'}^{(1)}(p) = \left( e^{i(p, \ell)} - e^{i(p, \ell')} \right) / \sqrt{|\Lambda|}$$
$$\lambda(p) = 2J\mathcal{E}(p) \widehat{K}_\Lambda^{(1)}(p) \qquad p \in \Lambda_* \quad [46]$$

For $j = 1, \ldots, d$, let $\theta_j \in \mathbb{Z}^d$ be the unit vector with the $j$th component equal to 1. Then for $\langle \ell, \ell' \rangle \in E$, there exists $\theta_j$ such that $\ell - \ell' = \pm \theta_j$. Since the edge $\langle \ell, \ell' \rangle$ is an unordered set, let us fix $\ell' = \ell + \theta_j$. Thereby,

$$\frac{1}{|\Lambda|^{1/2}} \sum_{\langle \ell, \ell' \rangle \in E} \left( x_\ell^{(1)} - x_{\ell'}^{(1)} \right) \left( e^{i(p, \ell)} - e^{i(p, \ell')} \right)$$
$$= \frac{2}{|\Lambda|^{1/2}} \sum_{\ell \in \Lambda} \sum_{j=1}^{d} \left[ x_\ell^{(1)} e^{i(p, \ell)} - x_\ell^{(1)} e^{i(p, \ell)} \cos(p, \theta_j) \right]$$
$$= 2\hat{x}^{(1)}(p) \mathcal{E}(p)$$

In view of [41], one has

$$\phi_\Lambda[\hat{x}^{(1)}(p) \hat{x}^{(1)}(p')] = \delta_{0, p+p'} \widehat{K}_\Lambda^{(1)}(p)$$

Then employing the latter two facts and [37], we get

$$J \sum_{\langle \ell_2, \ell_2' \rangle \in E} \phi_\Lambda \left[ \left( x_{\ell_1}^{(1)} - x_{\ell_1'}^{(1)} \right) \left( x_{\ell_2}^{(1)} - x_{\ell_2'}^{(1)} \right) h_{\ell_2 \ell_2'}(p) \right.$$
$$= 2J\mathcal{E}(p) \phi_\Lambda \left[ \left( x_{\ell_1}^{(1)} - x_{\ell_1'}^{(1)} \right) \hat{x}^{(1)}(p) \right]$$
$$= 2J\mathcal{E}(p) \cdot \frac{1}{|\Lambda|^{1/2}} \sum_{p' \in \Lambda_*} \phi_\Lambda \left[ \hat{x}^{(1)}(p') \hat{x}^{(1)}(p) \right]$$
$$\times \left( e^{-i(p', \ell_1)} - e^{-i(p', \ell_1')} \right)$$
$$= 2J\mathcal{E}(p) \widehat{K}_\Lambda^{(1)}(p) h_{\ell_1 \ell_1'}(p)$$

which proves [46]. Then by [45] $\widehat{K}_\Lambda^{(1)}(p) \le 1/2J\mathcal{E}(p)$, for $p \ne 0$. The same holds for $\widehat{K}_\Lambda^{(k)}(p), k = 2, \ldots, N$, which by [39] yields [43]. □

The result just proved and the convergence of $K_\Lambda(\ell, \ell') \to K(\ell, \ell')$, as $L \to +\infty$, imply the infrared bound [4]. It turns out that the estimate [43]

may be used directly to prove the phase transition. Consider

$$P_\Lambda \stackrel{\text{def}}{=} \frac{1}{|\Lambda|^2} \sum_{\ell_1, \ell_2 \in \Lambda} \phi_\Lambda[(x_{\ell_1}, x_{\ell_2})] = \phi_\Lambda\left(\left|\frac{1}{|\Lambda|}\sum_{\ell \in \Lambda} x_\ell\right|^2\right) \geq 0 \quad [47]$$

where $\Lambda$ is the box [35]. By [40] and [41], we have

$$P_\Lambda = \frac{1}{|\Lambda|}\widehat{K}_\Lambda(0) \quad [48]$$

One can show that if $P \stackrel{\text{def}}{=} \lim_{L \to +\infty} P_\Lambda$ is positive, then there exist multiple Gibbs states. By [40], [41], and [48], we get that for any $\ell \in \Lambda$,

$$K_\Lambda(\ell, \ell) = P_\Lambda + \frac{1}{|\Lambda|}\sum_{p \in \Lambda_* \setminus \{0\}} \widehat{K}(p) \quad [49]$$

Suppose that, cf. [5],

$$K_\Lambda(\ell, \ell) \geq \varkappa > 0 \quad [50]$$

with $\varkappa$ independent of $\Lambda$ and $J$. Employing in [49] this estimate and [43], and passing to the limit $L \to +\infty$, we get

$$P \geq \varkappa - \mathcal{I}(d)N/2J \quad [51]$$

where

$$\mathcal{I}(d) \stackrel{\text{def}}{=} \frac{1}{(2\pi)^d}\int_{(-\pi,\pi]^d} \frac{\mathrm{d}p}{\mathcal{E}(p)} \quad [52]$$

which is finite for $d \geq 3$. Thereby, we have proved the following:

**Theorem 11** *For the spin model* [22], [23], *there exist multiple Gibbs states, and hence multiple phases, if* $d \geq 3$ *and* $J > \mathcal{I}(d)N/2\varkappa$.

Finally, let us pay some attention to the estimate [50], which is closely related with the properties of the single-spin measure $\chi$ (note that $\chi$ played no role in obtaining [26] and [43]). If it is the uniform measure on the unit sphere $S_{N-1} \subset \mathbb{R}^N$, then $K_\Lambda(\ell, \ell) = 1$ and [50] is trivial. In general, one has to employ some technique to obtain such an estimate.

## Reflection Positivity and Phase Transitions in Quantum Systems

As in the classical case, the way of proving the phase transition for appropriate models leads from an estimate like [17] to Gaussian domination and then to the infrared bound. However, here this way is much more complicated, so in the frames of this article we can only sketch its main elements basing on the original paper by Dyson *et al.* (1978), where the interested reader can find the details. As above, we start by studying reflection positive functionals.

### Reflection Positivity in Nonabelian Case

Again we consider a finite set $\Lambda$, $|\Lambda|$ being even. For every $\ell \in \Lambda$, let a complex Hilbert space $\mathcal{H}_\ell$ be given. This is the single-spin physical Hilbert space for our quantum system. We suppose that all $\mathcal{H}_\ell$, $\ell \in \Lambda$, are the copies of a certain finite-dimensional space $\mathcal{H}$. The physical Hilbert space $\mathcal{H}_\Lambda$ corresponding to $\Lambda$ is the tensor product of $\mathcal{H}_\ell$, $\ell \in \Lambda$. Let $\mathcal{A}_\Lambda$ be the algebra of all linear operators defined on $\mathcal{H}_\Lambda$. This is the algebra of observables in our case; it is noncommutative (nonabelian) and contains the unit element $I$ – the identity operator. As above, $\Lambda$ splits into two subsets $\Lambda_\pm$, which are the mirror images of each other, that is, we are given a reflection $\rho : \Lambda \to \Lambda$, such that $\rho(\Lambda_+) = \Lambda_-$. This allows us to introduce the corresponding subalgebras $\mathcal{A}_\Lambda^\pm$ by setting the elements of $\mathcal{A}_\Lambda^+$ to be of the form $A \otimes I$, where $A : \mathcal{H}_{\Lambda_+} \to \mathcal{H}_{\Lambda_+}$ is a linear operator and $I$ is the identity operator on $\mathcal{H}_{\Lambda_-}$. Respectively, the elements of $\mathcal{A}_\Lambda^-$ are to be of the form $I \otimes A$. Then we define the map $\vartheta : \mathcal{A}_\Lambda^+ \to \mathcal{A}_\Lambda^-$ as

$$\vartheta(A \otimes I) = I \otimes \bar{A} \quad [53]$$

where $A \mapsto \bar{A}$ is complex (not Hermitian) conjugation; it may be realized as transposing and taking Hermitian conjugation. For $A_1, \ldots, A_n \in \mathcal{A}$, one has $\bar{A}_1 \cdots \bar{A}_n = \overline{A_1, \cdots A_n}$. We also suppose that $\vartheta$ possesses the properties [8]. A linear functional $\phi : \mathcal{A}_\Lambda \to \mathbb{R}$ is called RP (with respect to the pair $\rho, \vartheta$) if it has the property [9].

**Definition 12** A functional $\phi$ is called generalized reflection positive (GRP) if for any $A_1, \ldots, A_n \in \mathcal{A}_\Lambda^+$,

$$\phi[A_1\vartheta(A_1) \cdots A_n\vartheta(A_n)] \geq 0 \quad [54]$$

In principle, this notion differs from the reflection positivity only in the nonabelian case. However, if the algebras $\mathcal{A}_\Lambda^\pm$ commute (they do commute in our case), a functional $\phi$ is RP if and only if it is GRP.

**Example 13** Let

$$\phi(A) = \operatorname{trace}(A), \quad A \in \mathcal{A}_\Lambda \quad [55]$$

Since the space $\mathcal{H}_\Lambda$ is finite dimensional, this $\phi$ is well defined. It is GRP. Indeed, as the algebras $\mathcal{A}_\Lambda^\pm$ commute, we have

$$\begin{aligned}
&\phi[A_1 \otimes I \cdot \vartheta(A_1 \otimes I) \cdots A_n \otimes I \cdot \vartheta(A_n \otimes I)] \\
&\quad = \phi[A_1 \otimes I \cdots A_n \otimes I \cdot \vartheta(A_1 \otimes I) \cdots \vartheta(A_n \otimes I)] \\
&\quad = \phi[A_1 \otimes I \cdots A_n \otimes I \cdot \vartheta(A_1 \otimes I \cdots A_n \otimes I)] \\
&\quad = \operatorname{trace}[A_1 \cdots A_n] \cdot \operatorname{trace}[\bar{A}_1 \cdots \bar{A}_n] \\
&\quad = |\operatorname{trace}[A_1 \cdots A_n]|^2 \geq 0
\end{aligned}$$

The Cauchy–Schwarz inequality [13] obviously holds also in the quantum case. By means of this inequality and the Trotter product formula

$$\exp(A+B) = \lim_{n\to+\infty} [\exp(A/n)\exp(B/n)]^n \quad [56]$$

one can prove that every RP functional obeys an estimate like [17]. Thereby, we have the following analog of Lemma 6:

**Lemma 14** *Let $A, B, C_1, \ldots, C_n \in \mathcal{A}_\Lambda^+$ be any self-adjoint operators possessing real matrix representation and $a_1, \ldots, a_m$ be any real numbers. Then*

$$\left[\mathrm{trace}\left\{\exp\left(A+\vartheta(B)-\sum_{n=1}^{m}[C_n-\vartheta(C_n)-a_n]^2\right)\right\}\right]^2 \leq \mathrm{trace}\left\{\exp\left(A+\vartheta(A)-\sum_{n=1}^{m}[C_n-\vartheta(C_n)]^2\right)\right\} \times \mathrm{trace}\left\{\exp\left(B+\vartheta(B)-\sum_{n=1}^{m}[C_n-\vartheta(C_n)]^2\right)\right\} \quad [57]$$

### Gaussian Domination and Phase Transitions

To proceed further we need a concrete model with finite-dimensional physical Hilbert spaces. As every quantum model, it is defined by its Hamiltonian. Let $\Lambda \subset \mathbb{Z}^d$ be the box [35] and $(\Lambda, E)$ be the same graph as in the subsection "Infrared bound." The periodic Hamiltonian of our model is

$$H_\Lambda = \sum_{\ell\in\Lambda} Q_\ell + \frac{1}{2}\sum_{\langle\ell,\ell'\rangle\in E} |S_\ell - S_{\ell'}|^2 \quad [58]$$

where at each $\ell \in \Lambda$ we have the copies $Q_\ell$, $S_\ell^{(1)}, \ldots, S_\ell^{(N)}$ of $N+1$ basic operators, acting in the Hilbert space $\mathcal{H}_\ell$, and

$$|S_\ell - S_{\ell'}|^2 = \sum_{k=1}^{N}\left(S_\ell^{(k)} - S_{\ell'}^{(k)}\right)^2$$

The only condition we impose so far is that all these operators can simultaneously be chosen as real matrices. For $h = (h_{\ell\ell'})_{\langle\ell,\ell'\rangle\in E} \in \mathbb{R}^{N|E|}$, we set

$$Z_\Lambda(h) = \mathrm{trace}\left\{\exp\left(-\beta\sum_{\ell\in\Lambda}Q_\ell - \frac{\beta}{2}\sum_{\langle\ell,\ell'\rangle\in E}|S_\ell - S_{\ell'} - h_{\ell\ell'}|^2\right)\right\} \quad [59]$$

where $\beta > 0$ is the inverse temperature.

**Theorem 15** *For the model [58] and any $h = (h_{\ell\ell'})_{\langle\ell,\ell'\rangle\in E} \in \mathbb{R}^{N|E|}$,*

$$Z_\Lambda(h) \leq Z_\Lambda(0) \quad [60]$$

The proof is performed by means of Lemma 14.

The periodic local Gibbs state of the model [58] at the inverse temperature $\beta$, analogous to the state [31], is

$$\phi_\Lambda(A) = \mathrm{trace}\{A\exp(-\beta H_\Lambda)\}/Z_\Lambda(0), \quad A \in \mathcal{A}_\Lambda \quad [61]$$

As in the classical case, one can define the parameter [47]. However, now the fact that $\lim_{L\to+\infty} P_\Lambda > 0$ does not yet imply the phase transition. One has to prove a more general fact

$$\lim_{L'\to+\infty}\left\{\lim_{L\to+\infty}\phi_\Lambda\left(\left|\frac{1}{|\Lambda'|}\sum_{\ell\in\Lambda'}S_\ell\right|^2\right)\right\} > 0 \quad [62]$$

where $\Lambda'$ is the box [35] of side $2L'$. Furthermore, in the quantum case the Gaussian domination [60] does not lead directly to the estimate [43], which yields [51]. Instead, one can get a bound like [43] but for the Duhamel two-point function (DTF). Given $A, B \in \mathcal{A}_\Lambda$, their DTF is

$$(A,B) = \int_0^1 \phi_\Lambda(A\mathrm{e}^{-\xi\beta H_\Lambda}B\mathrm{e}^{\xi\beta H_\Lambda})\mathrm{d}\xi \quad [63]$$

By means of [56] one can show that

$$(A,B) = \frac{1}{Z_\Lambda(0)} \times \left\{\frac{\partial^2}{\partial\xi\partial\eta}\mathrm{trace}[\exp(\xi A + \eta B - \beta H_\Lambda)]\right\}_{\xi=\eta=0} \quad [64]$$

Let $\hat{S}(p) = (\hat{S}^{(1)}(p), \ldots, \hat{S}^{(N)}(p)), p \in \Lambda_*$, be the Fourier image of $S_\ell$, defined by [37], [38]. Then

$$\left(\hat{S}(p), \hat{S}(-p)\right) = \sum_{k=1}^{N}\left(\hat{S}^{(k)}(p), \hat{S}^{(k)}(-p)\right)$$

**Theorem 16** *For all $p \in \Lambda_*\backslash\{0\}$, it follows that*

$$\left(\hat{S}(p), \hat{S}(-p)\right) \leq \frac{N}{2\beta\mathcal{E}(p)} \quad [65]$$

To prove this statement one has to use the Gaussian bound [60] exactly as in the case of Theorem 10. The second derivative with respect to $\xi$ gives the corresponding DTF (see [64]).

Now let us indicate how the infrared bound [65] leads to the phase transition. To this end we use the simplest quantum spin model with the Hamiltonian [58], for which $Q_\ell = 0, N = 2$, and $S_\ell^{(k)}, k = 1, 2$, being the copies of the Pauli matrices

$$S^{(1)} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \qquad S^{(2)} = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$$

Then

$$K_\Lambda^{(k)}(\ell,\ell) = \phi_\Lambda\left(S_\ell^{(k)}\cdot S_\ell^{(k)}\right) = 1 \quad \text{for all } \ell \in \Lambda, \quad k = 1, 2 \quad [66]$$

which gives the bound $\varkappa$ (see [50]). For $A, B \in \mathcal{A}_\Lambda$, by $[A, B]$ we denote the commutator $AB - BA$. Set

$$\Sigma_\Lambda^{(k)}(p) = \phi_\Lambda\left(\left[\hat{S}^{(k)}(p), \left[H_\Lambda, \hat{S}^{(k)}(-p)\right]\right]\right)$$
$$k = 1, 2 \qquad [67]$$

The phase transition in the model we consider can be established by means of the following statement (see Dyson 1978, Theorem 5.1).

**Proposition 17** *Suppose there exist* $\Sigma^{(k)}(p), k = 1, 2$, $p \in (-\pi, \pi]^d$ *such that, for all* $L \in \mathbb{N}$,

$$\Sigma_\Lambda^{(k)}(p) \le \Sigma^{(k)}(p), \quad k = 1, 2, \ p \in \Lambda_* \qquad [68]$$

*Then the model undergoes a phase transition at a certain finite* $\beta$ *if* $d \ge 3$ *and*

$$\frac{1}{(2\pi)^d}\int_{(-\pi,\pi]^d}\left[\frac{\Sigma^{(k)}(p)}{8\mathcal{E}(p)}\right]^{1/2} \mathrm{d}p < 1 \qquad [69]$$

*for a certain, and hence for both,* $k = 1, 2$.

Thus to prove the phase transition we have to estimate $\Sigma_\Lambda^{(k)}(p), k = 1, 2$. By means of the Cauchy–Schwarz inequality, the estimate [69] may be transformed into the following:

$$\frac{1}{(2\pi)^d}\int_{(-\pi,\pi]^d}\left[\Sigma^{(1)}(p) + \Sigma^{(2)}(p)\right]\mathrm{d}p < 16/\mathcal{I}(d)$$

where $\mathcal{I}(d)$ is the same as in [52]. The integral on the left-hand side can be estimated from above by $8\sqrt{d(d+1)}$; hence, the latter inequality holds if

$$\mathcal{I}(d)\sqrt{d(d+1)} < 2$$

which holds for all $d \ge 3$. In particular, $\mathcal{I}(3) \approx 0.505$.

## Bibliographic Notes

As the original sources on the RP method in the theory of phase transitions we mention the papers Fröhlich *et al.* (1976) (classical case), Dyson *et al.* (1978) (quantum case), and Fröhlich and Lieb (1978) (both cases). In a unified way and with many examples, this method is described in Fröhlich *et al.* (1978, 1980). A detailed analysis of the method, especially in its applications to classical models with unbounded spins, was given in Shlosman (1986). The techniques based on the chessboard and contour estimates are described in Fröhlich and Lieb (1978) and Shlosman (1986). As was mentioned above, the quantum case is much more complicated; it gets even more complicated if one deals with quantum models employing infinite-dimensional physical Hilbert spaces and unbounded operators, such as quantum crystals. The adaptation of the RP method to such models was made in Driessler *et al.* (1979), Pastur and Khoruzhenko (1987), Barbulyak and Kondratiev (1992), and Kondratiev (1994). In the latter two papers a general version of the quantum crystal was studied in the framework of the Euclidean approach, based on functional integrals (see Albeverio *et al.* (2002)). In this approach the quantum crystal is represented as a lattice spin model with unbounded infinite-dimensional spins. Like in the case of classical models with unbounded spins, here establishing the estimate [5] becomes a highly nontrivial task. In particular cases, for example, for $\phi^4$-models, one applies special tools like the Bogoliubov inequalities (see Driessler *et al.* (1979) and Pastur and Khoruzhenko (1987)). In the general case quasiclassical asymptotics allow us to get the lower bound [5] (see Barbulyak and Kondratiev (1992) and Kondratiev (1994)). There is one more technique based on reflection positivity (see Lieb (1989)). It employs reflections in spin spaces, whereas the properties of the index sets (lattices) play no role. This technique proved to be useful in the theory of strongly correlated electron systems, see Tian (2004). Finally, we mention the books of Georgii (1988), Prum (1986), and Sinai (1982) where different aspects of the RP method are described. In Georgii (1988), one can also find extended bibliographical and historical comments on this subject.

# Regularization for Dynamical $\zeta$-Functions

**V Baladi**, Institut Mathématique de Jussieu, Paris, France

## Introduction

If $A$ is a finite, say $N \times N$, matrix with complex coefficients, the following easy equality gives an expression for the polynomial $\prod_{k=1}^{N}(1 - z\lambda_k) = \det(\mathrm{Id} - zA)$:

$$\det(\mathrm{Id} - zA) = \exp\left(-\sum_{n=1}^{\infty} \frac{z^n}{n} \mathrm{tr}\, A^n\right) \quad [1]$$

(here, Id denotes the identity matrix and tr is the trace of a matrix). Even in this trivial finite-dimensional case, the $z$-radius of convergence of the logarithm of the right-hand side only gives information about the spectral radius (the modulus of the largest eigenvalue) of $A$. The zeros of the left-hand side (i.e., the inverses $z = 1/\lambda_k$ of the nonzero eigenvalues of $A$) can only be located after extending holomorphically the right-hand side. The purpose of this article is to discuss some dynamical situations in which $A$ is replaced by a linear bounded operator $\mathcal{L}$, acting on an infinite-dimensional space, and for which a dynamical determinant (or dynamical $\zeta$-function), constructed from periodic orbits, takes the part of the right-hand side. In the examples presented, $\mathcal{L}$ will be a transfer operator associated to a weighted discrete-time dynamical system: given a transformation $f: M \to M$ on a compact manifold $M$ and a function $g: M \to \mathbb{C}$, we set

$$\mathcal{L}\varphi = g \cdot \varphi \circ f^{-1} \quad [2]$$

(If $f$ is not inversible, it is understood, e.g., that $f$ has at most finitely many inverse branches, and that the right-hand side of [2] is the sum over these inverse branches, see the next section.) We let $\mathcal{L}$ act on a Banach space of functions or distributions $\varphi$ on $M$. For suitable $g$ (in particular $g = |\det Tf^{-1}|$ when this Jacobian makes sense), the spectrum of $\mathcal{L}$ is related to the fine statistical properties of the dynamics $f$: existence and uniqueness of equilibrium states (related to the maximal eigenvector of $\mathcal{L}$), decay of correlations (related to the spectral gap), limit laws, entropies, etc: see, for example, Baladi (1998) or Cvitanović *et al.* (2005). The operator $\mathcal{L}$ is not always trace-class, indeed, it sometimes is not compact on any reasonable space. Even worse, its essential spectral radius may coincide with its spectral radius. (Recall that the essential spectral radius of a bounded linear operator $\mathcal{L}$ acting on a Banach space is the infimum of those $\rho > 0$, such that the spectrum of $\mathcal{L}$ outside of the disk of radius $\rho$ is a finite set of eigenvalues of finite algebraic multiplicity.) However, various techniques allow us to prove that a suitable dynamically defined replacement for the right-hand side of [1] extends holomorphically to a disk in which its zeros describe at least part of the spectrum of $\mathcal{L}$. Some of these techniques have a "regularization" flavor, and we shall concentrate on them.

In the following section, we present the simplest case: analytic expanding or hyperbolic dynamics, for which no regularization is necessary and the Grothendieck–Fredholm theory can be applied. Next, we consider analytic situations where finitely many neutral periodic orbits introduce branch cuts in the dynamical determinant, and see how to "regularize" them. Finally, we discuss a

kneading operator regularization approach, inspired by the work of Milnor and Thurston, and applicable to dynamical systems with finite smoothness.

Despite the terminology, none of the regularization techniques discussed below match the following "$\zeta$-regularization" formula:

$$\prod_{k=1}^{\infty} a_k = \exp\left(-\frac{\mathrm{d}}{\mathrm{d}s}\sum_{k=1}^{\infty} a_k^{-s}|_{s=0}\right) \qquad [3]$$

(For information about the above $\zeta$-regularization and its applications to physics, we refer, e.g., to Elizalde 1995. See also Voros (1987) and Fried (1986) for more geometrical approaches and further references, e.g., to the work of Ray and Singer.)

We do not cover all aspects of dynamical $\zeta$-functions here. For more information and references, we refer to our survey Baladi (1998), to the more recent surveys by Pollicott (2001) and Ruelle (2002), and also to the exhaustive account by Cvitanović *et al.* (2005), which contains a rich array of physical applications.

## The Grothendieck–Fredholm Case

Let $M$ be a real analytic compact manifold (e.g., the circle or the $d$-torus), and let $f: M \to M$ be real analytic and $g: M \to \mathbb{C}$ be analytic.

First suppose that $f$ is uniformly expanding, that is, there is $\lambda > 1$ so that $\|Tf(v)\| \geq \lambda\|v\|$. (For example, $f(z) = z^2$ on the unit circle, or a small analytic perturbation thereof.) Consider

$$\mathcal{L}_{f,g}\varphi(x) = \sum_{y:\, f(y)=x} g(y)\varphi(y) \qquad [4]$$

(For example, with $g(y) = 1/|\det Tf(y)|$ or $1/|\det Tf(y)|^s$.) Ruelle (1976) proved that an operator $\mathcal{L}_0$, which is essentially the same as $\mathcal{L}_{f,g}$ (the difference, if any, arises from the use of Markov partitions, especially in higher dimensions), acting on a Banach space of holomorphic and bounded functions, is not only compact, but is in fact a nuclear operator in the sense of Grothendieck. In particular, the traces of all its powers are well defined, and the Grothendieck–Fredholm (Gohberg *et al.* 2000) determinant

$$d_0(z) = \exp\left(-\sum_{n=1}^{\infty}\frac{z^n}{n}\operatorname{tr}\mathcal{L}_0^n\right) \qquad [5]$$

extends to an entire function of finite order, the zeros of which are exactly the inverses of the nonzero eigenvalues of $\mathcal{L}_0$. (The order of the zero coincides with the algebraic multiplicity of the eigenvalue.) Ruelle also proved that the traces can be written as sums over periodic orbits:

$$\operatorname{tr}\mathcal{L}_0^n = \sum_{x:\, f^n(x)=x}^{*} \frac{\prod_{k=0}^{n-1} g(f^k x)}{|\det(\mathrm{Id} - Tf_x^{-n})|}$$

where $\sum^*$ means that the fixed points of $f^n$ lying in the intersection of two or more elements of the Markov partition must be counted two or more times. (Note that if $f^n(x) = x$, then this closed orbit gives a natural inverse branch for $f^{-n}$.) Taking into account the periodic orbits on the boundaries of the Markov partition, Ruelle expresses the following "dynamical determinant":

$$d_{f,g}(z) = \exp\left[-\sum_{n=1}^{\infty}\frac{z^n}{n}\sum_{x:\, f^n(x)=x}\frac{\prod_{k=0}^{n-1} g(f^k x)}{|\det(\mathrm{Id} - Tf_x^{-n})|}\right] \qquad [6]$$

as an alternated product of determinants $d_0(z)$ as in [5].

The expression [6] is sometimes also called a "dynamical $\zeta$-function," but we prefer to reserve this terminology for the following power series:

$$\zeta_{f,g}(z) = \exp\left[+\sum_{n=1}^{\infty}\frac{z^n}{n}\sum_{x:\, f^n(x)=x}\prod_{k=0}^{n-1} g(f^k x)\right] \qquad [7]$$

It is not difficult to write $\zeta_{f,g}(z)$ as (Baladi 1998) an alternated product of determinants $d_{f,g_i}$, for $i = 0, \ldots, d$, and appropriate weights $g_i$.

In fact, the results just described hold in more generality, for example, for piecewise bijective and analytic interval maps. Such maps, $f$, appear naturally, for example, when considering Schottky subgroups of $PSL(2,\mathbb{Z})$. We mention the recent work of Guillopé–Lin–Zworski (2004), who let the transfer operator associated to such $f$ and weights $g_s(y) = 1/|f'(y)|^s$ act (as trace-class operators) on suitable Hilbert spaces of holomorphic functions. This allows them to obtain precise estimates for the number of zeros of $s \mapsto d_{f,g_s}$ [1] in the complex plane: these zeros are the resonances (in the sense of the spectrum of the Laplacian).

Note that the nuclearity properties extend also to the Gauss map $f(x) = \{1/x\}$, which has infinitely many inverse branches, if the weight $g$ has summability properties over the branches (e.g., $g_s(y) = |1/f'(y)|^s$, where $s$ is a complex parameter, with $\Re s > 1/2$). The dynamical determinant $d_{f,g_s}(z)$ for the transfer operator of the Gauss map is related to the Selberg $\zeta$-function (see e.g., Chang and Mayer (2001) and references therein).

Next, assume that $M$ and $g$ are as before, but $f$ is a uniformly hyperbolic real analytic diffeomorphism.

For example, $M$ is the 2-torus and $f$ is a small real analytic perturbation of the linear automorphism

$$\begin{pmatrix} 2 & 1 \\ 1 & 1 \end{pmatrix}$$

More generally, we may assume that $f$ is a real analytic Anosov diffeomorphism, that is, there are $C \geq 1$ and $\lambda > 1$ such that the tangent bundle decomposes as $TM = E^u \oplus E^s$, where the dynamical bundles $E^u$ and $E^s$ are $Tf$-invariant, with $\|Tf^n|_{E^s}\| \leq C\lambda^{-n}$ and $\|Tf^{-n}|_{E^u}\| \leq C\lambda^{-n}$ for all $n \in \mathbb{Z}_+$. In general, the smoothness of $x \mapsto E^u(x)$ and $E^s(x)$ is only Hölder. Under the very strong additional assumption that $E^u(x)$ and $E^s(x)$ are real analytic, Ruelle (1976) (see also Fried (1986)) showed that the power series $d_{f,g}(z)$ can again be written as a finite alternated product (this product being again an artifact of the Markov partition) of entire functions of finite order. For this, he constructed auxiliary transfer operators associated to the expanding (and analytic!) quotiented dynamics acting on holomorphic functions on disks. The analyticity assumption on the dynamical bundles was later lifted by Rugh (1996) (see also Fried (1995)), who let their transfer operators act on Banach topological tensor products of spaces of holomorphic functions on a disk with the dual of such a space. In all these cases, the transfer operator is a nuclear operator in the sense of Grothendieck and no regularization is needed. (More recent work of Kitaev (1999), when applied to this analytic setting, shows that the "meromorphic" function $d_{f,g}(z)$ in fact does not have poles.)

## Regularization and Intermittency

Consider the interval $M = [0, 1]$, and $f$ defined on $M$ by $f(x) = f_1(x) = x/(1-x)$ on $[0, 1/2]$, and $f(x) = f_2(x) = (1-x)/x$ on $[1/2, 1]$. (This is the Farey map, which appears naturally when considering continued fractions.) Each of the two branches is an analytic bijection onto [0, 1]. The second branch is expanding, but the first one, $f_1$, has a (parabolic) neutral fixed point at $x = 0$ (the expansion is $f(x) = x + x^2 + x^3 + \cdots$). Let $g = g_s$ be an analytic weight of the form $g(y) = 1/|f'(y)|^s$ for $\Re s \geq 1/2$. We are interested in the spectrum of the operator $\mathcal{L}_{f,g}$ associated with the pair $(f, g)$ by [4]. Clearly, the expression [6] is not a good candidate for an analog of the Fredholm determinant of $\mathcal{L}_{f,g}$. Rugh (1996) introduced a Banach space $\mathcal{B}$ of functions in a complex neighborhood of $M$, having a controlled singularity at 0, and such that the spectral radius of $\mathcal{L}_{f,g}$ on $\mathcal{B}$ is equal to 1, and such that the following regularized determinant

$$d_{f,g}(z) = \exp\left[-\sum_{n=1}^{\infty}\frac{z^n}{n}\sum_{x\in(0,1]:\, f^n(x)=x}\frac{\prod_{k=0}^{n-1} g_s(f^k x)}{1 - Tf_x^{-n}}\right] \quad [8]$$

is a holomorphic function in the cut complex plane $\{z \in \mathbb{C} \mid z \notin [1, \infty)\}$. Furthermore, its zeros $z$ in this cut plane are in bijection with the spectrum of $\mathcal{L}_{f,g}|_{\mathcal{B}}$ outside of the unit interval $[0, 1]$, and this spectrum consists of eigenvalues $1/z$ of finite multiplicities. Finally, these eigenvalues can only accumulate at 0 or 1, although each point in the unit interval belongs to the spectrum of $\mathcal{L}_{f,g}$. In particular, the essential spectral radius of $\mathcal{L}_{f,g}$ on $\mathcal{B}$ coincides with its spectral radius.

Let us define the Banach space $\mathcal{B}$ and explain the key ideas in the proof of the above result (Rugh's claim is in fact more general than the statement above and applies to a class of maps $f$ with neutral fixed points). The starting point is the decomposition

$$\mathcal{L}_{f,g} = \mathcal{L}_1 + \mathcal{L}_2$$

where $\mathcal{L}_i\varphi = \varphi \circ f_i^{-1} \cdot |(f_i^{-1})'|^s$. The operator $\mathcal{L}_2$ is of the type discussed in the previous section, and it is nuclear when acting, for example, on bounded holomorphic functions in a complex neighborhood of $M$. Since $f_1$ is not expanding (because of the parabolic fixed point at 0), other ideas must be used to handle the operator $\mathcal{L}_1$. The change of coordinates (this idea goes back to Fatou) $w = 1/x$ replaces the weak contraction $f_1^{-1}$ by the translation $w \mapsto w + 1$ in a suitable domain containing a half-plane $\Re w > w_0$. In order to take into account the weight $g_s$, it is convenient to use the change of variables $\Psi(w) = \varphi(1/w) \cdot w^{-2s}$. Indeed, in the new coordinates the operator $\mathcal{L}_1$ reads as

$$\mathcal{M}_1\Psi(w) = \Psi(w+1)$$

The next step consists in letting $\mathcal{M}_1$ act on the Banach space $\mathcal{B}_w$ of Laplace transforms of $L^1(\mathbb{R}^+, \text{Lebesgue})$, that is, functions

$$\Psi(w) = \int_0^{\infty} \mathrm{e}^{-(w-w_0)t}\psi(t)\,\mathrm{d}t$$

with the induced norm $\|\Psi\|_{\mathcal{B}_w} = \int |\psi(t)|\,\mathrm{d}t$. Since $\mathcal{M}_1$ maps $\psi$ to $\mathrm{e}^{-t}\psi(t)$, it is not difficult to see that the spectrum of $\mathcal{M}_1$ on $\mathcal{B}_w$ (and thus of $\mathcal{L}_1$ on the pullback $\mathcal{B}$ of $\mathcal{B}_w$ by $\Phi$, which consists of functions in a complex neighborhood of [0,1], holomorphic in a sector at 0, and with a possible, but controlled, singularity at 0) is the closed unit interval. One can check that $\mathcal{L}_2$ is nuclear on $\mathcal{B}$. Composing a bounded operator with a

nuclear operator gives a nuclear operator. If $1/z \notin [0,1]$, the resolvent $(1 - z\mathcal{L}_1)^{-1}$ is a bounded operator, and therefore, for such $z$, the operator

$$\mathcal{P}(z) := z\mathcal{L}_2(1 - z\mathcal{L}_1)^{-1} \quad [9]$$

is nuclear on $\mathcal{B}$. We view $\mathcal{P}(z)$ as a "regularized" version of $\mathcal{L}_{f,g} = \mathcal{L}_1 + \mathcal{L}_2$. Now, since

$$\begin{aligned}(1 - z\mathcal{L}_{f,g})^{-1} &= (1 - z(\mathcal{L}_1 + \mathcal{L}_2))^{-1} \\ &= (1 - z\mathcal{L}_1)^{-1}\left(1 - z\mathcal{L}_2(1 - z\mathcal{L}_1)^{-1}\right)^{-1}\end{aligned}$$

it is not surprising that one can prove (Rugh 1996) that the Fredholm determinant

$$u \mapsto \det\left(1 - \mathcal{L}_2(u - \mathcal{L}_1)^{-1}\right)$$

(which is holomorphic in $u \notin [0,1]$) has as its zero set $\mathrm{sp}(\mathcal{L}_{f,g}|_{\mathcal{B}}) \setminus [0,1]$, and that this set consists in isolated eigenvalues of finite multiplicity (equal to the order of the corresponding zero) for $\mathcal{L}_{f,g}$. Formally,

$$(1 - z\mathcal{L}_1)^{-1} = \sum_{k=0}^{\infty} z^k \mathcal{L}_1^k \quad [10]$$

so that the regularization we just described can be viewed as mirroring an induction (or renormalization) procedure, where the dynamics $f$ is replaced by the first-return map to the "chaotic" part of the phase space [0, 1/2]. (For the Farey map, the induced map is just the Gauss map.) The formal equality [10] is also behind the fact that (Rugh 1996)

$$\mathrm{tr}\,\mathcal{P}(z)^n = \sum_{x \neq 0:\, f^n(x) = x} \frac{\prod_{k=0}^{n-1} g_s(f^k x)}{1 - Tf_x^{-n}}$$

An extension of this theory to the two-dimensional setting has been obtained by Baladi, Pujals, and Sambarino.

## Regularization and Kneading Determinants

Up to now we have only discussed analytic dynamical systems, for which hyperbolicity (or uniform expansion) guaranteed that the transfer operator (or a regularized version thereof) was compact, even nuclear, on a natural Banach space. When considering hyperbolic invertible (or expanding noninvertible) maps $f$, and weights $g$ with "finite smoothness," say $C^r$ for some finite $r > 1$, the transfer operator defined by [2] or [4] is usually not compact on any infinite-dimensional space. However, one can often prove a "Lasota–Yorke" type inequality (see e.g., Baladi (1998)) which ensures that the essential spectral radius $\rho_{\mathrm{ess}}(\mathcal{L}_{f,g})$, defined in the "Introduction," is strictly smaller than the spectral radius. Then, the goal is to prove that the dynamical determinant [6] defines a holomorphic function in the disk of radius $1/\rho_{\mathrm{ess}}$, and that its zeros in this disk are exactly the inverses of the eigenvalues of $\mathcal{L}_{f,g}$. For uniformly expanding $C^r$ maps $f$ on compact manifolds, and $C^r$ weights, denoting by $\lambda > 1$ the expansion coefficient as in the section "The Grothendieck–Fredholm case," this goal was essentially attained by Ruelle (1990). For $\mathcal{L}_{f,g}$ acting on the Banach space of $C^r$ functions on $M$, Ruelle proved $\rho_{\mathrm{ess}}(\mathcal{L}_{f,g}) \leq \lambda^{-r}$ and was able to extend $d_{f,g}(z)$ (and interpret its zeros) in the disk of radius $\lambda^r$.

For $C^r$ Anosov diffeomorphisms $f$, and $C^r$ weights $g$, Pollicott, Ruelle, Haydn, and others obtained important results using the symbolic dynamics description (for which the maximal smoothness which can be used is $r \leq 1$, because of the metric-space model). Later, Kitaev (1999) was able to show that $d_{f,g}(z)$ extends to a holomorphic function in the disk of radius $\lambda^{-r/2}$, but did not give any spectral interpretation of the zeros of $d_{f,g}(z)$. More recently, Liverani (2005) was able to give such an interpretation, in a smaller disk however.

All the works mentioned in the previous paragraph are based on some approximation scheme (Taylor expansion style). In the early 1990s, a new approach, with a regularization flavor, was launched (see e.g., Baladi and Ruelle (1996)), initially for piecewise monotone interval maps. We present it next.

Consider a finite set of local homeomorphisms $\psi_\omega : U_\omega \to \psi_\omega(U_\omega)$, where each $U_\omega$ is a bounded open interval of $\mathbb{R}$, and of associated weight functions $g_\omega$ which are continuous, of bounded variation, and have support inside $U_\omega$. For example, the $\psi_\omega$ can be the inverse branches of a single piecewise monotone interval map $f$, and $g_\omega$ can be $g \circ \psi_\omega$ for a single $g$. (No contraction assumption is required on the $\psi_\omega$: their graph can even coincide with the diagonal on a segment.) The transfer operator is now

$$\mathcal{M}\varphi = \sum_\omega g_\omega \cdot (\varphi \circ \psi_\omega)$$

Ruelle obtained an estimate, noted $\widehat{R}$, for the essential spectral radius of $\mathcal{M}$ acting on the Banach space BV of functions of bounded variation. The main result of Baladi and Ruelle (1996) links the eigenvalues of $\mathcal{M} : \mathrm{BV} \to \mathrm{BV}$ outside of the disk of radius $\widehat{R}$, with the zeros of the following "sharp determinant":

$$\det{}^{\#}(\mathrm{Id} - z\mathcal{M}) = \exp\left(-\sum_{n=1}^{\infty} \frac{z^n}{n} \mathrm{tr}^{\#} \mathcal{M}^n\right) \quad [11]$$

where (with the understanding that $y/|y| = 0$ if $y = 0$)

$$\mathrm{tr}^{\#}\mathcal{M} = \sum_\omega \int \frac{1}{2} \frac{\psi_\omega(x) - x}{|\psi_\omega(x) - x|}\, \mathrm{d}g_\omega(x)$$

If the $\psi_\omega$ are strict contractions which form the set of inverse branches of a piecewise monotone interval map $f$, and $g_\omega = g \circ \psi_\omega$, then integration by parts together with the key property that

$$\mathrm{d}\frac{x}{2|x|} = \delta, \text{the Dirac delta at the origin of } \mathbb{R}$$

show that $\det^\#(\mathrm{Id} - z\mathcal{M}) = 1/\zeta_{f,g}(z)$ (recall [7]). If one assumes instead only that the graph of each admissible composition $\psi^n_{\boldsymbol{\omega}}$ of $n$ successive $\psi_\omega$'s (with $n \geq 1$) intersects the diagonal transversally, then

$$\det{}^\#(\mathrm{Id} - z\mathcal{M}) = \exp\left[-\sum_{n=1}^{\infty}\frac{z^n}{n}\sum_{\text{admissible } \psi^n_{\boldsymbol{\omega}}}\sum_{x:\psi^n_{\boldsymbol{\omega}}(x)=x} L\left(x, \psi^n_{\boldsymbol{\omega}}\right) \times \prod_{k=0}^{n-1} g_{\omega_k}\left(\psi^k_{\boldsymbol{\omega}}(x)\right)\right] \qquad [12]$$

where $L(x,\psi) \in \{-1,1\}$ is the Lefschetz number of a transversal fixed point $x = \psi(x)$ (if $\psi$ is $C^1$ this is just $\mathrm{sgn}\,(1 - \psi'(x))$). Therefore, we call the sharp determinant $\det^\#(\mathrm{Id} - z\mathcal{M})$ a Ruelle–Lefschetz (dynamical) determinant. For a class of "unimodal" interval maps $f$ and constant weight $g = 1$, the expression [12] with Lefschetz numbers, coming from the additional transversality assumption, gives that $\det^\#(\mathrm{Id} - z\mathcal{M})$ is just $1/\zeta^-(z)$, where the "negative $\zeta$-function"

$$\zeta^-(z) = \exp\left[+\sum_{n=1}^{\infty}\frac{z^n}{n}(2\#\mathrm{Fix}^-(f^n) - 1)\right] \qquad [13]$$

is defined by counting (twice) the sets

$$\mathrm{Fix}^-(f^n) = \{x | f^n(x) = x,\ f \text{ strictly decreasing in a neighborhood of } x\}$$

of "negative fixed points." This negative $\zeta$-function was studied by Milnor and Thurston, who proved the remarkable identity

$$(\zeta^-(z))^{-1} = \det(1 + \widehat{D}(z))$$

where $\widehat{D}(z)$ is a $1 \times 1$ "matrix," which is just a power series in $z$ with coefficients in $\{-1, 0, +1\}$, given by the signed itinerary of the image of the turning point (the so-called "kneading" data).

Returning now to the general setup $\psi_\omega$, $g_\omega$, the crucial step in the proof of the spectral interpretation of the zeros of this Ruelle–Lefschetz determinant consists in establishing the following continuous version of the Milnor–Thurston identity:

$$\det{}^\#(\mathrm{Id} - z\mathcal{M}) = \det{}^*(\mathrm{Id} + \widehat{\mathcal{D}}(z)) \qquad [14]$$

where the "kneading operator" $\widehat{\mathcal{D}}(z)$ replaces (formally) the finite kneading matrix of Milnor and Thurston. In a suitable $z$-disk, one proves that this operator $\widehat{\mathcal{D}}(z)$ is a Hilbert–Schmidt operator on an $L^2$ space (its kernel is bounded and compactly supported), thus allowing the use of regularized determinants of order 2 (see e.g., Gohberg *et al.* (2000)). By definition, $\det^*(\mathrm{Id} + \widehat{\mathcal{D}}(z))$ is the product of this regularized determinant with the exponential of the average of the kernel of $\widehat{\mathcal{D}}(z)$ along the diagonal, which is well defined. Another kneading operator, $\mathcal{D}(z)$, is essential. If $1/z$ is not in the spectrum of $\mathcal{M}$ (on BV), then $\mathcal{D}(z)$ is also Hilbert–Schmidt, and one can show $\det^*(\mathrm{Id} + \widehat{\mathcal{D}}(z)) = \det^*(\mathrm{Id} + \mathcal{D}(z))^{-1}$. The initial definitions of $\widehat{\mathcal{D}}(z)$ and $\mathcal{D}(z)$ were technical and we shall not give them here. However, a more conceptual definition of the $\mathcal{D}(z)$ was later implemented:

$$\mathcal{D}(z) = \mathcal{N}(\mathrm{Id} - z\mathcal{M})^{-1}\mathcal{S} \qquad [15]$$

where $\mathcal{N}$ is an auxiliary transfer operator and $\mathcal{S}$ is the convolution

$$\mathcal{S}\varphi(x) = \int \frac{1}{2}\frac{x-y}{|x-y|}\varphi(y)\,\mathrm{d}\mu$$

where $\mu$ is an auxiliary non-negative finite measure. From [15], it becomes clear that the kneading operator is a regularized (through the convolution $\mathcal{S}$) object which describes the inverse spectrum of the transfer operator: the resolvent $(\mathrm{Id} - z\mathcal{M})^{-1}$ in [15] means that poles can only appear if $1/z$ is an eigenvalue. Since $\det^*(\mathrm{Id} + \widehat{\mathcal{D}}(z)) = \det^*(\mathrm{Id} + \mathcal{D}(z))^{-1}$, this can be translated into a statement for zeros of $\det^*(\mathrm{Id} + \widehat{\mathcal{D}}(z))$. The Milnor–Thurston identity [14] then implies that any zero of $\det^\#(\mathrm{Id} - z\mathcal{M})$ is an inverse eigenvalue of $\mathcal{M}$.

The one-dimensional kneading regularization we just presented is well understood. The higher-dimensional theory is not as developed yet. Let $U_\omega$ be now finitely many bounded open subsets of $\mathbb{R}^d$, $\psi_\omega : U_\omega \to \psi_\omega(U_\omega)$ be local $C^r$ homeomorphisms or diffeomorphisms, while $g_\omega : U_\omega \to \mathbb{C}$ are compactly supported $C^r$ functions, for $r \geq 1$.

In 1995, A Kitaev wrote a two-page sketch proving a higher-dimensional Milnor–Thurston formula, under an additional transversality assumption. This assumption guarantees that the set of fixed points of each fixed period $m$ is finite, so that the Ruelle–Lefschetz determinant $\det^\#(\mathrm{Id} - z\mathcal{M})$ can be defined through [12]. Inspired by Kitaev's unpublished note, Baillif (2004) proved the following Milnor–Thurston formula:

$$\det{}^\#(\mathrm{Id} - z\mathcal{M}) = \prod_{k=0}^{d-1} \det{}^\flat(\mathrm{Id} + \mathcal{D}_k(z))^{(-1)^{k+1}} \qquad [16]$$

Here, the $\mathcal{D}_k(z)$ are kernel operators acting on $(k+1)$-forms, constructed with the resolvent $(\mathrm{Id} - z\mathcal{M}_k)^{-1}$, together with a convolution operator $\mathcal{S}_k$, mapping

$(k+1)$-forms to $k$-forms and which satisfies the homotopy equation $\mathrm{d}\mathcal{S}+\mathcal{S}\mathrm{d}=1$. The kernel $\sigma_k(x,y)$ of $\mathcal{S}_k$ has singularities of the form $(x-y)/\|x-y\|^d$. The transversality assumption allows Baillif to interpret the determinant obtained by integrating the kernels along the diagonal as a flat determinant in the sense of Atiyah and Bott, whence the notation $\det^\flat$ in the right-hand side of [16].

Baillif (2004) did not give a spectral interpretation of zeros or poles of the sharp determinant [16], but he noticed that for $|z|$ very small, suitably high iterates of the $\mathcal{D}_k(z)$ are trace-class on $L^2(\mathbb{R}^d)$, showing that the corresponding regularized determinant has a nonzero radius of convergence under weak assumptions. The spectral interpretation of the sharp determinant [12] in arbitrary dimension, but under additional assumptions, was subsequently carried out by Baillif and the author of the present article, giving a new proof of some of the results in Ruelle (1990).

# Relativistic Wave Equations Including Higher Spin Fields

**R Illge and V Wünsch**, Friedrich-Schiller-Universität Jena, Jena, Germany

## Introduction

The description of phenomena at high energies requires the investigation of relativistic wave equations, that is, equations which are invariant under Lorentz transformations. Our discussion will be given classically (i.e., nonquantum). A classification of the wave equations may be based on the spin of the particles (or physical fields), which was discovered for the electron by Goudsmith and Uhlenbeck in 1925. For the greater part of physics, the three spin numbers $s=0, 1/2$, and 1 are sufficient; the respective equations named after their discoverers Klein–Gordon, Dirac, and Proca for massive fields and D'Alembert, Weyl, and Maxwell for massless fields, respectively (see the following section).

In their original form, these equations look rather different. However, their translation into spinor form shows that the wave equations for bosons and fermions

have the same structure, if $s > 0$. Therefore, most of the equations dealt with in this article are formulated for spinor fields. (Strictly speaking, the exclusive use of 2-spinors restricts the relativistic invariance to the proper Lorentz group $SO^+(1,3)$. However, all the results presented here can be "translated back" into tensor or bispinor form, respectively (Illge 1993).) Relativistic wave equations for free fields with arbitrary spin $s > 0$ in Minkowski spacetime are discussed in the section "Higher spin in Minkowski spacetime"; they were first given by Dirac (1936).

In the subsequent section, we explain how the field theory can be extended to curved spacetimes. If a Lagrangian is known, then there exists a well-known mathematical procedure ("Lagrange formalism") to obtain the field equations, the energy–momentum tensor, etc. All field equations for "low" spin $s \leq 1$ arise from an action principle. Consequently, they can be extended to curved spacetime by simply replacing the flat metric and connection with their curved versions.

If $s > 1$, then the wave equations do not follow from a variation principle without supplementary conditions. Nevertheless, one can try to generalize the equations of the section "Higher spin in Minkowski spacetime" to curved spacetime by the "principle of minimal coupling," too. However, the arising equations are not satisfactory, since there is an algebraic consistency condition in curved space if $s > 1$ (Buchdahl 1962), and another for charged fields in the presence of electromagnetism if $s > 1/2$ (Fierz and Pauli 1939).

There have been numerous attempts to avoid these inconsistencies. As a rule, the alternative theories require an extended spacetime structure or additional new fields or they give up some important principle. An extensive literature is devoted to just this problem – unfortunately, a survey article or book is missing.

Finally, we present a possibility to describe fields with arbitrary spin $s > 0$ within the framework of Einstein's general relativity without any auxiliary fields and subsidiary conditions in a uniform manner. The approach is based on irreducible representations of type $D(s,0)$ and $D(s-1/2,1/2)$ instead of $D(s/2,s/2)$ in the Fierz theory for bosons and $D(s/2+1/4,s/2-1/4)$ in the Rarita–Schwinger theory for fermions. It was first pointed out by Buchdahl (1982) that this type of field equations can be generalized to a curved spacetime if the mass is positive. After a short time Wünsch (1985) simplified them to their final form:

$$\begin{aligned} \nabla^A_{P'}\varphi_{AB\ldots E} + m_1\chi_{B\ldots EP'} &= 0 \\ \nabla^{P'}_{(A}\chi_{B\ldots E)P'} - m_2\varphi_{AB\ldots E} &= 0 \end{aligned} \qquad [1]$$

This system contains the well-known wave equations for low spin $s = 1/2$ and $s = 1$ as special cases. By iteration we obtain second-order wave equations of normal hyperbolic type. Further, Cauchy's initial-value problem is well posed and a Lagrangian is known. For zero mass, we state the wave equations

$$\nabla^A_{(A'}\Theta_{|A|B'\ldots E')} = 0 \qquad [2]$$

which are just the curved versions of the equations for the potential of a massless field. They are consistent in curved spacetime, too, and the Cauchy problem is well posed (Illge 1988).

Last but not least, let us mention the esthetic aspect. Equations [1] and [2] satisfy Dirac's demand: "Physical laws should have mathematical beauty."

In the following, we assume that the spacetime and all the spinor and tensor fields are of class $C^\infty$. All considerations are purely local. We will call a symmetric ("irreducible") spinor to be of type $(n,k)$ if and only if it has $n$ unprimed and $k$ primed indices (irrespective of their position). Moreover, we use the notations and conventions of Penrose and Rindler (1984), especially for the curvature spinors $\Psi_{ABCD}$ and $\Phi_{ABA'B'}$.

## Wave Equations for Low Spin in Minkowski Spacetime

The spin (or intrinsic angular momentum) of a particle is found to be quantized. Its projection on any fixed direction is an integer or half-integer multiple of Planck's constant $\hbar$; the only possible values are

$$-s\hbar,\ (-s+1)\hbar,\ \ldots,\ (s-1)\hbar,\ s\hbar$$

The spin quantum number $s$ so defined can have one of the values $s = 0, 1/2, 1, 3/2, 2, \ldots$ and is a characteristic for all elementary particles along with their mass $m$ and electric charge $e$. The particles with integer $s$ are called "bosons," those with half-integer $s$ "fermions." The three numbers $s = 0, 1/2$, and 1 are referred to as "low" spin; they are sufficient for the greater part of physics.

The principle of first quantization associates a type of field and a field equation to each type of elementary particles. Massive particles, with rest mass $m > 0$, and massless particles, with rest mass $m = 0$, are to be distinguished. Accordingly, we obtain six linear wave equations for $s \leq 1$, which read as follows in units such that $c = \hbar = 1$ (see Table 1):

For the sake of simplicity, we consider only free fields in Table 1; no source terms or interaction terms appear here. The associated "free" Lagrangians are given in Table 2.

Since the electromagnetic field tensor $F_{ab}$ satisfies the first part of Maxwell's equations $\partial_{[c}F_{ab]} = 0$, it follows

**Table 1** Relativistic wave equations for low spin $s = 0, 1/2$, and 1

| *Spin, mass* | *Wave equation* | *Associated particles* |
|---|---|---|
| $s = 0,\ m > 0$ | Klein–Gordon eqn. $(\approx + m^2)u = 0$ | Scalar mesons $\pi, \eta, K, \ldots$ |
| $s = 0,\ m = 0$ | D'Alembert eqn. $\approx u = 0$ | – |
| $s = 1/2,\ m > 0$ | Dirac eqn. $\partial^A_{A'}\varphi_A + \frac{im}{\sqrt{2}}\chi_{A'} = 0$ $\partial^{A'}_A\chi_{A'} - \frac{im}{\sqrt{2}}\varphi_A = 0$ | Leptons $e, \mu, \tau$ Baryons $p, n, \Lambda, \Xi, \Sigma, \ldots$ |
| $s = 1/2,\ m = 0$ | Weyl eqn. $\partial^A_{A'}\nu_A = 0$ | Massless(?) neutrinos $\nu_e, \nu_\mu, \nu_\tau$ |
| $s = 1,\ m > 0$ | Proca eqn. $H_{ab} = \partial_a U_b - \partial_b U_a$ $\partial^c H_{ca} + m^2 U_a = 0$ | Vector mesons $\rho, \omega, \psi, \Phi, \ldots$ |
| $s = 1,\ m = 0$ | Maxwell eqn. $\partial_{[a}F_{bc]} = 0$ $\partial_a F^{ab} = 0$ | Photon $\gamma$ |

**Table 2** The Lagrangian densities for free (i.e., noninteracting) fields with low spin

| *Field* | *Lagrangian density* |
|---|---|
| Scalar field | $\mathfrak{L} = \frac{1}{2}\{(\partial^a u)(\partial_a u) - m^2 u^2\}$ |
| Dirac field | $\mathfrak{L} = \frac{i}{\sqrt{2}}(\bar{\chi}_A\partial^{AA'}\chi_{A'} + \bar{\varphi}^{B'}\partial_{BB'}\varphi^B - \varphi^B\partial_{BB'}\bar{\varphi}^{B'} - \chi_{A'}\partial^{AA'}\bar{\chi}_A) + m(\bar{\chi}_A\varphi^A + \bar{\varphi}^{A'}\chi_{A'})$ |
| Weyl field | $\mathfrak{L} = \frac{i}{\sqrt{2}}(\bar{\nu}_{A'}\partial^{AA'}\nu_A - \nu_A\partial^{AA'}\bar{\nu}_{A'})$ |
| Proca field | $\mathfrak{L} = \frac{1}{4}H_{ab}H^{ab} - H^{ab}\partial_{[a}U_{b]} + \frac{m^2}{2}U_a U^a$ |
| Maxwell field | $\mathfrak{L} = -\frac{1}{4}F_{ab}F^{ab} = -(\partial_{[a}A_{b]})(\partial^{[a}A^{b]})$ |

that a vector field $A_a$ exists such that $F_{ab} = \partial_a A_b - \partial_b A_a$. This vector field is called the "electromagnetic 4-potential." It is not uniquely determined by the field $F_{ab}$; the freedom in $A_a$ is $A_a \to A_a + \partial_a\tau$ where $\tau = \tau(x)$ is a real-valued function. This gauge transformation of $A_a$ can be used, for example, to obtain the Lorentz gauge condition $\partial^a A_a = 0$.

The wave equations listed in Table 1 look rather different, but this formal disadvantage can be overcome. To begin with, we remark that fermions require spinors for their description. The Dirac and Weyl equations are not describable by linear equations for tensor fields. On the other hand, bosons can be described by spinors as well. All tensor equations can be "translated" into spinor form using the mixed spinor–tensor $\sigma^a_{AA'}$. We will demonstrate this procedure for the Proca field in some detail.

The (possibly complex) skew-symmetric tensor $H_{ab}$ and the vector $U_a$ have the spinor equivalents

$$H_{ab}\sigma^a_{AA'}\sigma^b_{BB'} = \varphi_{AB}\varepsilon_{A'B'} + \xi_{A'B'}\varepsilon_{AB}$$
$$U_a\sigma^a_{AA'} = \chi_{AA'}$$

where $\varphi$ and $\xi$ are both symmetric spinors: $\varphi_{AB} = \varphi_{(AB)}$, $\xi_{A'B'} = \xi_{(A'B')}$. After a straightforward calculation the Proca equation yields

$$\partial^{C'}_{(A}\chi_{B)C'} + \varphi_{AB} = 0, \qquad \partial^{C'}_{(A'}\chi_{B')C} + \xi_{A'B'} = 0$$
$$\partial^C_{A'}\varphi_{CA} + \partial^{C'}_A\xi_{C'A'} + m^2\chi_{AA'} = 0$$

Further, from the equation $\partial_{[c}H_{ab]} = 0$, we obtain $\partial^{C'}_A\xi_{A'C'} = \partial^C_{A'}\varphi_{AC}$; thus, the first and second summand in the third equation are equal. Consequently, we find the following spinor form of the Proca equations:

$$\partial^C_{A'}\varphi_{CA} + \frac{m^2}{2}\chi_{AA'} = 0, \qquad \partial^{C'}_{(A}\chi_{B)C'} + \varphi_{AB} = 0$$
$$\partial^{C'}_A\xi_{C'A'} + \frac{m^2}{2}\chi_{AA'} = 0, \qquad \partial^{C'}_{(A'}\chi_{B')C} + \xi_{A'B'} = 0 \qquad [3]$$

If the tensor fields $H$ and $U$ are real, then we have $\xi_{A'B'} = \bar{\varphi}_{A'B'}$, $\chi_{AA'} = \bar{\chi}_{AA'}$, and the second pair of equations is just the complex conjugate of the first.

Now it is readily seen that the Dirac and Proca equations have the same structure. They are coupled first-order systems of differential equations for pairs of spinor fields. The only decisive difference is that the spinors have one index if $s = 1/2$ and two indices if $s = 1$.

We obtain a similar result for Maxwell fields. The real tensor $F_{ab}$ has the spinor equivalent

$$F_{ab}\sigma^a_{AA'}\sigma^b_{BB'} = \varphi_{AB}\varepsilon_{A'B'} + \bar{\varphi}_{A'B'}\varepsilon_{AB}$$

with a symmetric spinor $\varphi_{AB}$. The spinor form of Maxwell's equations is (Penrose and Rindler 1984)

$$\partial^A_{A'}\varphi_{AB} = 0 \qquad [4]$$

and has the same structure as the Weyl equation.

Here we found an example for the power and utility of spinor techniques since they allow the formulation of the wave equations for bosons and fermions in a uniform manner. Only the cases $m > 0$ and $m = 0$ are to be distinguished. Moreover, the above results suggest the way for generalizing the wave equations to higher spin. Therefore, we can already end the discussion of the fields with low spin and take them as special cases of those with arbitrary spin.

## Higher Spin in Minkowski Spacetime

### Massive Fields

Relativistic wave equations for particles with arbitrary spin were first considered by Dirac (1936). His equations read

$$\partial^A_{P'}\varphi_{AB\ldots DQ'\ldots T'} + m_1\chi_{B\ldots DP'Q'\ldots T'} = 0$$
$$\partial^{P'}_A\chi_{B\ldots DP'Q'\ldots T'} - m_2\varphi_{AB\ldots DQ'\ldots T'} = 0 \qquad [5]$$

where the spinors $\varphi$ and $\chi$ are of type $(n,k)$ and $(n-1,k+1)$, respectively (corresponding to irreducible representations of the restricted Lorentz group $SO^{+}(1,3)$). The constants $m_1$ and $m_2$ are mass parameters ($m^2 = -2m_1m_2$) and the spin $s$ is one half of the total number of indices of each spinor, $s = (1/2)(n+k)$. As in the preceding section, we assume that electromagnetism and other interactions are absent. We should mention that equations for higher spin were not motivated by observations or empirical facts in that period of time, because only a few elementary particles were known (proton, neutron, electron, positron, and photon), and all of them have low spin (see **Table 1**). Since that time, particles with $s > 1$ were found in nature, for example, resonances in scattering experiments.

The system [5] allows a uniform description of free fields with arbitrary spin $s > 0$, including Dirac and Proca fields, as we know from the preceding section. (Remark: The symmetrization in eqns [3] can be omitted since the vector field $U$ is divergence-free as a consequence of the second Proca equation.) Various other field equations proposed subsequently can be comprehended as its special cases (Corson 1953). Examples are the Rarita–Schwinger equations for fermions: if they are written in terms of 2-spinors, then one obtains just the system [5] where the spinor $\varphi$ is of type $(s+1/2,\ s-1/2)$ and the spinor $\chi$ is of type $(s-1/2,\ s+1/2)$.

If we apply $\partial_E^{P'}$ to the first of the equations in [5] and use the second, we obtain

$$(\Box + m^2)\varphi_{AB\ldots DQ'\ldots T'} = 0 \qquad [6a]$$

since the second derivatives commute in flat spacetimes. Similarly,

$$(\Box + m^2)\chi_{B\ldots DP'Q'\ldots T'} = 0 \qquad [6b]$$

so both fields $\varphi$ and $\chi$ satisfy a Klein–Gordon type equation. Moreover, eqns [5] imply that each of $\varphi$ and $\chi$ is divergence-free

$$\partial^{AQ'}\varphi_{AB\ldots DQ'\ldots T'} = 0 = \partial^{BP'}\chi_{B\ldots DP'Q'\ldots T'} \qquad [7]$$

if they have at least one index of each kind.

In a sense, this procedure can be reversed. Let a symmetric spinor field $\varphi$ be given that satisfies [6a] and [7]. (Remark: A significant example is the Fierz system

$$(\Box + m^2)U_{ab\ldots d} = 0, \qquad \partial^a U_{ab\ldots d} = 0$$

for a symmetric, tracefree tensor field $U$, since the spinor equivalent of $U$ is of type $(k,k)$.)

Define

$$\chi_{B\ldots DP'Q'\ldots T'} := \partial^A_{P'}\varphi_{AB\ldots DQ'\ldots T'}$$

Then $\chi$ is symmetric in all its indices since $\varphi$ is divergence-free. Further, we obtain

$$\begin{aligned}\partial_E^{P'}\chi_{B\ldots DP'Q'\ldots T'} &= \partial_E^{P'}\partial^A_{P'}\varphi_{AB\ldots DQ'\ldots T'} \\ &\equiv -\frac{1}{2}\Box\varphi_{EB\ldots DQ'\ldots T'} \\ &= \frac{m^2}{2}\varphi_{EB\ldots DQ'\ldots T'}\end{aligned}$$

since $\varphi$ satisfies the Klein–Gordon equation [6a]. Consequently, the pair $(\varphi,\chi)$ satisfies a system [5]. Obviously, this procedure can be continued: define

$$\eta_{C\ldots DO'P'Q'\ldots T'} := \partial^B_{O'}\chi_{B\ldots DP'Q'\ldots T'}$$

etc. We obtain a sequence of spinors of type $(0,2s)$, $(1,2s-1), \ldots, (2s,0)$ each of which is obtainable from its immediate neighbors by a differentiation contracted on one index. Together, these spinors form an invariant exact set (Penrose and Rindler 1984).

The just given arguments show that there is an ambiguity in the system [5]. The spin $s$ fixes only the total number of indices of $\varphi$ and $\chi$. However, their partition into primed and unprimed ones is not *a priori* fixed. Therefore, we can choose a "convenient" partition for the respective needs.

### Massless Fields

If $m=0$, then the Dirac system [5] is decoupled. Therefore, we have to state a single equation for a single field. Let $\varphi$ be a spinor field of type $(n,0)$. The massless free-field equation for spin $(1/2)n$ is then taken to be

$$\partial^A_{A'}\varphi_{AB\ldots E} = 0 \qquad [8]$$

More precisely, the solutions of [8] represent left-handed massless particles with helicity $-(1/2)n\hbar$, whereas the solutions of the complex-conjugate form of this equation are right-handed particles (helicity $+(1/2)n\hbar$). Recall that the Weyl equation ($n=1$) and the source-free Maxwell equation ($n=2$) have this form. (Remark: The Bianchi identity in Einstein spaces also falls in this category, with the Weyl spinor $\Psi_{ABCD}$ taking the place of $\varphi\ldots$. Moreover, we may think of [8] with $n=4$ as the gauge-invariant equation for the weak vacuum gravitational field.)

The massless field equation [8] can be solved using methods of twistor geometry. Moreover, there is an explicit integral formula for representing massless free fields in terms of arbitrarily chosen null data on a light cone (Penrose and Rindler 1984, 1986, Ward and Wells 1990). We do not discuss eqns [8] in detail since they are generally inconsistent in curved spacetimes if $n > 2$ (see the next

section). We only indicate that each solution of [8] satisfies the second-order wave equation

$$\Box\varphi_{AB\ldots E}=0$$

Maxwell's equations imply the existence of an electromagnetic potential (cf. section "Wave equations for low spin in Minkowski spacetime"). This concept can be generalized to higher spin. A "potential" for a spinor field $\varphi_{AB\ldots E}$ of type $(n,0)$ is a spinor field $\Theta_{AB'\ldots E'}$ of type $(1,n-1)$ such that

$$\partial^{A}_{(A'}\Theta_{|A|B'\ldots E')}=0 \qquad [9]$$

and

$$\varphi_{AB\ldots E}=\partial^{B'}_{(B}\cdots\partial^{E'}_{E}\Theta_{A)B'\ldots E'} \qquad [10]$$

One can check in a straightforward manner that a spinor field $\varphi$ that is given by [9] and [10] satisfies the massless equation [8]. If $n>1$, there is a gauge freedom in these potentials; it turns out to be

$$\Theta_{AB'\ldots E'}\to\Theta_{AB'\ldots E'}+\partial_{A(B'}\omega_{C'\ldots E')}$$

for any spinor field $\omega$ of type $(0,n-2)$. Furthermore, the general massless field $\varphi$ can locally be expressed in this way (Penrose and Rindler 1986).

## Wave Equations in Curved Spacetimes, Consistency Conditions

First of all we emphasize that Hamilton's principle of stationary action is extremely important in field theories (see, e.g., Schmutzer (1968)). Assume that the Lagrangian $\mathfrak{L}$ contains at most first derivatives of a field $\psi_\Sigma:\mathfrak{L}=\mathfrak{L}(\psi_\Sigma(x),\partial_a\psi_\Sigma(x))$. "Special relativity" states that $\mathfrak{L}$ is invariant under Lorentz transformations. The Euler–Lagrange equations with respect to variation of $\psi_\Sigma$ read

$$\frac{\partial\mathfrak{L}}{\partial\psi_\Sigma}-\partial_a\frac{\partial\mathfrak{L}}{\partial(\partial_a\psi_\Sigma)}=0 \qquad [11]$$

and these are the field equations that $\psi_\Sigma$ is required to satisfy.

In "general relativity," the Lagrangian $\mathfrak{L}$ has to be generally covariant. So we have $\mathfrak{L}=\mathfrak{L}(\psi_\Sigma(x),\nabla_a\psi_\Sigma(x))$ and the Euler–Lagrange equations

$$\frac{\partial\mathfrak{L}}{\partial\psi_\Sigma}-\nabla_a\frac{\partial\mathfrak{L}}{\partial(\nabla_a\psi_\Sigma)}=0 \qquad [12]$$

emerge. If we assume that the Lagrangian $\mathfrak{L}$ does not contain the curvature tensors and their derivatives explicitly and compare [11] and [12], then it is easily seen how the wave equations in curved spacetime can be obtained: by simply replacing the flat metric and connection with their curved versions. This procedure is called the "principle of minimal coupling."

All equations for low spin in Minkowski spacetime are the Euler–Lagrange equations of a variation principle (see Table 2). Consequently, they can be extended to curved spacetime by simply using the principle of minimal coupling. The arising equations are perfectly acceptable. No complications arise, and so we do not repeat them in this section.

If $s>1$, then neither the massive nor the massless wave equations follow from a variation principle without supplementary conditions. Nevertheless, we can try to generalize the equations of the previous section to a curved spacetime by formally replacing the flat metric and connection with their curved versions, too. However, serious problems arise:

Let us first consider massless fields of helicity $-(1/2)n\hbar$. The principle of minimal coupling yields

$$\nabla^{A}_{A'}\varphi_{AB\ldots E}=0 \qquad [13]$$

If we apply $\nabla^{A'}_{F}$ to this equation, we obtain

$$\nabla^{A'}_{F}\nabla^{A}_{A'}\varphi_{AB\ldots E}=0$$

Since the covariant derivatives do not commute with each other, the term on the left-hand side is not completely symmetric in the unprimed indices. Therefore, this equation can be decomposed into two nontrivial irreducible parts if $n>1$: symmetrization yields the covariant D'Alembert equation

$$\nabla^a\nabla_a\varphi_{B\ldots EF}=0$$

as required, while antisymmetrization yields by use of the spinor Ricci identities

$$(n-2)\Psi^{KLM}{}_{(C}\varphi_{D\ldots E)KLM}=0 \qquad [14]$$

where $\Psi_{ABCD}$ is the Weyl spinor. If $n>2$ and the spacetime is not conformally flat, then this algebraic consistency condition effectively renders eqn [13] useless as physical field equations.

If $m>0$, the situation is not better. In somewhat similar way, we obtain the algebraic consistency conditions

$$\begin{aligned}&(n-2)\Psi^{KLM}{}_{(C}\varphi_{D\ldots E)KLMQ'P'\ldots T'}\\&\quad+k\Phi^{KLX'}{}_{(Q'}\varphi_{|KLC\ldots E|P'\ldots T')X'}=0\quad(n>1)\\&(k-1)\bar{\Psi}^{X'Y'Z'}{}_{(S'}\chi_{|B\ldots DX'Y'Z'|T'\ldots U')}\\&\quad+(n-1)\Phi_{(B}{}^{KX'Y'}\chi_{C\ldots D)KX'Y'S'T'\ldots U'}=0\quad(k>0)\end{aligned} \qquad [15]$$

if the spinor field $\varphi$ is of type $(n,k)$ (Buchdahl 1962).

We remark that similar consistency conditions occur if we have no gravitation, but an interaction with an electromagnetic field. Then the partial

derivative is to be replaced by $D_a = \partial_a - ieA_a$ and we obtain consistency conditions like [14] and [15], where the curvature spinors are to be replaced by the electromagnetic spinor (Fierz and Pauli 1939).

So far one is left with the problem: "Find the 'correct' laws for arbitrary spin, that means field equations which coincide with the well-known approved ones for low spin and which remain consistent even for higher spin when electromagnetism and/or gravitation is coupled!"

An extensive literature is devoted to just this problem. Let us briefly sketch some means by which the authors tried to solve it:

- derivation of the desired field equations from a variation principle where the original spinor fields are supplemented by auxiliary fields;
- extension of the four-dimensional spacetime geometry to a richer one: higher number of dimensions, complexification, addition of torsion, nonmetrical connection, ...;
- replacement of the algebra of spinors by some richer algebra;
- disclaim of the principle of minimal coupling; and
- supergravity theories.

Some of these attempts are able to solve the problem, at least partially. But, as a rule, they pay a price of new difficulties. In the next section, we offer "good" equations for arbitrary $s > 0$ within the conventional framework of the minimal coupling principle and of a curved spacetime background.

## Wave Equations for Arbitrary Spin without Consistency Conditions

### Massive Fields

The ansatz which leads to the desired result is surprisingly simple. We avoid the ambiguity in the Dirac system [5] that has been discussed earlier as well as any consistency condition if we state the wave equations

$$\begin{aligned} \nabla^A_{P'}\varphi_{AB\ldots E} + m_1\chi_{B\ldots EP'} &= 0 \\ \nabla^{P'}_{(A}\chi_{B\ldots E)P'} - m_2\varphi_{AB\ldots E} &= 0 \end{aligned} \qquad [16]$$

This system was first proposed by Wünsch (1985); it is equivalent to a pair of equations given by Buchdahl (1982) which contains the Weyl spinor explicitly. As before, $\varphi$ and $\chi$ are symmetric spinor fields, $\varphi$ has $n$ unprimed indices (and no one else!) and the constants $m_1, m_2$ are mass parameters ($m^2 = -2m_1m_2$). We assume $m_1 \neq 0$ in this section. Obviously, the Dirac and Proca equations are special cases of [16], choose $n=1$ and $n=2$, respectively. (Remark: An electromagnetic field can be included in [16] by $\nabla_a \to D_a = \nabla_a - ieA_a$, and the equations remain consistent (Illge 1993).)

First of all, we remark that eqns [16] are the Euler–Lagrange equations of an action principle. The existence of a Lagrangian is plausible since the number of equations and the number of degrees of freedom are equal. We do not state the Lagrangian, the energy–momentum tensor, and the current vector in this article and refer the reader to Illge (1993).

If $n > 1$, we can apply $\nabla^{BP'}$ to the first equation of [16] and obtain using the spinor Ricci identities:

$$\begin{aligned} \nabla^{BP'}\chi_{BC\ldots EP'} &= -\frac{1}{m_1}\nabla^{BP'}\nabla^A_{P'}\varphi_{ABC\ldots E} \\ &= -\frac{n-2}{m_1}\Psi^{KLM}{}_{(C}\varphi_{D\ldots E)KLM} \end{aligned} \qquad [17]$$

Hence the divergence of $\chi$ vanishes if $n=2$ or if the spacetime is conformally flat. These are exactly the cases where the symmetrization in the second equation of [16] can be omitted.

Now we are going to derive the second-order equations for $\varphi$ and $\chi$. Substituting

$$\chi_{BC\ldots EP'} = -\frac{1}{m_1}\nabla^A_{P'}\varphi_{AB\ldots E} \qquad [18]$$

into the second equation of [16], we obtain, after a bit of algebra,

$$\begin{aligned} &\nabla^a\nabla_a\varphi_{AB\ldots E} - 2(n-1)\Psi^{KL}{}_{(AB}\varphi_{C\ldots E)KL} \\ &\quad + \left(\frac{n+2}{12}R + m^2\right)\varphi_{AB\ldots E} = 0 \end{aligned} \qquad [19]$$

This is a linear second-order equation of normal hyperbolic type for the spinor field $\varphi$. It can be used to solve Cauchy's problem for the system [16].

Similarly, we get a second-order equation for $\chi$:

$$\begin{aligned} &\nabla^a\nabla_a\chi_{B\ldots EP'} - 2(n-1)\Phi_{(B}{}^K{}_{P'}{}^{W'}\chi_{C\ldots E)KW'} \\ &\quad + \left(\frac{R}{4} + m^2\right)\chi_{B\ldots EP'} \\ &= 2\frac{n-1}{n}\nabla_{(BP'}\nabla^{KW'}\chi_{C\ldots E)KW'} \end{aligned} \qquad [20]$$

Seemingly this is not an equation of hyperbolic type if $n > 1$. However, the second derivatives of $\chi$ on the right-hand side of [20] can be eliminated using [17]. Therefore, if the spinor field $\varphi$ is already known by solving [19], then [20] is an equation of Klein–Gordon type, too. However, it is generally inhomogeneous if $n > 2$. A wave equation that contains the spinor field $\chi$ alone exists only if $n=1, n=2$, or the spacetime is conformally flat.

Now we are going to discuss the "Cauchy problem" for the wave equations [16] (for details see Wünsch (1985)). Let a spacelike hypersurface $S$ be given and let $n^a$ denote the future-directed unit normal vector on $S$ and $\nabla_n = n^a \nabla_a$. The local Cauchy problem is to find a solution $(\varphi, \chi)$ of [16] with given Cauchy data $\varphi^0, \chi^0$ on $S$.

In general, the initial data $\varphi^0$ and $\chi^0$ cannot be prescribed arbitrarily. Suppose that a solution $(\varphi, \chi)$ of [16] does exist. Then the differential equations have to be satisfied on $S$, too. Thus, we obtain

$$(\nabla_n \varphi_{AB\ldots E})_{|S} = 2n_A^{A'} \left(\tilde{\nabla}^F_{A'} \varphi_{B\ldots EF} + m_1 \chi_{B\ldots EA'}\right)_{|S} \quad [21]$$

where the differential operator $\tilde{\nabla}_{AA'} = \nabla_{AA'} - n_{AA'} \nabla_n$ is just the tangential part of $\nabla_{AA'}$ with respect to $S$. Therefore, the right-hand side of [21] is completely determined by the initial data. Now the symmetry of the solution $\varphi_{AB\ldots E}$ implies the symmetry of $\nabla_n \varphi_{AB\ldots E}$. Consequently, the right-hand side of [21] has to be symmetric with respect to the unprimed indices and so we obtain the following constraints for the initial data if $\varphi$ has at least two indices:

$$n^{BA'} \left(\tilde{\nabla}^F_{A'} \varphi^0{}_{B\ldots EF} + m_1 \chi^0{}_{B\ldots EA'}\right)_{|S} = 0 \quad [22]$$

Now we can state:

**Theorem 1** *If the Cauchy data $\varphi^0$ and $\chi^0$ satisfy the constraints [22], then the Cauchy problem has a unique solution in a neighborhood of $S$.*

For each differential equation of hyperbolic type we can ask the question whether the wave propagation is "sharp," that is, free of tails. If this property is valid we say that the equation satisfies "Huygens' principle" (for an exact definition, see, e.g., Wünsch (1994)). Using invariant Taylor expansions of the parallel propagator and of the Riesz kernels in normal coordinates we can prove (Wünsch 1985):

**Theorem 2** *The massive wave equations [16] for spin $s > 0$ satisfy Huygens' principle if and only if the spacetime is of constant curvature and $R = -(6m^2/s)$.*

### Massless Fields

In the preceding section, we have seen that the premise $m_1 \neq 0$ is decisive for the consistency of [16] if $s > 1$. This fact agrees with the result of the previous section, that eqn [13] is inconsistent if $s > 1$ and the spacetime is not conformally flat. On the other hand, $m_2 = 0$ is possible. Therefore we state the wave equations

$$\nabla^A_{(A'} \Theta_{|A|B'\ldots E')} = 0 \quad [23]$$

for a spinor field $\Theta$ of type $(1, n-1)$. This is just eqn [9] for the potential of a massless field. We will show that [23] is a satisfactory equation in a generally curved spacetime (Illge 1988). Unfortunately, no Lagrangian has been found if $n > 1$.

To begin with, we remark that there is a gauge freedom in curved spacetimes, too, since the solution $\Theta$ of [23] cannot be uniquely determined if $n > 1$. We use this freedom to prescribe the divergence of $\Theta$. So let an arbitrary spinor field $\omega$ of type $(0, n-2)$ be given. We consider eqns [23] and

$$\nabla^{AB'} \Theta_{AB'C'\ldots E'} = \omega_{C'\ldots E'}$$

or, together,

$$\nabla^A_{A'} \Theta_{AB'\ldots E'} = -\frac{n-1}{n} \varepsilon_{A'(B'} \omega_{C'\ldots E')} \quad [24]$$

If we apply $\nabla^{A'}_B$ to this equation, we obtain using the spinor Ricci identities

$$\nabla^a \nabla_a \Theta_{BB'\ldots E'} - 2(n-1) \Phi_B{}^K{}_{(B'}{}^{W'} \Theta_{|K|C'\ldots E')W'} + \frac{R}{4} \Theta_{BB'\ldots E'} = \frac{2(n-1)}{n} \nabla_{B(B'} \omega_{C'\ldots E')} \quad [25]$$

This is a linear second-order equation of normal hyperbolic type for the spinor field $\Theta$ (cf. [20]).

Now let us discuss some particular cases. If $n = 1$, then [23] is just the Weyl equation itself. Therefore, the equations for the field and its potential are identical and there is no gauge freedom. If $n = 2$, then the spinor field $\Theta_{AA'}$ is a (complex) vector field and eqn [23] yields

$$\nabla^A_{(A'} \Theta_{|A|B')} = 0$$

The gauge field $\omega$ is just a scalar function, especially we can choose $\omega = 0$ (Lorentz gauge). As in eqn [10] we define the field spinor as

$$\varphi_{AB} = \nabla^{B'}_{(A} \Theta_{B)B'}$$

Since we have the identity

$$\nabla^A_{B'} \nabla^{A'}_{(B} \eta_{A)A'} = \nabla^{A'}_B \nabla^A_{(B'} \eta_{|A|A')}$$

for arbitrary spinor fields $\eta_{AA'}$ (which must not have additional free indices!), the spinor field $\varphi_{AB}$ satisfies the massless free-field equation

$$\nabla^A_{B'} \varphi_{AB} = 0$$

If $n > 2$, we can define a field $\varphi_{AB\ldots E}$ via the relation [10], too, replacing the partial with the covariant derivatives. But the field equation for $\varphi_{AB\ldots E}$ becomes more complicated than [13]. This

fact is not surprising, since eqn [23] is a consistent one, whereas [13] is inconsistent.

We continue with some remarks on "conformal rescalings of the metric." The equations for massless fields have to be invariant with respect to such transformations. Therefore, the "curved space" scalar wave equation is

$$\left(\Box + \frac{R}{6}\right)\varphi = 0 \qquad [26]$$

Further, the equations

$$\nabla^{A}_{(A'}\eta_{|AB\ldots E|B'\ldots F')} = 0 \qquad [27]$$

for any spinor field $\eta$ of type $(n, k)$ are conformally invariant (Penrose and Rindler 1984). Especially, eqns [23] for the massless potential and [13] for the massless field have this property.

We mention a further special case of [27]. If $\eta$ is of type $(k+1, k)$, then these equations are consistent, too (Frauendiener and Sparling 1999). The Cauchy problem is well posed and a Lagrangian is known. Unfortunately, the solutions do not satisfy a wave equation of second order if $k > 0$.

We conclude with the discussion of the Cauchy problem for eqn [24]. As in the preceding section, let a spacelike hypersurface $S$ and initial data $\Theta^0$ on $S$ be given. We can state:

**Theorem 3** *If a symmetric spinor field $\omega$ of type $(0, n-2)$ is given, then there exists a neighborhood of $S$ in which eqn [24] has one and only one solution satisfying $\Theta_{|S} = \Theta^0$.*

The proof is given in Illge (1988). We emphasize that there are no constraints on the Cauchy data for the massless equation [24].

In contrast to massive fields we are far away from an answer to the question whether Huygens principle is valid for the massless equations. A particular result is Wünsch (1994):

**Theorem 4** *Huygen's principle for the conformally invariant scalar wave equation [26], the Weyl, and the Maxwell equations is valid only for conformally flat and plane wave metrics within the classes of centrally symmetric, recurrent, $(2,2)$-decomposable, Petrov type N, III or D spacetimes as well as those with $\nabla_{[a}R_{b]c} = 0$.*

## Introduction

Quantum field theories (QFTs) provide a natural framework for quantum theories that obey the principles of special relativity. Among their most striking features are ultraviolet (UV) divergences, which at first sight invalidate the existence of the theories. The divergences arise from Fourier modes of very high wave number, and hence from the structure of the theories at very short distances. In the very restricted class of theories called "renormalizable," the divergences may be removed by a singular redefinition of the parameters of the theory. This is the process of renormalization that defines a QFT as a nontrivial limit of a theory with a UV cutoff.

A very important QFT is the standard model, an accurate and successful theory for all the known interactions except gravity. Calculations using renormalization and related methods are vital to the theory's success.

The basic idea of renormalization predates QFT. Suppose we treat an observed electron as a combination of a bare electron of mass $m_0$ and the associated classical electromagnetic field down to a radius $a$. The observed mass of the electron is its bare mass plus the energy in the field (divided by $c^2$). The field energy is substantial, for example, 0.7 MeV when $a = 10^{-15}$ m, and it diverges when $a \to 0$. The observed mass, 0.5 MeV, is the sum of the large (or infinite) field contribution compensated by a negative and large (or infinite) bare mass. This calculation needs replacing by a more correct version for short distances, of course, but it remains a good motivation.

In this article, we review the theory of renormalization in its classic form, as applied to weak-coupling perturbation theory, or Feynman graphs. It is this method, rather than the Wilsonian approach (*see* Exact Renormalization Group), that is typically used in practice for perturbative calculations in the standard model, especially its QCD part.

Much of the emphasis is on weak-coupling perturbation theory, where there are well-known algorithmic rules for performing calculations and renormalization. Applications (*see* Quantum Chromodynamics for some important nontrivial examples) involve further related results, such as the operator product expansion, factorization theorems, and the renormalization group (RG), to go far beyond simple fixed-order perturbation theory. The construction of fully rigorous mathematical treatments for the exact theory is a topic of future research.

## Formulation of QFT

A QFT is specified by its Lagrangian density. A simple example is $\phi^4$ theory:

$$\mathcal{L} \stackrel{?}{=} \frac{(\partial\phi)^2}{2} - \frac{m^2\phi^2}{2} - \frac{\lambda\phi^4}{4!} \qquad [1]$$

where $\phi(x) = \phi(t, \boldsymbol{x})$ is a single component Hermitian field. The Lagrangian density and the resulting equation of motion, $\partial^2\phi + m^2\phi + (1/6)\lambda\phi^3 = 0$, are local; they involve only products of fields at the same spacetime point. Such locality is characteristic of relativistic theories, where otherwise it is difficult or impossible to preserve causality, but it is also the source of the UV divergences. The question mark over the equality symbol in eqn [1] is a reminder that renormalization of UV divergences will force us to modify the equation.

The Feynman rules for perturbation theory are given by a free propagator $\mathrm{i}/(p^2 - m^2 + \mathrm{i}0)$ and an interaction vertex $-\mathrm{i}\lambda$. Although we will usually work in four spacetime dimensions, it is useful also to consider the theory in a general spacetime dimensionality $n$, where the coupling has energy dimension $[\lambda] = E^{4-n}$. We use "natural units," that is, with $\hbar = c = 1$. The "i0" in the propagator $\mathrm{i}/(p^2 - m^2 + \mathrm{i}0)$ symbolizes the location of the pole relative to the integration contour; it is often written as $\mathrm{i}\epsilon$.

The primary targets of calculations are the vacuum expectation values of time-ordered products of $\phi$; in QFT these are called the Green functions of the theory. From these can be reconstructed the scattering matrix, scattering cross sections, and other measurable quantities.

## One-Loop Calculations

Low-order graphs for the connected and amputated four-point Green function are shown in Figure 1. Each one-loop graph has the form

$$-\mathrm{i}\lambda^2 I(p^2) \stackrel{?}{=} \frac{\lambda^2}{2}\int \frac{\mathrm{d}^4k}{(2\pi)^4} \frac{1}{(k^2 - m^2 + \mathrm{i}0)[(p-k)^2 - m^2 + \mathrm{i}0]} \qquad [2]$$

where $p$ is a combination of external momenta. There is a divergence from where the loop

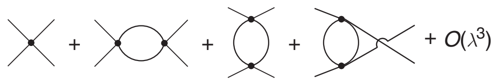

**Figure 1** One-loop approximation to connected and amputated four-point function, before renormalization.

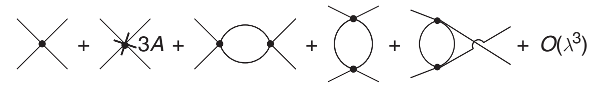

**Figure 2** One-loop approximation to renormalized connected and amputated four-point function, with counter-term.

momentum $k$ goes to infinity. We define the degree of divergence, $\Delta$, by counting powers of $k$ at large $k$, to get $\Delta = 0$. In an $n$-dimensional spacetime we would have $\Delta = n - 4$. The integral is divergent whenever $\Delta \geq 0$. Comparing the dimensions of the one-loop and tree graphs shows that $\Delta$ equals the negative of the energy dimension of the coupling $\lambda$. Thus, the dimensionlessness of $\lambda$ at the physical spacetime dimension is equivalent to the integral being just divergent.

The infinity in the integral implies that the theory *in its naive formulation* is not defined. With the aid of RG methods, it has been shown that the problem is with the complete theory, not just perturbation theory.

The divergence only arises because we use a continuum spacetime. So suppose that we formulate the theory initially on a lattice of spacing $a$ (in space or spacetime). Our loop graph is now

$$-\mathrm{i}\lambda^2 I(p; m, a) = \frac{-\lambda^2}{32\pi^4} \int \mathrm{d}^4 k\, S(k, m; a)\, S(p - k, m; a) \qquad [3]$$

where the free propagator $S(k, m; a)$ approaches the usual value $\mathrm{i}/(k^2 - m^2 + \mathrm{i}0)$ when $k$ is much smaller than $1/a$, and it falls off more rapidly for large $k$. The basic observation that propels the renormalization program is that the divergence as $a \to 0$ is independent of $p$. This is most easily seen by differentiating once with respect to $p$, after which the integral is convergent when $a = 0$, because the differentiated integral has degree of divergence –1.

Thus we can cancel the divergence in eqn [2] by replacing the coupling in the first term in Figure 1, by the so-called bare coupling

$$\lambda_0 = \lambda + 3A(a)\lambda^2 + O(\lambda^3) \qquad [4]$$

Here $A(a)$ is chosen so that the renormalized value of our one-loop graph,

$$-\mathrm{i}\lambda^2 I_R(p^2, m^2) = -\mathrm{i}\lambda^2 \lim_{a \to 0} [I(p; m, a) + A(a)] \qquad [5]$$

exists, at $a = 0$, with $A(a)$ in fact being real valued. The factor 3 multiplying $A(a)$ in eqn [4] is because there are three one-loop graphs, with equal divergent parts. The replacement for the coupling is made in the tree graph in Figure 1, but not yet at the vertices of the other graphs, because at the moment we are only doing a calculation accurate to order $\lambda^2$; the appropriate expansion parameter of the theory is the finite renormalized coupling $\lambda$, held fixed as $a \to 0$. We call the extra term in eqn [5] a counter-term. The diagrams for the correct renormalized calculation are represented in Figure 2, which has a counter-term graph compared with Figure 1.

In the physics terminology, used here, the cutting-off of the divergence by using a modified theory is called a regularization. This contrasts with the mathematics literature, where "regularized integral" usually means the same as a physicist's "renormalized integral."

There is always freedom to add a finite term to a counter-term. When we discuss the RG, we will see that this corresponds to a reorganization of the perturbation expansion and provides a powerful tool for improving perturbatively based calculations, especially in QCD. Contrary to the impression given in some parts of the literature, it is not necessary that a renormalized mass equal a corresponding physical particle mass, with similar statements for coupling and field renormalization. While such a prescription is common and natural in a simple theory like QED, it is by no means required and certainly may not always be best. If nothing else, the correspondence between fields and stable particles may be poor or nonexistent (as in QCD).

One classic possibility is to subtract the value of the graph at $p = 0$, a prescription associated with Bogoliubov, Parasiuk, and Hepp (BPH), which leads to

$$-\mathrm{i}\lambda^2 I_{\mathrm{R,\,BPH}}(p^2) = \frac{-\mathrm{i}\lambda^2}{32\pi^2} \int_0^1 \mathrm{d}x \ln\left[1 - p^2 x(1 - x)/m^2\right] \qquad [6]$$

In obtaining this from [2], we used a standard Feynman parameter formula,

$$\frac{1}{AB} = \int_0^1 \mathrm{d}x \frac{1}{[Ax + B(1 - x)]^2} \qquad [7]$$

to combine the propagator denominators, after which the integral over the momentum variable $k$ is elementary. We then obtain the renormalized one-loop (four-point and amputated) Green function

$$-\mathrm{i}\lambda - \mathrm{i}\lambda^2 [I_{\mathrm{R}}(s) + I_{\mathrm{R}}(t) + I_{\mathrm{R}}(u)] + O(\lambda^3) \qquad [8]$$

where $s$, $t$, and $u$ are the three standard Mandelstam invariants for the Green function. (For a $2 \to 2$

scattering process, or a corresponding off-shell Green function, in which particles of momenta $p_1$ and $p_2$ scatter to particles of momenta $p'_1$ and $p'_2$, the Mandelstam variables are defined as $s = (p_1 + p_2)^2$, $t = (p_1 - p'_1)^2$, and $u = (p_1 - p'_2)^2$.)

In the general case, with a nonzero degree of divergence, the divergent part of an integral is a polynomial in $p$ and $m$ of degree $D$, where $D$ is the smallest positive integer less than or equal to $\Delta$. In a higher spacetime dimension, this implies that renormalization of the original, momentum-independent, interaction vertex is not sufficient to cancel the divergences. We would need higher derivative terms, and this is evidence that the theory is not renormalizable in higher than 4 spacetime dimensions. Even so, the terms needed would be local, because of the polynomiality in $p$.

## Complete Formulation of Renormalization Program

The full renormalization program motivated by example calculations is:

- the theory is regulated to cut off the divergences;
- the numerical value of each coefficient in $\mathcal{L}$ is allowed to depend on the regulator parameter (e.g., $a$); and
- these dependences are adjusted so that finite results for Green functions are obtained after removal of the regulator.

In $\phi^4$ theory, we therefore replace $\mathcal{L}$ by

$$\mathcal{L} = \frac{Z}{2}(\partial\phi)^2 - \frac{Zm_0^2}{2}\phi^2 - \frac{Z^2\lambda_0}{4!}\phi^4 \qquad [9]$$

with the bare parameters, $Z$, $m_0$ and $\lambda_0$, having a regulator dependence such that Green functions of $\phi$ are finite at $a = 0$.

The slightly odd labeling of the coefficients in eqn [9] arises because observables like cross sections are invariant under a redefinition of the field by a factor. In terms of the bare field $\phi_0 \stackrel{\text{def}}{=} \sqrt{Z}\phi$, we have

$$\mathcal{L} = \frac{1}{2}(\partial\phi_0)^2 - \frac{m_0^2}{2}\phi_0^2 - \frac{\lambda_0}{4!}\phi_0^4 \qquad [10]$$

The unit coefficient of $(1/2)(\partial\phi_0)^2$ implies that $\phi_0$ has canonical commutation relations (in the regulated theory). This provides a natural standard for the normalization of the bare mass $m_0$ and the bare coupling $\lambda_0$.

All terms in $\mathcal{L}$ have coefficients with dimension zero or larger. This is commonly characterized by saying that the terms $\mathcal{L}$ "have dimension 4 or less," which refers to the products of field operators and derivatives in each term. A generalization of the power-counting analysis shows that if we start with a theory whose $\mathcal{L}$ only has terms of dimension 4 or less, then no terms of higher dimension are needed as counter-terms, at least not in perturbation theory. This is a very powerful restriction on self-contained QFTs, and was critical in the discovery of the standard model.

Sometimes it is found that the description of some piece of physics appears to need higher-dimension operators, as was the case originally with weak-interaction physics. The lack of renormalizability of such theories indicates that they cannot be complete, and an upper bound on the scale of their applicability can be computed, for example, a few hundred GeV for the four-fermion theory of weak interactions. Eventually, this theory was superseded by the renormalizable Weinberg–Salam theory of weak interactions, now a part of the standard model, to which the four-fermion theory provides a low-energy approximation for charged current weak interactions.

Certain operators of allowed dimensions are missing in eqn [9]: the unit operator, and $\phi$ and $\phi^3$. Symmetry under the transformation $\phi \to -\phi$ implies that Green functions with an odd number of fields vanish, so that no $\phi$ and $\phi^3$ counter-terms are needed. Divergences with the unit operator do appear, but not for ordinary Green functions. In gravitational physics, the coefficient of the unit operator gives renormalization of the cosmological constant.

To implement renormalized perturbation theory, we partition $\mathcal{L}$ (nonuniquely) as

$$\mathcal{L} = \mathcal{L}_{\text{free}} + \mathcal{L}_{\text{basic interaction}} + \mathcal{L}_{\text{counter-term}} \qquad [11]$$

where the free, the basic interaction, and the counter-term Lagrangians are

$$\mathcal{L}_{\text{free}} = \frac{1}{2}(\partial\phi)^2 - \frac{m^2}{2}\phi^2 \qquad [12]$$

$$\mathcal{L}_{\text{basic interaction}} = -\frac{\lambda}{4!}\phi^4 \qquad [13]$$

$$\mathcal{L}_{\text{counter-term}} = \frac{Z-1}{2}(\partial\phi)^2 - \frac{(Zm_0^2 - m^2)}{2}\phi^2 - \frac{(Z^2\lambda_0 - \lambda)}{4!}\phi^4 \qquad [14]$$

The renormalized coupling and mass, $\lambda$ and $m$, are to be fixed and finite when the UV regulator is removed. Both the basic interaction and the counter-terms are treated as interactions. First we compute "basic graphs" for Green functions using only the basic

interaction. The counter-terms are expanded in powers of $\lambda$, and then all graphs involving counter-term vertices at the chosen order in $\lambda$ are added to the calculation. The counter-terms are arranged to cancel all the divergences, so that the UV regulator can be removed, with $m$ and $\lambda$ held fixed. The counter-terms cancel the parts of the basic Feynman graphs associated with large loop momenta. An algorithmic specification of the otherwise arbitrary finite parts of the counter-terms is called a renormalization prescription or a renormalization scheme. Thus, it gives a definite relation between the renormalized and bare parameters, and hence a definite specification of the partitioning of $\mathcal{L}$ into its three parts.

It has been proved that this procedure works to all orders in $\lambda$, with corresponding results for other theories. Even in the absence of fully rigorous nonperturbative proofs, it appears clear that the results extend beyond perturbation theory, at least in asymptotically free theories like QCD: see the discussion on Wilsonian RG (*see* Exact Renormalization Group).

## Dimensional Regularization and Minimal Subtraction

The final result for renormalized graphs does not depend on the particular regularization procedure. A particularly convenient procedure, especially in QCD, is dimensional regularization, where divergences are removed by going to a low spacetime dimension $n$. To make a useful regularization method, $n$ is treated as a continuous variable, $n = 4 - 2\epsilon$.

Great advantages of the method are that it preserves Poincaré invariance and many other symmetries (including the gauge symmetry of QCD), and that Feynman graph calculations are minimally more complicated than for finite graphs at $n = 4$, particularly when all the lines are massless, as in many QCD calculations.

Although there is no such object as a genuine vector space of finite noninteger dimension, it is possible to construct an operation that behaves as if it were an integration over such a space. The operation was proved unique by Wilson, and explicit constructions have been made, so that consistency is assured at the level of all Feynman graphs. Whether a satisfactory definition beyond perturbation theory exists remains to be determined.

It is convenient to arrange that the renormalized coupling is dimensionless in the regulated theory. This is done by changing the normalization of $\lambda$ with the aid of an extra parameter, the unit of mass $\mu$:

$$\lambda_0 = \mu^{2\epsilon}(\lambda + \text{counter-terms}) \qquad [15]$$

with $\lambda$ and $\mu$ being held fixed when $\epsilon \longrightarrow 0$. (Thus, the basic interaction in eqn [13] is changed to $-\lambda\mu^{2\epsilon}\phi^4/4!$.) Then for the one-loop graph of eqn [2], dimensionally regularized Feynman parameter methods give

$$-\mathrm{i}\lambda^2 I(p; m, \epsilon) = \frac{\mathrm{i}\lambda^2}{32\pi^2}(4\pi)^\epsilon \Gamma(\epsilon) \times \int_0^1 \mathrm{d}x \left[\frac{m^2 - p^2 x(1-x) - \mathrm{i}0}{\mu^2}\right]^{-\epsilon} \qquad [16]$$

A natural renormalization procedure is to subtract the pole at $\epsilon = 0$, but it is convenient to accompany this with other factors to remove some universally occurring finite terms. So $\overline{\mathrm{MS}}$ renormalization ("modified minimal subtraction") is defined by using the counter-term

$$-\mathrm{i}A(\epsilon)\lambda^2 = -\mathrm{i}\frac{\lambda^2 S_\epsilon}{32\pi^2\epsilon} \qquad [17]$$

where $S_\epsilon \stackrel{\text{def}}{=} (4\pi\, \mathrm{e}^{-\gamma_{\mathrm{E}}})^\epsilon$, with $\gamma_{\mathrm{E}} = 0.5772\ldots$ being the Euler constant. This gives a renormalized integral (at $\epsilon = 0$)

$$-\frac{\mathrm{i}\lambda^2}{32\pi^2}\int_0^1 \mathrm{d}x \ln\left[\frac{m^2 - p^2 x(1-x)}{\mu^2}\right] \qquad [18]$$

which can be evaluated easily. A particularly simple result is obtained at $m = 0$:

$$\frac{\mathrm{i}\lambda^2}{32\pi^2}\left[-\ln\frac{-p^2}{\mu^2} + 2\right] \qquad [19]$$

This formula symptomizes important and very useful algorithmic simplifications in the higher-order massless calculations common in QCD.

The $\overline{\mathrm{MS}}$ scheme amounts to a *de facto* standard for QCD. At higher orders a factor of ${S_\epsilon}^L$ is used in the counter-terms, with $L$ being the number of loops.

## Coordinate Space

Quantum fields are written as if they are functions of $x$, but they are in fact distributions or generalized functions, with quantum-mechanical operator values. This indicates that using products of fields is dangerous and in need of careful definition. The relation with ordinary distribution theory is simplest in the coordinate-space version of Feynman graphs. Indeed in the 1950s, Bogoliubov and Shirkov formulated renormalization as a problem of defining products of the singular numeric-valued distributions in coordinate-space Feynman graphs; theirs was perhaps the best treatment of renormalization in that era.

For example, the coordinate-space version of eqn [5] is

$$-\lambda^2 \lim_{a\to 0} \int \mathrm{d}^4x\,\mathrm{d}^4y\, f(x,y) \times \left[\tfrac{1}{2}\tilde{S}(x-y;m,a)^2 + \mathrm{i}A(a)\delta^{(4)}(x-y)\right] \quad [20]$$

where $x$ and $y$ are the coordinates for the interaction vertices, $f(x,y)$ is the product of external-line free propagators, and $\tilde{S}(x-y;m,a)$ is the coordinate-space free propagator, which at $a=0$ has a singularity

$$\frac{1}{4\pi^2[-(x-y)^2 + \mathrm{i}0]} \quad [21]$$

as $(x-y)^2 \to 0$. We see in eqn [20] a version of the Hadamard finite part of a divergent integral, and renormalization theory generalizes this to particular kinds of arbitrarily high-dimension integrals. The physical realization and justification of the use of the finite-part procedure is in terms of renormalization of parameters in the Lagrangian; this also gives the procedure a significance that goes beyond the integrals themselves and involves the full nonperturbative formulation of QFT.

## General Counter-Term Formulation

We have written $\mathcal{L}$ as a basic Lagrangian density plus counter-terms, and have seen in an example how to cancel divergences at one-loop order. In this section, we will see how the procedure works to all orders. The central mathematical tool is Bogoliubov's $R$-operation. Here the counter-terms are expanded as a sum of terms, one for each basic one-particle irreducible (1PI) graph with a non-negative degree of divergence. To each basic graph for a Green function is added a set of counter-term graphs associated with divergences for subgraphs. The central theorem of renormalization is that this procedure does in fact remove all the UV divergences, with the form of the counter-terms being determined by the simple computation of the degree of divergence for 1PI graphs.

To see the essential difficulty to be solved, consider a two-loop graph like the first one in Figure 3. Its divergence is not a polynomial in external momenta, and is therefore not canceled by an allowed counter-term. This is shown by differentiation with respect to external momenta, which does not produce a finite result because of the divergent one-loop subgraph. But for consistency of the theory, the one-loop counter-terms already computed must be themselves put into loop graphs. Among others, this gives the second graph of Figure 3, where the cross denotes that a counter-term contribution is used. The contribution used here is actually 2/3 of the total one-loop counter-term, for reasons of symmetry factors that are not fully evident at first sight. The remainder of the one-loop coupling renormalization cancels a subdivergence in another two-loop graph. It is readily shown that the divergence of the sum of the first two graphs in Figure 3 is momentum independent, and thus can be canceled by a vertex counter-term.

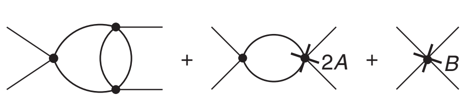

**Figure 3** A two-loop graph and its counter-terms. The label $B$ indicates that it is the two-loop overall counter-term for this graph.

This method is fully general, and is formalized in the Bogoliubov $R$-operation, which gives a recursive specification of the renormalized value $R(G)$ of a graph $G$:

$$R(G) \stackrel{\text{def}}{=} G + \sum_{\{\gamma_1,\ldots,\gamma_n\}} G|_{\gamma_i\to C(\gamma_i)} \quad [22]$$

The sum is over all sets of nonintersecting 1PI subgraphs of $G$, and the notation $G|_{\gamma_i\to C(\gamma_i)}$ denotes $G$ with all the subgraphs $\gamma_i$ replaced by associated counter-terms $C(\gamma_i)$. The counter-term $C(\gamma)$ of a 1PI graph $\gamma$ has the form

$$C(\gamma) \stackrel{\text{def}}{=} -T(\gamma + \text{counter-terms for subdivergences}) \quad [23]$$

Here $T$ is an operation that extracts the divergent part of its argument and whose precise definition gives the renormalization scheme. For example, in minimal subtraction we define

$$T(\Gamma) = \text{pole part at } \epsilon = 0 \text{ of } \Gamma \quad [24]$$

We formalize the term inside parentheses in eqn [23] as

$$\bar{R}(\gamma) \stackrel{\text{def}}{=} \gamma + \text{counterterms for subdivergences} = \gamma + {\sum_{\{\gamma_1,\ldots,\gamma_n\}}}' G|_{\gamma_i\to C(\gamma_i)} \quad [25]$$

where the prime on the $\sum'$ denotes that we sum over all sets of nonintersecting 1PI subgraphs except for the case that there is a single $\gamma_i$ equal to the whole graph (i.e., the term with $n=1$ and $\gamma_1=\gamma$ is omitted).

Note that, for the $\overline{\text{MS}}$ scheme, we define the $T$ operation to be applied to a factor of constant dimension obtained by taking the appropriate power of $\mu^\epsilon$ outside of the pole-part operation. Moreover, it is not a strict pole-part operation; instead each

pole is to be multiplied by ${S_\epsilon}^L$, where $L$ is the number of loops, and $S_\epsilon$ is defined after eqn [17].

Equations [22]–[25] give a recursive construction of the renormalization of an arbitrary graph. The recursion starts on one-loop graphs, since they have no subdivergences, that is, $C(\gamma) = -T(\gamma)$ for a one-loop 1PI graph.

Each counter-term $C(\gamma)$ is implemented as a contribution to the counter-term Lagrangian. The Feynman rules ensure that once $C(\gamma)$ has been computed, it appears as a vertex in bigger graphs in such a way as to give exactly the counter-terms for subdivergences used in the $R$-operation. It has been proved that the $R$-operation does in fact give finite results for Feynman graphs, and that basic power counting in exactly the same fashion as at one-loop determines the relevant operators.

In early treatments of renormalization, a problem was caused by graphs like **Figure 4**. This graph has three divergent subgraphs which overlap, rather than being nested. Within the $R$-operation approach, such cases are no harder to deal with than merely nested divergences.

The recursive specification of $R$-operation can be converted to a nonrecursive formulation by the forest formula of Zavyalov and Stepanov, later rediscovered by Zimmerman. It is normally the recursive formulation that is suited to all-orders proofs.

Whether these results, proved to all orders of perturbation theory, genuinely extend to the complete theory is not so easy to answer, certainly in a realistic four-dimensional QFT. One illuminating case is of a nonrelativistic quantum mechanics model with a delta-function potential in a two-dimensional space. Renormalization can be applied just as in field theory, but the model can also be treated exactly, and it has been shown that the results agree with perturbation theory.

Perturbation series in relativistic QFTs can at best be expected to be asymptotic, not convergent. So instead of a radius of convergence, we should talk about a region of applicability of a weak-coupling expansion. In a direct calculation of counter-terms, etc., the radius of applicability shrinks to zero as the regulator is removed. However, we can deduce the expansion for a renormalized quantity, whose expansion is expected to have a nonzero range of applicability. We can therefore appeal to the uniqueness of power series expansions to allow the

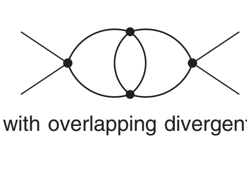

**Figure 4** Graph with overlapping divergent subgraphs.

calculation, at intermediate stages, to use bare quantities that are divergent as the regulator is removed.

## Renormalizability, Non-Renormalizability, and Super-Renormalizability

The basic power-counting method shows that if a theory with conventional fields (at $n = 4$) has only operators of dimension 4 or less in its $\mathcal{L}$, then the necessary counter-term operators are also of dimension 4 or less. So if we start with a Lagrangian with all possible such operators, given the field content, then the theory is renormalizable. This is not the whole story, as we will see in the discussion of gauge theories.

If we start with a Lagrangian containing operators of dimension higher than 4, then renormalization requires operators of ever higher dimension as counter-terms when one goes to higher orders in perturbation theory. Therefore, such a theory is said to be perturbatively non-renormalizable. Some very powerful methods of cancelation or some nonperturbative effects are needed to evade this result.

In the case of dimension-4 interactions, there is only a finite set of operators given the set of basic fields, but divergences occur at arbitrarily high orders in perturbation theory. If, instead, all the operators have at most dimension 3, then only a finite number of graphs need counter-terms. Such theories are called super-renormalizable. The divergent graphs also occur as subgraphs inside bigger graphs, of course. There is only one such theory in a four-dimensional spacetime: $\phi^3$ theory, which suffers from an energy density that is unbounded from below, so it is not physical. In lower spacetime dimension, where the requirements on operator dimension are different, there are many more known super-renormalizable theories, some with a very rigorous proof of existence.

All the above characterizations rely primarily on perturbative analysis, so they are subject to being not quite accurate in an exact theory, but they form a guide to the relevant issues.

## Renormalization and Symmetries: Gauge Theories

In most physical applications, we are interested in QFTs whose Lagrangian is restricted to obey certain symmetry requirements. Are these symmetries preserved by renormalization? That is, is the Lagrangian with all necessary counter-terms still invariant under the symmetry?

We first discuss nonchiral symmetries; these are symmetries in which the left-handed and right-handed parts of Dirac fields transform identically.

For Poincaré invariance and simple global internal symmetries, it is simplest to use a regulator, like dimensional regularization, which respects the symmetries. Then it is easily shown that the symmetries are preserved under renormalization. This holds even if the internal symmetries are spontaneously broken (as happens with a "wrong-sign mass term," e.g., negative $m^2$ in eqn [1]).

The case of local gauge symmetries is harder. But their preservation is more important, because gauge theories contain vector fields which, without a gauge symmetry, generally give unphysical features to the theory. For perturbation theory, BRST quantization is usually used, in which, instead of gauge symmetry, there is a BRST supersymmetry. This is manifested at the Green function level by Slavnov–Taylor identities that are more complicated, in general, than the Ward identities for simple global symmetries and for abelian local symmetries.

Dimensional regularization preserves these symmetries and the Slavnov–Taylor identities. Moreover, the $R$-operation still produces finite results with local counter-terms, but cancelations and relations occur between divergences for different graphs in order to preserve the symmetry. A simple example is QED, which has an abelian U(1) gauge symmetry, and whose gauge-invariant Lagrangian is

$$\mathcal{L} = -\frac{1}{4}\left(\partial_\mu A_\nu^{(0)} - \partial_\nu A_\mu^{(0)}\right)^2 + \bar{\psi}_0\left(\mathrm{i}\gamma^\mu\partial_\mu - e_0 A_\mu^{(0)} - m_0\right)\psi_0 \qquad [26]$$

At the level of individual divergent 1PI graphs, we get counter-terms proportional to ${A_\mu}^2$ and to $({A_\mu}^2)^2$, operators not present in the gauge-invariant Lagrangian. The Ward identities and Slavnov–Taylor identities show that these counter-terms cancel when they are summed over all graphs at a given order of renormalized perturbation theory. Moreover, the renormalization of coupling and the gauge field are inverse, so that $e_0 A_\mu^{(0)}$ equals the corresponding object with renormalized quantities, $\mu^\epsilon e A_\mu$. Naturally, sums of contributions to a counter-term in $\mathcal{L}$ can only be quantified with use of a regulator.

In nonabelian theories, the gauge-invariance properties are not just the absence of certain terms in $\mathcal{L}$ but quantitative relations between the coefficients of terms with different numbers of fields. Even so, the argument with Slavnov–Taylor identities generalizes appropriately and proves renormalizability of QCD, for example. But note that the relation concerning the product of the coupling and the gauge field does not generally hold; the form of the gauge transformation is itself renormalized, in a certain sense.

## Anomalies

Chiral symmetries, as in the weak-interaction part of the gauge symmetry of the standard model, are much harder to deal with. Chiral symmetries are ones for which the left-handed and right-handed components of Dirac field transform independently under different components of the symmetry group, local or global as the case may be. Occasionally, some or other of the left-handed or right-handed components may not even be present.

In general, chiral symmetries are not preserved by regularization, at least not without some other pathology. At best one can adjust the finite parts of counter-terms such that in the limit of the removal of the regulator, the Ward or Slavnov–Taylor identities hold. But in general, this cannot be done consistently, and the theory is said to suffer from an anomaly. In the case of chiral gauge theories, the presence of an anomaly prevents the (candidate) theory from being valid. A dramatic and nontrivial result (Adler–Bardeen theorem and some nontrivial generalizations) is that if chiral anomalies cancel at the one-loop level, then they cancel at all orders.

Similar results, but more difficult ones, hold for supersymmetries.

The anomaly cancelation conditions in the standard model lead to constraints that relate the lepton content to the quark content in each generation. For example, given the existence of the $b$ quark, and the $\tau$ and $\nu_\tau$ leptons (of masses around 4.5 GeV, 1.8 GeV, and zero respectively), it was strongly predicted on the grounds of anomaly cancelation that there must be a $t$ quark partner of the $b$ to complete the third generation of quark doublets. This prediction was much later vindicated by the discovery of the much heavier top quark with $m_t \simeq 175$ GeV.

## Renormalization Schemes

A precise definition of the counter-terms entails a specification of the renormalization prescription (or scheme), so that the finite parts of the counter-terms are determined. This apparently induces extra arbitrariness in the results. However, in the $\phi^4$ Lagrangian (for example), there are really only two independent parameters. (A scaling of the field does not affect any observables, so we do not count $Z$ as a parameter here.) Thus, at fixed regulator parameter $a$ or $\epsilon$, renormalization actually just gives a reparametrization of a two-parameter collection of theories. A renormalization prescription gives the

change of variables between bare and renormalized parameters, a rather singular transformation when the regulator is removed. If we have two different prescriptions, we can deduce a transformation between the renormalized parameters in the two schemes. The renormalized mass and coupling $m_1$ and $\lambda_1$ in one scheme can be obtained as functions of their values $m_2$ and $\lambda_2$ in the other scheme, with the bare parameters, and hence the physics, being the same in both schemes. Since these are renormalized parameters, the removal of the regulator leaves the transformation well behaved.

Generalization to all renormalizable theories is immediate.

## Renormalization Group and Applications and Generalizations

One part of the choice of renormalization scheme is that of a scale parameter such as the unit of mass $\mu$ of the $\overline{\text{MS}}$ scheme. The physical predictions of the theory are invariant if a change of $\mu$ is accompanied by a suitable change of the renormalized parameters, now considered as $\mu$-dependent parameters $\lambda(\mu)$ and $m(\mu)$. These are called the effective, or running, coupling and mass. The transformation of the parametrization of the theory is called an RG transformation.

The bare coupling and mass $\lambda_0$ and $m_0$ are RG invariant, and this can be used to obtain equations for the RG evolution of the effective parameters from the perturbatively computed counter-terms. For example, in $\phi^4$ theory, we have (in the renormalized theory after removal of the regulator)

$$\frac{d\lambda}{d\ln\mu^2} = \beta(\lambda) \qquad [27]$$

with $\beta(\lambda) = 3\lambda^2/(16\pi^2) + O(\lambda^3)$. As exemplified in eqns. [18] and [19], Feynman diagrams depend logarithmically on $\mu$. By choosing $\mu$ to be comparable to the physical external momentum scale, we remove possible large logarithms in this and higher orders. Thus, provided that the effective coupling at this scale is weak, we get an effective perturbation expansion.

This is a basic technique for exploiting perturbation theory in QCD, for the strong interactions, where the interactions are not automatically weak. In this theory the RG $\beta$ function is negative so that the coupling decreases to zero as $\mu \to \infty$; this is the asymptotic freedom of QCD.

A closely related method is that associated with the Callan–Symanzik equation, which is a formulation of a Ward identity for anomalously broken scale invariance. However, RG methods are the actually used ones, normally, even if sometimes an RG equation is incorrectly labeled as a Callan–Symanzik equation.

The elementary use of the RG is not sufficient for most interesting processes, which involve a set of widely different scales. Then more powerful theorems come into play. Typical are the factorization theorems of QCD (*see* Quantum Chromodynamics). These express differential cross sections for certain important reactions as a product of quantities that involve a single scale:

$$d\sigma = C(Q, \mu, \lambda(\mu)) \otimes f(m, \mu, \lambda(\mu)) + \text{small correction} \qquad [28]$$

The product is typically a matrix or a convolution product. The factors obey nontrivial RG equations, and these enable different values of $\mu$ to be used in the different factors. Predictions arise because some factors and the kernels of the RG equation are perturbatively calculable, with a weak effective coupling. Other factors, such as $f$ in eqn [28], are not perturbative. These are quantities with names like "parton distribution functions," and they are universal between many different processes. Thus, the nonperturbative functions can be measured in a limited set of reactions and used to predict cross sections for many other reactions with the aid of calculations of the perturbative factors.

Ultimately, this whole area depends on physical phenomena associated with renormalization.

## Concluding Remarks

The actual ability to remove the divergences in certain QFTs to produce consistent, finite, and nontrivial theories is a quite dramatic result. Moreover, associated with the integrals that give the divergences is behavior of the kind that is analyzed with RG methods and generalizations. So the properties of QFTs associated with renormalization get tightly coupled to many interesting consequences of the theories, most notably in QCD.

QFTs are actually very abstruse and difficult theories; only certain aspects currently lend themselves to practical calculations. So the reader should not assume that all aspects of their rigorous mathematical treatment are perfect. Experience, both within the theories and in their comparison with experiment, indicates, nevertheless, that we have a good approximation to the truth.

When one examines the mathematics associated with the *R*-operation and its generalizations with factorization theorems, there are clearly present some interesting mathematical structures that are not yet formulated in their most general terms. Some

indications of this can be seen in the work by Connes and Kreimer (*see* Hopf Algebra Structure of Renormalizable Quantum Field Theory), where it is seen that renormalization is associated with a Hopf algebra structure for Feynman graphs.

With such a deep subject, it is not surprising that it lends itself to other approaches, notably the Connes–Kreimer one and the Wilsonian one (*see* Exact Renormalization Group). Readers new to the subject should not be surprised if it is difficult to get a fully unified view of these different approaches.

## Notes on Bibliography

Reliable textbooks on quantum field theory are Sterman (1993) and Weinberg (1995). A clear account of the foundations of perturbative QCD methods is given by Sterman (1996).

A pedagogical account of renormalization and related subjects may be found in Collins (1984). The best account of renormalization theory before the 1970s is given by Bogoliubov and Shirkov (1959); the viewpoint is very modern, including a coordinate-space distribution-theoretic view. A full account of the Wilsonian method as applied to renormalization is given by Polchinski (1984).

Manuel and Tarrach (1994) give an excellent account of renormalization for a theory with a non-relativistic delta-function potential in 2 space dimensions, which provides a fully tractable model.

Tkachov (1994) reviews a systematic application of distribution theoretic methods to asymptotic problems in QFT. Finally, Weinzierl (1999) provides a construction of dimensional regularization with the aid of *K*-theory using an underlying vector space of the physical integer dimension. Other constructions, referred to in this paper, follow Wilson and use an infinite-dimensional underlying space.

# Renormalization: Statistical Mechanics and Condensed Matter

**M Salmhofer**, Universität Leipzig, Leipzig, Germany

## Renormalization Group and Condensed Matter

Statistical mechanical systems at critical points exhibit scaling laws of order parameters, susceptibilities, and other observables. The exponents of these laws are universal, that is, independent of most details of the system. For example, the liquid–gas transition for real gases has the same exponents as the magnetization transition in the three-dimensional Ising model.

The renormalization group (RG) was developed by Kadanoff, Wilson, and Wegner, to understand these critical phenomena (Domb and Green 1976). The central idea is that the system becomes scale invariant at the critical point, which makes it natural to average over degrees of freedom on increasing length scales successively in the

calculation of the partition function. This leads to a map between effective interactions associated to different length scales. Thus, the focus shifts from the analysis of a single interaction to that of a flow on a space of interactions. This space is in general much larger than the original formulation of the model would suggest: the description of long-distance or low-energy properties may be in terms of variables that were not even present in the original formulation of the system. Phenomenologically, this corresponds to the emergence of collective degrees of freedom.

Condensed matter theory is itself already an effective theory, and its "microscopic" formulation gets inputs from the underlying theories, which determine in particular the statistics of the particles and their interactions at the scale of atomic energies. At much lower-energy scales, which are relevant for low-temperature phenomena in condensed matter, collective excitations of different, sometimes exotic, statistics may emerge, but the starting point is given naturally in terms of fermionic and bosonic particles. For this reason, the discussion given below will be split in these two cases.

A major difference between high-energy and condensed matter systems is that the latter have a well-defined Hamiltonian which can be used to define the finite-volume ensembles of quantum statistical mechanics and which determines the time evolution, as well as various analyticity properties.

The relevant spatial dimensions in condensed matter are $d \leq 3$, but some results in higher dimensions relevant for the development of the method will also be discussed below. The cases $d = 1$ and $d = 2$ have always been of mathematical interest but in recent years have become important for the theory of new materials.

Some interesting topics cannot be covered here due to space restrictions, notably the application of renormalization methods to membrane theory (see Wiese (2001)) and renormalization methods for operators (see Bach *et al.* (1998)).

## The Renormalization Group

In this section we briefly describe the setup of two important versions of the RG, namely the block spin RG and the RG based on scale decompositions of singular covariances.

### Block spin RG

Let $\Lambda$ be a finite lattice, for example, a finite subset of $\mathbb{Z}^d$. For the following, it is convenient to take $\Lambda$ to be a cube of side-length $L^K$ for $L > 1$ and some large $K$. Let $T$ be a set and $\Phi_\Lambda = \{\phi : \Lambda \to T\}$ be the set of spin configurations. Common examples for the target space $T$ are $T = \{-1, 1\}$ for the Ising model, $T = S^{N-1}$ for the O($N$) model, and $T = \mathbb{R}^n$ for unbounded spins. Let $S_\Lambda : \Phi_\Lambda \to \mathbb{R}, \phi \mapsto S_\Lambda(\phi)$ be an interaction and

$$Z(\Lambda, S_\Lambda) = \int \prod_{x \in \Lambda} \mathrm{d}\phi(x) \mathrm{e}^{-S_\Lambda(\phi)} \qquad [1]$$

In the unbounded case, $S_\Lambda$ is assumed to grow sufficiently fast for $|\phi| \to \infty$, so that $Z$ exists; for the case of a finite set $T$, the integral is replaced by a sum. Denote the corresponding Boltzmann factor by $\rho(\Lambda, S_\Lambda)$,

$$\rho(\Lambda, S_\Lambda)(\phi) = \frac{1}{Z(\Lambda, S_\Lambda)} \mathrm{e}^{-S_\Lambda(\phi)} \qquad [2]$$

The block spin transformation consists of an integration step and a rescaling step. Divide the lattice into cubic blocks of side-length $L$ and define a new lattice $\Lambda'$ by associating one lattice site of the new lattice to each $L$-block of the old lattice. For any $\phi' : \Lambda' \to T$, let

$$\rho'(\phi') = \int \prod_{x \in \Lambda} \mathrm{d}\phi(x) P(\phi', \phi) \mathrm{e}^{-S_\Lambda(\phi)} \qquad [3]$$

where $P(\phi', \phi) \geq 0$ and $\int \prod_{x' \in \Lambda'} \mathrm{d}\phi'(x') P(\phi', \phi) = 1$ for all $\phi$, so that $\rho'$ remains a probability distribution. Since $\rho'$ is positive, one defines

$$S'_{\Lambda'}(\phi') = -\log \rho'(\phi') \qquad [4]$$

By construction, the partition function is invariant: $Z(\Lambda', S'_{\Lambda'}) = Z(\Lambda, S_\Lambda)$. The new lattice $\Lambda'$ has spacing $L$; now rescale to make it a unit lattice. This completes the RG step in finite volume.

In an algorithmic sense, the "blocking rule" $P(\phi', \phi)$ can be viewed as a transition probability of a configuration $\phi$ to a configuration $\phi'$. $P$ may be deterministic, that is, simply fix $\phi'$ as a function of $\phi$. From the intuition of averaging over local fluctuations, $\phi'$ is often taken to be some average of $\phi(x)$ at $x$ in a block around $x'$, hence the name.

Obviously, the thus defined RG transformation often cannot be iterated arbitrarily, since in every application, the number of points of the lattice shrinks by a factor $L^d$, so that after $K$ iterations, a lattice with only a single point is left over. It is necessary to take the infinite-volume limit $L \to \infty$ to obtain a map that operates from a space to itself. However, [4] can become problematic in that limit: Gibbs measures $\rho$ can map to measures $\rho'$ whose large-deviation properties differ from those of Gibbs measures. The discussion of this problem and its solution is reviewed in Bricmont and Kupiainen (2001). The problem can be

solved in different ways, relaxing conditions on Gibbs measures or, in the Ising model, changing the description from the spins to the contours. The crucial point is that the difficulties arise only because [4] is applied globally, that is, to every $\phi'$. The set of bad $\phi'$ has very small probability.

Block spin methods have been used in mathematical construction of quantum field theories, for example, in the work of Gawedzki and Kupiainen (1985) and Balaban (1988) (see the subsection "Field theory and statistical mechanics"). The above-mentioned problem was avoided there by not taking a logarithm in the so-called large-field region (which has very small probability).

### Scale Decomposition RG

The generating functionals of quantum field theory and quantum statistical mechanics can be cast into the form

$$Z(C,V,\phi)=\int \mathrm{d}\mu_C(\phi')\,\mathrm{e}^{-V(\phi'+\phi)} \qquad [5]$$

Here $\mathrm{d}\mu_C$ denotes the Gaussian measure with covariance $C$, and $V$ is the two-body interaction between the particles. The field variables are real or complex for bosons and Grassmann-valued for fermions. Differentiating $\log Z$ with respect to the external field $\phi$ generates the connected amputated correlation functions. The covariance determines the free propagation of particles; the interaction their collisions.

In most cases, such functional integrals are *a priori* ill-defined, even if $V$ is small (and bounded from below) because the covariance $C$ is singular. That is, the integral kernel $C(X,X')$ of the operator $C$ either diverges as $|x-x'|\to 0$ (ultraviolet (UV) problem) or $C(X,X')$ has a slow decay as $|x-x'|\to\infty$ (infrared (IR) problem). In our notational convention, $X$ may, in addition to the configuration variable $x$, also contain discrete indices of the fields, such as a spin or color index. The dependence of $C$ on $x$ and $x'$ is assumed to be of the form $x-x'$. A typical example is the massless Gaussian field in $d$ dimensions, where $C$ is the inverse Fourier transform of $\hat{C}(k)=1/k^2$, $k\in\mathbb{R}^d$, which has both a UV and an IR problem, or its lattice analog,

$$\hat{D}(k)=\left(\frac{2}{a^2}\sum_{i=1}^{d}(1-\cos(ak_i)\right)^{-1}$$

with $a$ the lattice constant, which has only an IR problem. A typical interaction is of the type

$$V(\phi)=\int \mathrm{d}X\,\mathrm{d}Y\bar{\phi}(X)\phi(X)v(X,Y)\bar{\phi}(Y)\phi(Y) \qquad [6]$$

Again, we assume that the potential $v$ depends on $x$ and $y$ only via $x-y$, so that translation invariance holds. In both UV and IR cases, naive perturbation theory fails even as a formal power series. That is, writing $V=\lambda V_0$, with a coupling constant $\lambda$ which is treated as a formal expansion parameter, the singularity of $C$ leads to termwise divergences in the series. The theory is called perturbatively renormalizable if all divergences can be removed by posing counter-terms of certain types, which are fixed by physically sensible renormalization conditions. Identifying the UV renormalizable theories was a breakthrough in high-energy physics. The IR renormalization problem is different, and in some respects harder, because there is almost no freedom to put counter-terms: the microscopic model is given from the start. This will be discussed in more detail below for an example.

A much more ambitious, and largely open, project is to do this renormalization nonperturbatively, that is, to treat $\lambda$ as a real (typically, small) parameter. Some results will be discussed below.

The RG is set up by a scale decomposition $C=\sum_j C_j$. In the example of the massless Gaussian field, one would take each $\hat{C}_j$ to be a $C^\infty$ function supported in the region $\{k\in\mathbb{R}^d : M^j\le k^2\le M^{j+1}\}$, where $M>1$ is a fixed constant, and the summation over $j$ runs over $\mathbb{Z}$.

The scale decomposition of $C$ leads to a representation of [5] by an iteration of Gaussian convolution integrals with covariances $C_j$, hence a sequence of effective interactions $V_j$, defined recursively by

$$\mathrm{e}^{-V_j(\phi)}=\int \mathrm{d}\mu_{C_{j+1}}(\phi')\,\mathrm{e}^{-V_{j+1}(\phi'+\phi)}, \quad V_0=V \qquad [7]$$

For a singular covariance, the scale decomposition is an infinite sum. A formal object like [5] is now regularized by starting with a finite sum, that is, imposing a UV and IR cutoff, which is mathematically well defined, and then taking limits of the thus defined objects. Again, in condensed matter applications, imposing an IR cutoff is an operation that needs to be justified, for example, by showing that taking the limit as the cutoff is removed commutes with the infinite-volume limit.

Note that the RG map, which is the iteration $V_j\mapsto V_{j-1}$, goes to lower and lower $j$, corresponding to longer and longer length scales. The convention that the iteration starts at some fixed $j$, for example, $j=0$, is appropriate for IR problems. In UV problems, the iteration would start at some large $J_{\mathrm{UV}}$, which defines a UV cutoff and is taken to infinity, to remove the cutoff, at the end.

A variant using a continuous scale decomposition, $C=\int \mathrm{d}s\dot{C}_s$, originally due to Wegner and Houghton, became very popular after Polchinski (1984) used it

to give a short argument for perturbative renormalizability. Polchinski's equation, the analog of the recursion [7], reads

$$\frac{\partial V}{\partial s} = -\frac{1}{2} e^{V} \Delta_{\dot{C}_s} e^{-V} = \frac{1}{2} \Delta_{\dot{C}_s} V - \frac{1}{2} \left( \frac{\delta V}{\delta \phi}, \dot{C}_s \frac{\delta V}{\delta \phi} \right) \quad [8]$$

Here

$$\Delta_C = \left( \frac{\delta}{\delta \phi}, C \frac{\delta}{\delta \phi} \right)$$

denotes the Laplacian in field space associated to the covariance $C$. Polchinski's argument has been developed into a mathematical tool that applies to many models. For an introduction to perturbative renormalization using this method, see Salmhofer (1998). Equations of the type [8] have also been very useful beyond perturbation theory: much work has been done based on the beautiful representation of Mayer expansions found in Brydges and Kennedy (1987) using RG equations.

### Mathematical Structure and Difficulties

The RG flow is thus, depending on the implementation, either a sequence or a continuous flow of interactions. Setting up this flow in mathematical terms is not easy and indeed part of the mathematical RG analysis is to find a suitable space of interactions that is left invariant by the successive convolutions, and then to control the RG iteration. A serious problem is the proliferation of interactions: already a single application of the RG transformation [7] maps a simple interaction, such as [6], to a nonlocal functional of the fields,

$$V_j(\phi) = \sum_{m \geq 0} \int dX_1 \cdots dX_m \times v_m^{(j)}(X_1, \ldots, X_m)\, \phi(X_1) \cdots \phi(X_m) \quad [9]$$

Already for perturbative renormalization, one needs to extract local terms, calculate their flow more explicitly, and control the power counting of the remainder. The convergence of the series is not an issue in formal perturbation theory because in every finite order $r$ in $\lambda$, the sum over $m$ is finite.

For nonperturbative renormalization, however, the problem is much more serious. For bosonic systems, the expansion in powers of the fields in [9] is divergent, and one needs a split into small-field and large-field regions and cluster expansions to obtain a well-defined sequence of effective actions (Gawedzki and Kupiainen 1985, Feldman *et al.* 1987, Rivassean 1993). That is, the local parts are extracted and treated explicitly only in the small-field region, and this is combined with estimates on the rareness of large-field regions using cluster expansions. For fermions, the expansion in powers of the fields can be proved to converge for regular, summable covariances, which leads to substantial technical simplifications.

The spatial proliferation of interactions is absent only in certain one-dimensional and in specially constructed higher-dimensional models, the so-called "hierarchical models." In these models, the search for an RG fixed point is still a nonlinear fixed-point problem, whose treatment leads to interesting mathematical results.

This article will be restricted to the mathematical use of the RG both in perturbative and nonperturbative quantum field theory of condensed matter systems. Many nonrigorous but very interesting applications have also come out of this method, showing that it also works well in practice, but they will not be reviewed here. Before discussing condensed matter systems, the pioneering works done on the mathematical RG, which were largely motivated by high-energy physics, will be reviewed briefly, as they laid the foundation of much of the technique used later in the condensed matter case.

### Field Theory and Statistical Mechanics

Because of the close connection between quantum field theory and statistical mechanics given by formulas of the Feynman–Kac type, a significant amount of work on the mathematical RG focused on models of classical statistical mechanics in connection with field theories and gauge theories. Here we mention some of the pioneering results in that field.

The scale decomposition method was developed in a mathematical form and applied to perturbative UV renormalization of scalar field theories, as well as nonperturbative analysis of some models, by Gallavotti and Nicolò (Gallavotti 1985).

Infrared $\phi^4$ theory in four dimensions was constructed using block spin methods (Gawedzki and Kupiainen 1985) and scale decomposition RG (Feldman *et al.* 1987). An essential feature of the $\phi_4^4$ model is its IR asymptotic freedom, meaning that the local part of the effective quartic interaction tends to zero in the IR limit.

Block spin methods were used by Balaban (1988) to construct gauge theories in three and four dimensions. For gauge theories, the block spin RG has the major advantage that it allows to define a gauge-invariant RG flow. The scale decomposition violates gauge invariance, which creates substantial technical problems (Rivasseau 1993).

## Condensed Matter: Fermions

Starting with the seminal work of Feldman and Trubowitz (1990, 1991) and Benfatto and Gallavotti (1995), this field has become one of the most successful applications of the mathematical RG. We use this example to discuss the scale decomposition method in a bit more detail.

We shall mainly focus on models in $d \geq 2$ dimensions (the case $d = 1$ is described in detail in Benfatto and Gallavotti (1995)). The system is put into a finite (very large) box $\Lambda$ of side-length $L$. For simplicity we take periodic boundary conditions. The Hilbert space for spin-1/2 electrons is the fermionic Fock space $\mathcal{F} = \bigoplus_{n\geq 0} \bigwedge^n L^2(\Lambda, \mathbb{C}^2)$. The grand canonical ensemble in finite volume is given by the density operator $\rho = Z^{-1} e^{-\beta(H-\mu N)}$, with the Hamiltonian $H$ and the number operator $N$, in the usual second quantized form. The parameter $\beta = T^{-1}$ is the inverse temperature and the chemical potential $\mu$ is an auxiliary parameter used to fix the average particle number.

The grand canonical trace defining the ensemble can be rewritten in functional-integral form. It takes the form [5], but now $d\mu_C$ stands for a Grassmann Gaussian "measure," which is really only a linear functional (for definitions, see, e.g., Salmhofer (1998, chapter 4 and appendix B)). A two-body interaction corresponds to a quartic interaction polynomial $V$, as in [6]. The covariance is (in the infinite-volume limit $L \to \infty$)

$$C(\tau, x) = \frac{1}{\beta} \sum_{\omega \in \mathbb{M}_F} \int \frac{dk}{(2\pi)^d} e^{i(k\cdot x - \omega\tau)} \hat{C}(\omega, k)$$
$$\hat{C}(\omega, k) = \frac{1}{i\omega - e(k)} \qquad [10]$$

where $\tau \in (0, \beta]$ is a Euclidian time variable and $k$ is the spatial momentum. The summation over $\omega$ runs over the set of fermionic Matsubara frequencies $\mathbb{M}_F = \pi T(2\mathbb{Z} + 1)$. The function $e(k) = \varepsilon(k) - \mu$, where $\varepsilon(k)$ is the band function given by the single-particle term in the Hamiltonian. For a lattice system, $k \in \mathcal{B}_d$, the momentum space torus (e.g., for the lattice $\mathbb{Z}^d, \mathcal{B}_d = \mathbb{R}^d/2\pi\mathbb{Z}^d$); for a continuous system, $k \in \mathbb{R}^d$, hence there is a spatial UV problem. Electrons in a crystal have a natural spatial UV cutoff (see Salmhofer (1998, chapter 4) for a discussion) so we assume in the following that there is either a UV cutoff or that the system is on a lattice. A nonperturbative definition of the functional integral involves a limit from discrete times (by the Trotter product formula); see, for example, Salmhofer (1998) or Feldman *et al.* (2003, 2004).

### Perturbative Renormalization

**Renormalization of the Fermi surface at zero temperature** In the limit $T \to 0$, the Matsubara frequency $\omega$ becomes a real variable, hence the propagator has a singularity at $\omega = 0$ and $k \in S$, where $S = \{k : e(k) = 0\}$, a codimension-1 subset of $\mathcal{B}_d$, is the Fermi surface. The existence of a Fermi surface which does not degenerate to a point is a characteristic feature of systems showing metallic behavior.

The singularity implies that $\hat{C} \notin L^p(\mathbb{R} \times \mathcal{B}_d)$ for any $p \geq 2$. Because terms of the type

$$\int d\omega \int dk F(\omega, k)\hat{C}(\omega, k) \times \prod_{i=1}^{p-1} \Big(T_i(\omega, k)\hat{C}(\omega, k)\Big) \qquad [11]$$

appear for all $p \geq 1$ in the formal perturbation expansion, with functions $T_i$ and $F$ that do not vanish on the singularity set of $C$, the perturbation expansion for observables is termwise divergent. The deeper reason for these problems is that the interaction shifts the Fermi surface so that the true propagator has a singularity of the form $G(\omega, k) = (i\omega - e(k) - \sigma(\omega, k))^{-1}$. If the self-energy $\sigma$ is a sufficiently regular function, $G$ has the same integrability properties as $C$, but the singularity of $G$ is on the set $\tilde{S} = \{k : e(k) + \sigma(0, k) = 0\}$ (the singularity in $\omega$ remains at $\omega = 0$).

Let $1 = \sum_{j\leq 0} \chi_j(\omega, k)$ be a $C^\infty$ partition of unity such that

$$\text{for } j < 0 \quad \text{supp } \chi_j \subset \{(\omega, k) : \epsilon_0 M^{j-2} \leq |i\omega - e(k)| \leq \epsilon_0 M^j\} \qquad [12]$$

where $M > 1$ and $\epsilon_0$ is a fixed constant (an energy scale determined by the global properties of the function $e$; see Salmhofer (1998, chapter 4)). The corresponding covariances $\hat{C}_j = \hat{C}_{\chi_j}$ have the properties that for $j < 0, \|\hat{C}_j\|_1 \leq \text{const.} M^j$ and $\|\hat{C}_j\|_\infty \leq \text{const.} M^{-j}$. Using these bounds and expanding $v_m^{(j)} = \sum_{r\geq 1} v_{m,r}^{(j)} \lambda^r$, one can derive estimates for the coefficient functions $v_{m,r}^{(j)}$.

Of course, the scale decomposition by itself does not solve the problem of the moving singularity. It only allows us to pinpoint the problematic terms in the expansion. To construct the self-energy $\sigma$, as well as all higher Green functions, a two-step method is used (Feldman and Trubowitz 1990, 1991, Feldman *et al.* 1996, 2000). First, a counterterm function $K$ which modifies $e$ is introduced, so that all two-point insertions $T_i$ get subtracted on the Fermi surface, hence replaced by $\tilde{T}_i(\omega, k) = T_i(\omega, k) - T_i(0, k')$, with $k'$ obtained from $k$ by a

projection to the Fermi surface (Feldman and Trubouitz 1990, 1991). Consequently, the $\tilde{T}_i$ vanish linearly on the Fermi surface, so that the integral over $k$ in [11] converges. The effect of the counter-term function $K$ can be described less technically: it fixes the Fermi surface to be $S$, the zero set of $e$. Thus, $K$ forces $S$ to be the Fermi surface of the interacting system. To achieve this, $K$ must be chosen a function of $e$, $k$, and $\lambda V$. In contrast to the situation for covariances with point singularities, the function $K$ will, for a nontrivial Fermi surface, be very different from the original $e$. It can, however, be constructed to all orders in perturbation theory for a large class of Fermi surfaces. More precisely, one can prove: if $e \in C^2(\mathcal{B}_d, \mathbb{R})$, $\hat{v} \in C^2(\mathcal{B}_d, \mathbb{R})$, and the Fermi surface $S$ contains no points $k$ with $\nabla e(k) = 0$ and no flat sides, then $K = \sum_r \lambda^r K_r$ exists as a formal power series in $\lambda$ and the map $e \mapsto e + K$ is locally injective on this set of $e$'s (Feldman *et al.* 1996, 2000). With this counter-term, the order-$r$ $m$-point functions on scale $j$ satisfy the bounds

$$\left\| \hat{v}_{m,r}^{(j)} \right\|_\infty \leq w_{m,r} M^{(4-m)j/2} |j|^r$$

and

$$\left\| \hat{v}_{m,r}^{(j)} \right\|_1 \leq \tilde{w}_{m,r} \qquad [13]$$

with constants $w_{m,r}$ and $\tilde{w}_{m,r}$. Here $\hat{v}_{m,r}^{(j)}$ is the Fourier transform of $v_{m,r}^{(j)}$ (see [9], with the momentum conservation delta function from translation invariance removed.

Equation [13] implies that in the RG sense, the two-point function is relevant, the four-point function is marginal, and all higher $m$-point functions are irrelevant.

In one dimension, the Fermi "surface" reduces to two points which are related by a symmetry, so the counter-term function $K$ is just a constant, that is, an adjustment of the chemical potential $\mu$, which is justified because $\mu$ is only an auxiliary parameter used to fix the average value of the particle number. The counter-term function is a constant also in higher dimensions in the special case $e(k) = k^2 - \mu$: there, rotational symmetry implies that $K$ can be chosen independent of $k$ (if $v$ is also rotationally symmetric). However, in the generic case of non-spherical Fermi surfaces, $K$ depends nontrivially on $k$, and an inversion problem arises: adding the counter-term changes the model. To obtain the Green functions of a model with a given dispersion relation and interaction $(E, V)$, one needs to show that given $E$ in a suitable set, the equation

$$e(k) + K(\lambda, e, V)(k) = E(k) \qquad [14]$$

has a unique solution. If this is done, the procedure for renormalization is as follows. For a model given by dispersion relation and interaction $(E, V)$, solve [14], then add and subtract $e$ in the kinetic term. This automatically puts $K = E - e$ as a counter-term, and the expansion is now set up automatically with the right counter-term. The function $K$ describes the shift from the Fermi surface of the free system (the zero set of $E$) to that of the interacting system (the zero set of $e$). Proving that $K$ is sufficiently regular and solving [14] is nontrivial. Uniqueness of the solution follows from the above stated properties of $K$ as a function of $e$. Existence was shown for a class of Fermi surfaces with strictly positive curvature in Feldman *et al.* (1996, 2000), to every order in perturbation theory. This implies a bijective relation between the Fermi surfaces of the free and the interacting model.

**Positive temperature and the zero-limit temperature**
One advantage of the functional-integral approach is that the setup at positive temperatures is identical to that at zero temperature, save for the discreteness of the set $\mathbb{M}_\mathrm{F}$ at $T > 0$. Because $0 \notin \mathbb{M}_\mathrm{F}$, the temperature effectively provides an IR cutoff, so that all term-by-term divergences are regularized in a natural way. However, renormalization is still necessary because the temperature is a physical parameter and unrenormalized expansions give disastrous bounds for the behavior of observables as functions of the temperature. Renormalization carries over essentially unchanged (the counter-term function is constructed slightly differently).

Because $|\omega| \geq \pi/\beta$ for all $\omega \in \mathbb{M}_\mathrm{F}$, [12] implies $\mathrm{supp}\ \chi_j = \emptyset$ for $j < -J_\beta$, where

$$J_\beta = \log_M \frac{\beta \epsilon_0}{\pi} \qquad [15]$$

Thus, the scale decomposition is now a finite sum over $0 \geq j \geq -J_\beta$. This restriction is inessential for the problem of renormalizing the Fermi surface, but it puts a cutoff on the marginal growth of the four-point function: [15] and [13] imply that

$$\|\hat{v}_{m,r}^{(j)}\|_1 \leq \tilde{w}_{m,r} \left( \log \frac{\beta \epsilon_0}{\pi} \right)^r \qquad [16]$$

If one can show that $\tilde{w}_{m,r} \leq AB^r$ with constants $A$ and $B$, this implies that perturbation theory converges for $|\lambda| \log(\beta\epsilon_0/\pi) < B^{-1}$. Such a bound has been shown using constructive methods (Disertori and Rivasseau 2000, Feldman *et al.* 2003, 2004) (see below). The logarithm of $\beta$ is due to the Cooper instability (see Feldman and Trubowitz (1990, 1991) and Salmhofer (1998, section 4.5)).

The application of renormalization at positive temperature also led to the solution of a longstanding puzzle in solid-state physics, namely the (seeming) discontinuity of the results of perturbation theory as a function of the temperature claimed in the early literature. When renormalization is done correctly, there is no discontinuity in the temperature.

### Nonperturbative Renormalization for Fermions

It is a remarkable feature of fermionic field theories that for a covariance for which $\|\hat{C}\|_1$ and $\|C\|_1$ are both finite, the effective action defined in [7] exists and is analytic in the fields and in the original interaction $V$, thanks to determinant bounds. For a $V$ as in [6], with $\lambda v$ weak and of short range, the skeleton functions (where all relevant $m$-point functions are projected back to their initial values in the RG iteration) satisfy

$$\|\hat{v}_m^{(j)}\|_\infty \leq \text{const.} \|\hat{C}_j\|_1^{-(m/2)+1} \|C_j\|_1^{-1} \qquad [17]$$

For the many-electron covariance [10], with a positively curved $C^d$ Fermi surface and with the scale decomposition [12], $\|\hat{C}_j\|_1$ is of order $M^j$ and $\|C_j\|_1$ is of order $M^{-j(d+1)/2}$. The right-hand side of [17] then contains $M^{(d+3-m)j/2}$, which agrees (up to logarithms) with the perturbative power-counting bounds [13] only for $d=1$. In dimension $d=2$, the method has been refined by dividing the Fermi surface into angular sectors. The corresponding sectorized propagators have a better decay bound $\|C_j\|_1$, but the trade-off is sector sums at every vertex. Momentum conservation restricts these sector sums sufficiently in two dimensions to allow for good power-counting bounds. This has allowed for the construction of an interesting class of interacting fermionic models.

The major results obtained with the RG method are as follows.

Luttinger liquid behavior at zero temperature was proved for one-dimensional models with a repulsive interaction (Benfatto and Gallavotti 1995).

Fermi liquid behavior in the region where $|\lambda| \log(\beta\epsilon_0) \ll 1$ was proved for the two-dimensional model with $e(k)=k^2-1$, a local potential $V$, and a UV cutoff both on $k$ and the Matsubara frequencies $\omega$ in Disertori and Rivasseau (2000).

A two-dimensional model with a band function $e(k)$ that is nonsymmetric under $k \to -k$ and a general short-range interaction was proved to be a Fermi liquid at zero temperature (Feldman *et al.* 2003, 2004). Due to the asymmetry under $k \to -k$, the Cooper instability can be proved to be absent. In Feldman *et al.* (2003, 2004), a counter-term function as in Feldman *et al.* (1996, 2000) was used. The nonperturbative proof of the corresponding inversion theorem remains open.

In $d=3$, the proof of Fermi liquid behavior remains an open problem, despite some partial results.

## Condensed Matter: Bosons

Recent advances in quantum optice, in particular the trapping of ultracold atoms, have led to the experimental realization of Bose–Einstein condensation (BEC), which caused a surge of theoretical and mathematical works. For bosons, the definition of the ensembles is similar to, but more involved than in, the fermionic case. On a formal level, the functional-integral representation is analogous to fermions, except that the fields are not Grassmann fields but complex fields, and the covariance is given by a sum as in [10], but now the summation over $\omega$ runs over the bosonic Matsubara frequencies $\mathbb{M}_B = 2\pi T\mathbb{Z}$. The existence of even the free partition function in finite volume restricts the chemical potential (for free particles, $\mu < \inf_k \varepsilon(k)$ must hold). Note that $C$ is complex and Gaussian measures with complex covariances exist in infinite dimensions only under rather restricted conditions, which are not satisfied by [10]. This is inessential for perturbative studies, where everything can be reduced to finite-dimensional integrals involving the covariance, but a nonperturbative definition of functional integrals for such systems requires again a carefully regularized (e.g., discrete-time) definition of the functional integral.

### Bose–Einstein Condensation

The problem was treated to all orders in perturbation theory at positive particle density $\rho > 0$ by Benfatto (Benfatto and Gallavotti 1995). The initial interaction is again quartic, $\varepsilon(k)=k^2$, and one considers the problem at zero temperature, in the limit $\mu \to 0^-$, which is the limit in which BEC occurs for free particles. The interaction is expected to change the value of $\mu$, given the density, so a chemical potential term is included in the action, to give the interaction

$$V(\phi) = \int \mathrm{d}\tau \mathrm{d}x \mathrm{d}y |\phi(\tau,x)|^2 v(x-y) |\phi(\tau,y)|^2 + \nu \int \mathrm{d}\tau \mathrm{d}x |\phi(\tau,x)|^2 \qquad [18]$$

After writing $\phi(\tau,x)=\xi+\varphi(\tau,x)$, where $\xi$ is independent of $\tau$ and $x$, the density condition becomes $\rho=|\xi|^2$. $\nu$ now needs to be chosen such that the free energy has a minimum at $\xi=\sqrt{\rho}$. This can be reformulated in terms of the self-energy of the boson.

Benfatto uses the RG to prove that the propagator of the interacting system no longer has the singularity structure $(i\omega - k^2)^{-1}$ but instead $(\omega^2 + c^2k^2)^{-1}$, where $c$ is a constant. This requires a nontrivial analysis of Ward identities in the RG flow.

BEC has been proved in the Gross–Pitaevskii limit (Lieb *et al.* 2002). In the present formulation, this limit corresponds to an infinite-volume limit $L \to \infty$ where the density $\rho$ is taken to zero as an inverse power of $L$. A nonperturbative proof of BEC at fixed positive particle density remains an open problem.

### Superconductivity

Superconductivity (SC) occurs in fermionic systems, but it happens at energy scales where the relevant excitations have bosonic character: the Cooper pairs are bosons. In the RG framework, they arise naturally when the fermionic RG flow discussed above is stopped before it leaves the weak-coupling region and the dominant Cooper pairing term is rewritten by a Hubbard–Stratonovich transformation. The fermions can then be integrated over, resulting in the typical Mexican hat potential of an O(2) nonlinear sigma model. Effectively, one now has to deal with a problem similar to the one for BEC, but the action is considerably more complicated.

### The Nonlinear Sigma Models

The prototypical model, into whose universality class both examples mentioned above fall, is that of O($N$) nonlinear sigma models: both BEC and SC can be reformulated as spontaneous symmetry breaking (SSB) in the O(2) model in dimensions $d \geq 3$. For $d = 2$, long-range order is possible only at zero temperature because only then does the time direction truly represent a third dimension, preventing the Mermin–Wagner theorem from applying.

SSB has been proved for lattice O($N$) models by reflection positivity and Gaussian domination methods (Fröhlich *et al.* 1976). The elegance and simplicity of this method is unsurpassed, but only very special actions satisfy reflection positivity, so that the method cannot be used for the effective actions obtained in condensed matter models. Results in the direction of proving SSB in O($N$) models for $d \geq 3$ by RG methods, which apply to much more general actions, have been obtained by Balaban (1995).

# Resonances

**N Burq**, Université Paris-Sud, Orsay, France

## Introduction

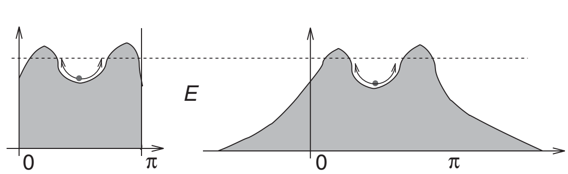
In quantum mechanics and wave propagation, eigenvalues (and eigenfunctions) appear naturally as they describe the behavior of a quantum system (or the vibration of a structure). There are however some cases where these simple notions do not suffice and one has to appeal to the more subtle notion of resonances. For example, if the vibration of a drum is well understood in terms of eigenvalues (the audible frequencies) and eigenfunctions (the corresponding vibrating modes), the notion of resonances is necessary to understand the propagation of waves in the exterior of a bounded obstacle. Another example (taken from Zworski (2002)) which allows us to understand both the similarities of resonances with eigenvalues and their differences is the following: consider the motion of a classical particle submitted to a force field deriving from the potential $V_1(x)$ on a bounded interval as shown in **Figure 1a**. If the classical momentum is denoted by $\xi$, then the classical energy is given by

$$E = |\xi|^2 + V_1(x)$$

and the classical motion is given by the relations of Hamiltonian mechanics:

$$\dot{x} = \frac{\partial E}{\partial \xi} = 2\xi, \qquad \dot{\xi} = -\frac{\partial E}{\partial x} = -V'(x)$$

Since energy is conserved, if the initial energy is smaller than the top of the barrier, then the classical particle bounces forever in the well. Now we can consider the same example with the potential $V_2(x)$ on $\mathbb{R}$ as shown in **Figure 1b**. Of course, if the particle is initially inside the well (with the same energy as before), the classical motion remains the same.



(a) (b)

**Figure 1a, b** A particle trapped in a well.

On the quantum mechanics point of view, both systems are described by the Hamiltonians

$$H_i = -h^2 \frac{d^2}{dx^2} + V_i(x)$$

acting on $L^2([-1,1])$ (with boundary conditions) and $L^2(\mathbb{R})$, respectively. In the first case, $H_1$ has a discrete spectrum, $\lambda_{j,h} \in \mathbb{R}$ with eigenfunctions $e_{j,h}(x), j \in \mathbb{N}$, and the time evolution of the system is given by

$$e^{itH_1} u = \sum_j e^{it\lambda_{j,h}} u_{j,h} \times e_{j,h} \qquad [1]$$

where $u_{j,h} \times e_{j,h}$ is the orthogonal projection of $u$ on the eigenspace $\mathbb{C}e_{j,h}$. In the second case, $H_2$ has no square integrable eigenfunction, and no simple description as [1] can consequently hold. However as $h \to 0$, the correspondence principle tells us that quantum mechanics should get close to classical mechanics. Since for both quantum problems the classical limit is the same (at least for initial states confined in the well with energy $E$), we expect that for the second potential there should exist a quantum state corresponding to the classical one. In fact, this is indeed the case and one can show that there exist resonant states $e_{j,h}$ associated to resonances $E_{j,h}$ which are solution of the equation

$$H_2 e_{j,h} - E_{j,h} e_{j,h}, \quad E_{j,h} \sim E$$

are not square integrable, but still have moderate growth at infinity and are confined in the interior of the well (see sections "Definition" and "Location of resonances"). On the other hand, the first quantum system is confined, whereas the second one is not and we know that even for initial states confined in the well, tunneling effect allows the quantum particle to escape to infinity. This fact should be described by the theory as a main difference between eigenvalues and resonances. This is indeed the case as the resonances $E_{j,h}$ are not real (contrarily to eigenvalues of self-adjoint operators) but have a nonvanishing imaginary part (see section "Resonance-free regions")

$$\operatorname{Im} E_{j,h} \sim e^{-C/h}$$

If we assume that a similar description as [1] still holds for the second system, at least locally in space (see section "Resonances and time asymptotics"), then, for time $t >> e^{C/h}$, the factor $e^{itE_h}$ becomes very small (the quantum particle has left the well due to tunneling effect).

There have been several studies on resonances and scattering theory and the presentation here cannot be complete. For a more in-depth presentation, one can

consult the books by Lax and Phillips (1989) and Hislop and Sigal (1987), or the reviews on resonances by Vodev (2001) and Zworski (1994) for example.

## Definition

There are different (equivalent) definitions of resonances. The most elegant is certainly the Helffer and Sjöstrand (1986) definition (see also the presentation of complex scaling by Combes *et al.* (1984) and the very general "black box" framework by Sjöstrand and Zworski (1991)). However, it requires a few prerequisites and we preferred to stick to the more elementary (but less general) resolvent point of view. The starting point for this definition of resonances is the fact that the eigenvalues of a (self-adjoint) operator $P$ are the points where $P$ is not injective. The more general resonances will be the points where the operator is not invertible (on suitable spaces).

More precisely, consider a perturbation of the Laplace operator on $\mathbb{R}^n$, $P_0(h) = -h^2\Delta$ in the following sense: let $\Theta \subset \mathbb{R}^d$ be a (possibly empty) smooth obstacle whose complementary, $\Omega = \Theta^c$, is connected. Consider a classical self-adjoint operator defined on $L^2(\Omega)$:

$$P_h u = (-h^2\Delta + V(x))u \qquad [2]$$

with boundary conditions (Dirichlet)

$$u\,|_{\partial\Theta} = 0 \qquad [3]$$

(Neumann boundary conditions could be used too). This setting contains both the Schrödinger operator ($P_h = -h^2\Delta + V(x) - E$ on $\Omega = \mathbb{R}^n$) and the Helmoltz equation with Dirichlet conditions, in the exterior of an obstacle (waves at large frequencies: $P = -\Delta - \tau^2$; in this case, define $h = \tau^{-1}$ and $P_h = -h^2\Delta$), which we shall define as acoustical scattering.

We assume that $P$ is a perturbation of $P_0$, that is, $V \to 0, |x| \to +\infty$ sufficiently fast (see Sjöstrand and Zworski (1991) for the very general black box assumptions). For example, this perturbation assumption is fulfilled if $V$ has compact support. Then the resolvent $P_h(z) = (P_h - z)^{-1}$ is well defined for $\mathrm{Im}\, z \neq 0$ as a bounded operator from $L^2(\Omega)$ to

$$H^2(\Omega) \cap H_0^1(\Omega)$$

(because the operator $P_h$ is self-adjoint). However, it is not bounded for $z > 0$ on $L^2(\Omega)$ because the essential spectrum of $P_h$ is precisely the semiaxis $z > 0$, but it admits a meromorphic continuation from $\mathbf{Im}\, z > 0$ toward the lower half-plane:

$$R_h(z) : L^2(\Omega)_{\mathrm{comp}} \to L^2(\Omega)_{\mathrm{loc}}$$

The poles of this resolvent $R_h$ are by definition the semiclassical resonances, $\mathrm{Res}_{\mathrm{sc}}(P_h)$.

**Remark 1** In the case of acoustical scattering ($P = -\Delta - \tau^2, \tau = h^{-1}$), the introduction of the additional parameter $z$ is pointless and one works directly with the parameter $\tau = h^{-1}\sqrt{z}$. In that case the resolvent $R(\tau)(-\Delta - \tau^2)^{-1}$ is well defined for $\mathbf{Im}\, \tau < 0$, the essential spectrum is precisely the axis $\tau \in \mathbb{R}$ and the resolvent admits a meromorphic continuation from $\mathbf{Im}\, z < 0$ toward the upper half-plane (with possibly a cut at 0):

$$R(\tau) : L^2(\Omega)_{\mathrm{comp}} \to L^2(\Omega)_{\mathrm{loc}}$$

The acoustic resonances are by definition the poles of this meromorphic continuation. They are related to semiclassical resonances by the relation

$$\mathrm{Res}_{\mathrm{sc}} = h\sqrt{\mathrm{Res}_{\mathrm{ac}}}$$

It can also be shown that if $z$ is a resonance, there exists an associated resonant state $e_z$ such that

$$(P_h - z)e_z = 0$$

the function $e_z$ satisfies Sommerfeld radiation conditions (in polar coordinates $(r, \theta) \in [0, +\infty) \times \mathbb{S}^{n-1}$)

$$|h\partial_r e - i\sqrt{z}e| \leq C|\mathrm{e}^{\mathrm{i}\sqrt{z}r}|/r^{1+n/2}$$

and the function

$$\frac{e_z}{1 + r^{(1/2)+\epsilon}}\ \mathrm{e}^{\mathrm{i}\sqrt{z}r}$$

is square integrable.

## Resonance-Free Regions

The very first result about resonance-free regions is based on Rellich uniqueness theorem (uniqueness for solutions of elliptic second-order equations) and says that there are no real resonances (except possibly 0). The more precise determination of resonance-free regions (originally in acoustical scattering) has been a subject of study from the 1960s and it has motivated a large range of works from the multiplier methods of Morawetz (1975) to the general propagation of singularity theorem of Melrose and Sjöstrand (1978). To state the main result in this direction, we need the notion of nontrapping perturbation.

**Definition 1** A generalized bicharacteristic at energy $E(x(s), \xi(s))$ is an integral curve of the Hamiltonian field

$$H_p = \frac{\partial p}{\partial \xi}\frac{\partial}{\partial x} - \frac{\partial p}{\partial x}\frac{\partial}{\partial \xi}$$

of the principal symbol $p(x, \xi) = |\xi|^2 + V(x)$ of the operator $P$, included in the characteristic set $p(x, \xi) = E$ and which, when hitting the boundary of the obstacle, reflects according to the laws of geometric optics (see (Melrose and Sjöstrand 1978)).

The operator $P$ (or by extension the obstacle in the case of acoustic scattering) is said to be nontrapping at energy $E$ if all generalized bicharacteristics go to the infinity:

$$\lim_{s\to\pm\infty} |x(s)| = +\infty$$

The operator $P$ (or by extension the obstacle in the case of acoustic scattering) is said to be nontrapping near energy $E$ if $P$ is nontrapping at energy $E'$ for $E'$ in a neighborhood of $E$.

The following result was obtained in different generalities by Morawetz (1975), Melrose and Sjöstrand (1978), and others.

**Theorem 1** *Assume that the operator $P$ is nontrapping near energy $E$. Then for any $N > 0$ there exist $h_0 > 0$ such that for $0 < h < h_0$ there are no resonances in the set*

$$\{z; |\mathrm{Im}\, z| \leq -Nh\log(h)\}$$

In the case of analytic geometries (and coefficients), this result (see Bardos *et al.* 1987) can be improved to

**Theorem 2** *Assume that the operator $P$ is non trapping. Then there exist $\epsilon > 0, N_0 > 0$ and $h_0 > 0$ such that for $0 < h < h_0$ there are no resonances in the set*

$$\{z; |\mathrm{Im}\, z| \leq N_0 h^{1-(1/3)}\} \cap \{|z - E| \leq \epsilon\}$$

**Remark 2** In the case of acoustical scattering, with the new definition of resonances, $\tau = h^{-1}\sqrt{z}$, the resonance-free zones have respectively the forms

$$\{z; |\mathrm{Im}\, z| \leq -N\log(|z|), |z| >> 1\}$$

$$\{z; |\mathrm{Im}\, z| \leq N_0|z|^{1/3}, |z| >> 1\}$$

In the case of trapping perturbations, the first result was obtained by Burq (1998).

**Theorem 3** *There exist $C > 0$ and $h_0 > 0$ such that for $0 < h < h_0$ there are no resonances in the set*

$$\{z; |\mathrm{Im}\, z| \leq N_0\, \mathrm{e}^{-C/h}\} \cap \{|z - E| \leq \epsilon\}$$

## Resonances and Time Asymptotics

The relationship between eigenfunctions/eigenvalues and time asymptotics is straightforward. This is no longer the case for resonances. For nontrapping problems however, this question has been studied in the late 1960s by Lax and Phillips (1989) and Vainberg (1968). In particular, this approach was decisive to study the local energy decay in acoustical scattering. As a consequence of Theorem 1, we have

**Theorem 4** *If the acoustical problem is nontrapping, then there exist $C, \alpha > 0$ such that for any solution of the wave equation*

$$\Box u = 0,\quad u|_{t=0} = u_0,\ \partial_t u|_{t=0} = u_1,\ u|_{\Gamma_D} = 0,\ \frac{\partial u}{\partial_n}|_{\Gamma_N} = 0$$

*with compactly supported initial data $(u_0, u_1)$ (in a fixed compact), one has*

$$E_{\mathrm{loc}}(u) = \int_{\Omega\cap\{|x|\leq C} |\nabla u|^2 + |\partial_t u|^2 \leq \begin{cases} C\mathrm{e}^{-\alpha t} & \text{if the space dimension is even} \\ \dfrac{C}{t^d} & \text{if the space dimension is odd} \end{cases} \quad [4]$$

Trapping perturbations were investigated more recently. In that case, the local energy decays, but the rate cannot be uniform. The first trapping example in acoustic scattering was studied by Ikawa (1983): the obstacle is the union of a finite number (and at least two) convex bodies. In that case, one has

**Theorem 5** *For any $\epsilon > 0$ there exists $C > 0$ such that for any initial data supported in a fixed compact set*

$$E_{\mathrm{loc}}(u)(t) \leq C\mathrm{e}^{-\alpha t}\|(u_0, u_1)\|^2_{D((1-\Delta)^{(1+\epsilon)/2})}$$

*where $D((1-\Delta)^{(1+\epsilon)/2})$ is the domain of the operator $(1-\Delta)^{(1+\epsilon)/2}$. Remark that the norm in $D((1-\Delta)^{1/2})$ is the natural energy and consequently the estimate above exhibits a loss of $\epsilon$ derivatives. For strongly trapping perturbations, the results are worse. They are consequences of Theorem 3.*

**Theorem 6** *For any $k$ there exists $C_k > 0$ such that for any initial data supported in a fixed compact set*

$$E_{\mathrm{loc}}(u)(t) \leq \frac{C_k}{\log(t)^{2k}}\|(u_0, u_1)\|^2_{D((1-\Delta)^{(1+k)/2})}$$

One can also obtain real asymptotic expansions in terms of resonances (see the work by Tang and Zworski (2000)).

**Theorem 7** *Let $\chi \in C_c^\infty(\mathbb{R}^n)$ and $\psi \in C_c^\infty((0,\infty))$ and let chsupp $\psi = [a, b]$. There exists $0 < \delta < c(h) < 2\delta$ such that for every $M > M_0$ there exists $L = L(M)$, and we have*

$$\chi\mathrm{e}^{-\mathrm{i}t\mu(P)/h}\chi\psi(P) = \sum_{z\in\Omega(h)\cap\mathrm{Res}(P)} \chi\mathrm{Res}(\mathrm{e}^{-\mathrm{i}t\mu(\bullet)/h} \times R(\bullet, h), z)\chi\psi(P) + \mathcal{O}_{\mathcal{H}\to\mathcal{H}}(h^\infty),\quad \text{for } t > h^{-L} \quad [5]$$

$$\Omega(h) = (a - c(h), b + c(h)) - \mathrm{i}[0, h^M)$$

*where* Res($f(\bullet), z$) *denotes the residue of a meromorphic family of operators*, $f$, *at* $z$.

The function $c(h)$ depends on the distribution of resonances: roughly speaking we cannot "cut" through a dense cloud of resonances. Even in the very well understood case of the modular surface there is, currently at least, a need for some nonexplicit grouping of terms. The same ideas can be applied to acoustic scattering.

## Trace Formulas

Trace formulas provide a description of the classical/quantum correspondence: one side is given by the trace of a certain function of the operator $f(P_h)$, whereas the other side is described in terms of classical objects (closed orbits of the classical flow). In the case of discrete eigenvalues, the question is relatively simple and can be solved by using the spectral theorem. In the case of continuous spectrum, the problem is much more subtle (self-adjoint operators with continuous spectrum behave in some ways as non-normal operators). It has been studied by Lax and Phillips (1989), Bardos *et al.* (1982), and Melrose (1982). More recently, Sjöstrand (1997) introduced a local notion of trace formulas.

Let $W \subset \Omega$ be an open precompact subsets of $e^{i[-2\theta_0, 0]}]0, +\infty[$. Assume that the intersections $I$ and $J$ of $W$ and $\Omega$ with the real axis are intervals and that $\Omega$ is simply connected.

**Theorem 8** *Let* $f(z, h)$ *be a family of holomorphic functions on* $z \in \Omega$ *such that* $|f|_{\Omega\setminus W}| \leq 1$. *Let* $\chi \in C_0^\infty(\mathbb{R})$ *equal to 1 on a neighborhood of* $\bar{I}$. *Then*

$$\begin{aligned}&\mathrm{Trace}\big((\chi f)(P_h) - (\chi f)(-h^2\Delta)\big)\\ &\quad = \sum_{\lambda \text{ a resonance of } P_h \cap \Omega} f(\lambda, h) + \mathcal{O}(h^{-n})\end{aligned}$$

The use of this result with a clever choice of functions $f$ allows Sjöstrand to show that an analytic singularity of the function $E \mapsto \mathrm{Vol}(\{x; V(x) \geq E\})$ (observe that if $V$ is bounded, this function vanishes for large $E$ and consequently it has analytic singularities) gives a lower bound for $\Omega$ a neighborhood of $E$

$$\sharp \mathrm{Res}(P_h) \cap \Omega \geq ch^{-n}$$

which coincides with the upper bound (see Zworski (2002) and the references given there).

## Location of Resonances

In some particular cases, one can expect to have a precise description of the location of resonances. This is the case in Ikawa's example in acoustic scattering where the obstacle is the union of two disjoint convex bodies. In this case, the line minimizing the distance, $d$, between the bodies is trapped. However, this trapped trajectory is isolated and of hyperbolic type (unstable). Ikawa (1983) and Gérard (1988) have obtained:

**Theorem 9** *There exist geometric positive constants* $k_p \to +\infty$ *as* $p \to +\infty$ *such that all resonances located above the line* $\mathrm{Im}\, z \geq -C$ (*C arbitrary large but fixed*) *have an asymptotic expansion*

$$\lambda \sim \lambda_{j,p} + \sum_l a_{l,p} \lambda_{j,p}^{-l/2} + \mathcal{O}(\lambda_{j,p}^{-\infty}), \quad j \to +\infty$$

*where the approximate resonances*

$$\lambda_{j,p} = j\frac{\pi}{d} - \mathrm{i}k_p$$

*are located on horizontal lines.*

Another example is when the obstacle is convex. This example is nontrapping and Sjöstrand and Zworski (1999) are able to prove that the resonances in any region $\mathrm{Im}\, z \geq N|z|^{1/3}$ ($N$ arbitrary large) are asymptotically distributed near cubic curves

$$\mathcal{C}_j = \{z \in \mathbb{C}; \mathrm{Im}\, z = -c_j |z|^{1/3}\}$$

Finally, the last main example where one can give a precise asymptotic for resonances is when there exists a stable (elliptic) periodic trajectory for the Hamiltonian flow. In that case it had been known from the 1960s (see the works by Babič (1968)) that one can construct quasimodes, that is, compactly supported approximate solutions of the eigenfunctions equation:

$$(P_h - E_h)e_j = \mathcal{O}(h^\infty)$$

It is only recently that Tang and Zworski (1998) and Stefanov (1999) proved that these quasimodes constructions imply the existence of resonances asymptotic to $E_h, h \to 0$.

# Riemann Surfaces

**K Hulek**, Universität Hannover, Hannover, Germany

## Introduction

Riemann surfaces were first studied as the natural domain of definition of (multivalued) holomorphic or meromorphic functions. They were the starting point for the development of the theory of real and complex manifolds (see Weyl (1997)). Nowadays, Riemann surfaces are simply defined as one-dimensional complex manifolds (see the next section). Compact Riemann surfaces can be embedded into projective spaces and are thus, by virtue of Chow's theorem, algebraic curves. By uniformization theory, the universal cover of a connected Riemann surface is either the unit disk, the complex plane, or the Riemann sphere (see the section "Uniformization").

This article discusses the basic theory of compact Riemann surfaces, such as their topology, their periods, and the definition of the Jacobian variety. Studying the zeros and poles of meromorphic functions leads to the notion of divisors and linear systems. In modern language this can be rephrased in terms of line bundles, resp. locally free sheaves (see the section "Divisors, linear systems, and line bundles"). One of the fundamental results is the Riemann–Roch theorem which expresses the difference between the dimension of a linear system and that of its adjoint system in terms of the degree of the linear system and the genus of the curve. This theorem has been vastly generalized and is truly one of the cornerstones of algebraic geometry. A formulation of this result and a discussion of some of its applications are also discussed.

A study of the subsets of the Jacobians parametrizing linear systems of given degree and dimension leads to Brill–Noether theory, which is discussed in the section "Brill–Noether theory." This is followed by a brief introduction to the theory of equations and syzygies of canonical curves.

Moduli spaces play a central role in the theory of complex variables and in algebraic geometry. Arguably, the most important of these is the moduli space of curves of genus $g$. This and related moduli problems are treated in the section "Moduli of compact Riemann surfaces." In particular, the space of stable maps is closely related to quantum cohomology. Finally, we present a brief discussion of the Verlinde formula and conformal blocks.

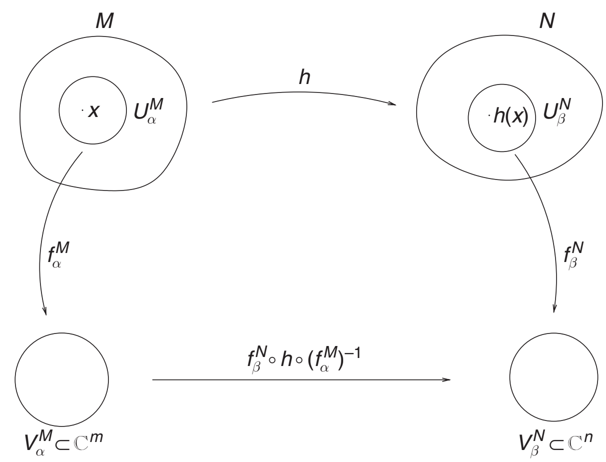

**Figure 2** Holomorphic map between manifolds.

## Basic Definitions

Riemann surfaces are one-dimensional complex manifolds. An $n$-dimensional complex manifold $M$ is a topological Hausdorff space (i.e., for any two points $x \neq y$ on $M$, there are disjoint open neighborhoods containing $x$ and $y$), which has a countable basis for its topology, together with a complex atlas $\mathcal{A}$. The latter is an open covering $(U_\alpha)_{\alpha \in \mathcal{A}}$ together with homeomorphisms $f_\alpha : U_\alpha \to V_\alpha \subset \mathbb{C}^n$, where the $U_\alpha$ are open subsets of $M$ and the $V_\alpha$ are open sets in $\mathbb{C}^n$. The main requirement is that these charts are holomorphically compatible, that is, for $U_\alpha \cap U_\beta \neq \emptyset$, the map shown in Figure 1,

$$f_\beta \circ f_\alpha^{-1}|_{f_\alpha(U_\alpha \cap U_\beta)} : f_\alpha(U_\alpha \cap U_\beta) \to f_\beta(U_\alpha \cap U_\beta) \subset \mathbb{C}^n$$

is biholomorphic. A map $h : M \to N$ between two complex manifolds is holomorphic if it is so with respect to the local charts. This means the following:

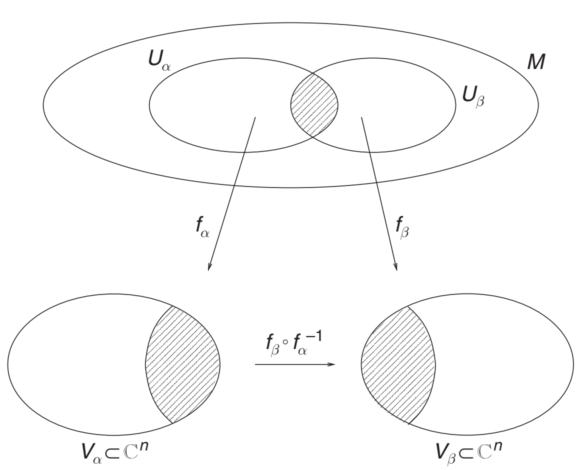

**Figure 1** Charts of a complex manifold.

for each point $x \in M$, there are charts $f_\alpha^M : U_\alpha^M \to V_\alpha^M \subset \mathbb{C}^n$ near $x$ and $f_\beta^N : U_\beta^N \to V_\beta^N \subset \mathbb{C}^m$ near $h(x)$ with $h(U_\alpha^M) \subset U_\beta^N$ such that the map shown in Figure 2

$$f_\beta^N \circ h \circ (f_\alpha^M)^{-1} : V_\alpha^M \to V_\beta^N \subset \mathbb{C}^m$$

is holomorphic (one checks easily that this does not depend on the choice of the charts).

A Riemann surface is a one-dimensional complex manifold. Trivial examples are given by open sets in $\mathbb{C}$ (where one chart suffices). Another example is the Riemann sphere $\hat{\mathbb{C}} = \mathbb{C} \cup \{\infty\}$, which can be covered by the two charts given by $z \neq \infty$ and $z \neq 0$. Both of these charts are homeomorphic to $\mathbb{C}$ with the transition function given by $z \mapsto 1/z$. Historically, Riemann surfaces were viewed as (branched) coverings of $\mathbb{C}$ or of the sphere, where they appear as the natural domain of definition of multivalued holomorphic or meromorphic functions.

## Uniformization

If $M$ is a Riemann surface, then its universal covering $\tilde{M}$ is again a Riemann surface. The connected and simply connected Riemann surfaces can be fully classified. Let

$$\mathbb{E} = \{z \in \mathbb{C}; |z| < 1\}$$

be the unit disk and $\hat{\mathbb{C}} = \mathbb{C} \cup \{\infty\}$ the Riemann sphere. The latter can be identified with the complex projective line $\mathbb{P}^1_\mathbb{C}$.

**Theorem 1** (Generalized Riemann mapping theorem). *Every connected and simply connected Riemann surface is biholomorphically equivalent*

*to the unit disk $\mathbb{E}$, the complex plane $\mathbb{C}$, or the Riemann sphere $\hat{\mathbb{C}}$.*

This theorem was proved rigorously by Koebe and Poincaré at the beginning of the twentieth century.

## Compact Riemann Surfaces

The topological structure of a compact Riemann surface $C$ is determined by its genus $g$ (Figure 3). Topologically, a Riemann surface of genus $g$ is a sphere with $g$ handles or, equivalently, a torus with $g$ holes.

Analytically, the genus can be characterized as the maximal number of linearly independent holomorphic forms on $C$ (see also the section "The Riemann–Roch theorem and applications").

There exists a very close link with algebraic geometry: every compact Riemann surface $C$ can be embedded into some projective space $\mathbb{P}^n_{\mathbb{C}}$ (in fact already into $\mathbb{P}^3_{\mathbb{C}}$). By Chow's theorem, $C$ is then a (projective) algebraic variety, that is, it can be described by finitely many homogeneous equations. It should be noted that such a phenomenon is special to complex dimension 1. The crucial point is that one can always construct a nonconstant meromorphic function on a Riemann surface (e.g., by Dirichlet's principle). Given such a function, it is not difficult to find a projective embedding of a compact Riemann surface $C$. On the other hand, it is easy to construct a compact two-dimensional torus $T=\mathbb{C}^2/L$ for some suitably chosen lattice $L$, which cannot be embedded into any projective space $\mathbb{P}^n_{\mathbb{C}}$.

The dichotomy Riemann surface/algebraic curve arises from different points of view: analysts think of a real two-dimensional surface with a Riemannian metric which, via isothermal coordinates, defines a holomorphic structure, whereas algebraic geometers think of a complex one-dimensional object.

In this article, the expressions compact Riemann surface and (projective) algebraic curve are both used interchangeably. The choice depends on which expression is more commonly used in the part of the theory which is discussed in the relevant section.

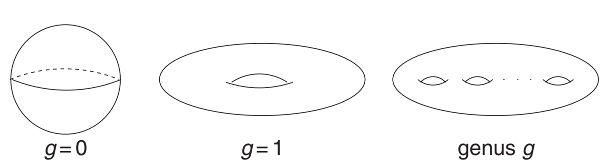

**Figure 3** Genus of Riemann surfaces.

## Periods and the Jacobian

On a compact Riemann surface $C$ of genus $g$, there exist $2g$ homologically independent paths, that is, $H_1(C,\mathbb{Z})\cong\mathbb{Z}^{2g}$.

Let $\gamma_1,\ldots,\gamma_{2g}$ be a basis of $H_1(C,\mathbb{Z})$ and let $\omega_1,\ldots,\omega_g$ be a basis of the space of holomorphic 1-forms on $C$. Integrating these forms over the paths $\gamma_1,\ldots,\gamma_{2g}$ defines the period matrix

$$\Omega=\begin{pmatrix}\int_{\gamma_1}\omega_1 & \cdots & \int_{\gamma_{2g}}\omega_1\\ \vdots & & \vdots\\ \int_{\gamma_1}\omega_g & \cdots & \int_{\gamma_{2g}}\omega_g\end{pmatrix}$$

If $Q=(\gamma_i,\gamma_j)$ is the intersection matrix of the paths $\gamma_1,\ldots,\gamma_{2g}$, then $\Omega$ satisfies the Riemann bilinear relations

$$\Omega Q\Omega^t=0,\quad \sqrt{-1}\,\Omega Q\overline{\Omega}^t>0 \qquad [1]$$

where the latter condition means positive definite. One can choose (see Figure 4) $\gamma_1,\ldots,\gamma_{2g}$ such that

$$Q=J=\begin{pmatrix}0 & \mathbf{1}_g\\ -\mathbf{1}_g & 0\end{pmatrix}$$

where $\mathbf{1}_g$ is the $g\times g$ unit matrix. Moreover, $\omega_1,\ldots,\omega_g$ can be chosen such that

$$\Omega=\begin{pmatrix}1 & \cdots & 0 & \tau_{11} & \cdots & \tau_{1g}\\ \vdots & \ddots & \vdots & \vdots & & \vdots\\ 0 & \cdots & 1 & \tau_{g1} & \cdots & \tau_{gg}\end{pmatrix}$$

Let

$$\Omega_0=(\tau_{ij})_{1\le i,j\le g}$$

Then the Riemann bilinear relations [1] become

$$\Omega_0=\Omega_0^t,\quad \operatorname{Im}\Omega_0^t>0$$

that is, $\Omega_0$ is an element of the Siegel upper half-space

$$\mathbb{H}_g=\{\tau\in\operatorname{Mat}(g\times g,\mathbb{C});\tau=\tau^t,\operatorname{Im}\tau>0\}$$

The matrix $\Omega_0$ is defined by the Riemann surface $C$ only up to the action of the symplectic group

$$\operatorname{Sp}(2g,\mathbb{Z})=\{M\in\operatorname{Mat}(2g\times 2g,\mathbb{Z});MJM^t=J\}$$

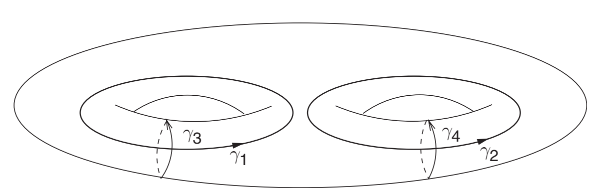

**Figure 4** Homology of a compact Riemann surface.

which acts on the Siegel space $\mathbb{H}_g$ by

$$M = \begin{pmatrix} A & B \\ C & D \end{pmatrix} : \tau \mapsto (A\tau + B)(C\tau + D)^{-1}$$

Here $A, \ldots, D$ are $g \times g$ blocks.

The rows of the matrix $\Omega$ define a rank-$2g$ lattice $L_\Omega$ in $\mathbb{C}^g$ and the Jacobian of $C$ is the torus

$$J(C) = \mathbb{C}^g / L_\Omega$$

More intrinsically, one can define $J(C)$ as follows. Let $H^0(C, \omega_C)$ be the space of holomorphic differential forms on $C$. Then, integration over cycles defines a monomorphism

$$H_1(C, \mathbb{Z}) \to H^0(C, \omega_C)^*$$
$$\gamma \mapsto \int_\gamma$$

and

$$J(C) = H^0(C, \omega_C)^* / H_1(C, \mathbb{Z})$$

For a fixed base point $P_0 \in C$, the Abel–Jacobi map is defined by

$$u : C \to J(C)$$
$$P \mapsto \left( \int_{P_0}^{P} \omega_1, \ldots, \int_{P_0}^{P} \omega_g \right)$$

Here, the integration is taken over some path from $P_0$ to $P$. Obviously, the integral depends on the choice of this path, but since $J(C)$ was obtained by dividing out the periods given by integrating over a basis of $H_1(C, \mathbb{Z})$, the map is well defined.

Let $C^d$ be the $d$th Cartesian product of $C$, that is, the set of all ordered $d$-tuples $(P_1, \ldots, P_d)$. Then, $u$ defines a map

$$u^d : C^d \to J(C)$$
$$(P_1, \ldots, P_d) \mapsto u(P_1) + \cdots + u(P_d)$$

where $+$ is the usual addition on the torus $J(C)$. If $d = g - 1$, then

$$\Theta = \mathrm{Im}(u^{g-1}) \subset J(C)$$

is a hypersurface (i.e., has codimension 1 in $J(C)$) and is called a theta divisor. A different choice of the base point $P_0$ results in a translation of the theta divisor. Using the theta divisor, one can show that $J(C)$ is an abelian variety, that is, $J(C)$ can be embedded into some projective space $\mathbb{P}^n_{\mathbb{C}}$. The pair $(J(C), \Theta)$ is a principally polarized abelian variety and Torelli's theorem states that $C$ can be reconstructed from its Jacobian $J(C)$ and the theta divisor $\Theta$.

## Divisors, Linear Systems, and Line Bundles

A divisor $D$ on $C$ is a formal sum

$$D = n_1 P_1 + \cdots + n_k P_k, \quad P_i \in C, \; n_i \in \mathbb{Z}$$

The degree of $D$ is defined as

$$\deg D = n_1 + \cdots + n_k$$

and $D$ is called "effective" if all $n_i \geq 0$. Every meromorphic function $f \neq 0$ defines a divisor

$$(f) = f_0 - f_\infty$$

where $f_0$ are the zeros of $f$ and $f_\infty$ the poles (each counted with multiplicity). Divisors of the form $(f)$ are called principal divisors and the degree of any principal divisor is 0 (see the next section). Two divisors $D_1$ and $D_2$ are called linearly equivalent ($D_1 \sim D_2$) if their difference is a principal divisor, that is,

$$D_1 - D_2 = (f)$$

for some meromorphic function $f \neq 0$. This defines an equivalence relation on the group $\mathrm{Div}(C)$ of all divisors on $C$. Since principal divisors have degree 0, the notion of degree also makes sense for classes of linearly equivalent divisors. We define the divisor class group of $C$ by

$$\mathrm{Cl}(C) = \mathrm{Div}(C)/\sim$$

The degree map defines an exact sequence

$$0 \to \mathrm{Cl}^0(C) \to \mathrm{Cl}(C) \overset{\deg}{\to} \mathbb{Z} \to 0$$

where $\mathrm{Cl}^0(C)$ is the subgroup of $\mathrm{Cl}(C)$ of divisor classes of degree 0.

Let $C_d$ be the set of unordered $d$-tuples of points on $C$, that is,

$$C_d = C^d / S_d$$

where the symmetric group $S_d$ acts on the Cartesian product $C^d$ by permutation. This is again a smooth projective variety and the Abel–Jacobi map $u^d : C^d \to J(C)$ clearly factors through a map

$$u_d : C_d \to J(C)$$

The fibers of this map are of particular interest.

**Theorem 2** (Abel). *Two effective divisors $D_1$ and $D_2$ on $C$ of the same degree $d$ are linearly equivalent if and only if $u_d(D_1) = u_d(D_2)$.*

One normally denotes the inverse image of $u_d(D)$ by

$$|D| = u_d^{-1}(u_d(D)) = \{D'; D' \geq 0, D' \sim D\}$$

Note that the latter description also makes sense if $D$ itself is not necessarily effective. One calls $|D|$ the

complete linear system defined by the divisor $D$. If $\deg D < 0$, then automatically $|D| = \emptyset$, but the converse is not necessarily true. Let $\mathcal{M}_C$ be the field of meromorphic (or equivalently rational) functions on $C$. Then, one defines

$$L(D) = \{f \in \mathcal{M}_C; (f) \geq -D\}$$

This is a $\mathbb{C}$-vector space and it is not difficult to see that $L(D)$ has finite dimension. To every function $0 \neq f \in L(D)$, one can associate the effective divisor

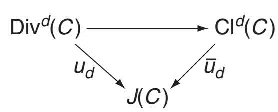
$$D_f = (f) + D \geq 0$$

Clearly, $D_f \sim D$ and every effective divisor with this property arises in this way. This gives a bijection

$$\mathbb{P}(L(D)) = |D|$$

showing that the complete linear system $|D|$ has the structure of a projective space. A linear system is a projective subspace of some complete linear system $|D|$.

Clearly, the map $u_d : C_d \to J(C)$ can be extended to the set $\mathrm{Div}^d(C)$ of degree $d$ divisors and Abel's theorem then states that this map factors through $\mathrm{Cl}^d(C)$, that is, that we have a commutative diagram



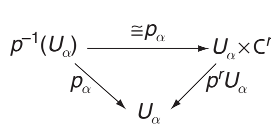
where $\overline{u}_d$ is injective.

**Theorem 3** (Jacobi's Inversion Theorem). *The map $u_d$ is surjective and hence induces an isomorphism*

$$\overline{u}_d : \mathrm{Cl}^d(C) \cong J(C)$$

It should be noted that the definition of the maps $u_d$ depends on the choice of a base point $P_0 \in C$. Hence, the maps $\overline{u}_d$ are not canonical, with the exception of the isomorphism $\overline{u}_0 : \mathrm{Cl}^0(C) \cong J(C)$ where the choice of $P_0$ drops out.

The concepts of divisors and linear systems can be rephrased in the language of line bundles. A (holomorphic) vector bundle on a complex manifold $M$ is a complex manifold $E$ together with a projection $p : E \to M$ which is a locally trivial $\mathbb{C}^r$-bundle. This means that an open covering $(U_\alpha)_{\alpha \in A}$ of $M$ and local trivializations



exist, such that the transition maps

$$\varphi_\beta \circ \varphi_\alpha^{-1}|_{(U_\alpha \cap U_\beta) \times \mathbb{C}^r} : \\ (U_\alpha \cap U_\beta) \times \mathbb{C}^r \to (U_\alpha \cap U_\beta) \times \mathbb{C}^r$$

are fiberwise linear isomorphisms. If $M$ is connected, then $r$ is constant and is called the rank of the vector bundle. A line bundle is simply a rank-1 vector bundle.

Alternatively, one can view vector bundles as locally free $\mathcal{O}_M$-modules, where $\mathcal{O}_M$ denotes the structure sheaf of holomorphic (or in the algebro-geometric setting regular) functions on $M$. An $\mathcal{O}_M$-module $\mathcal{E}$ is called locally free of rank $r$, if an open covering $(U_\alpha)_{\alpha \in A}$ of $M$ exists such that $\mathcal{E}|_{U_\alpha} \cong \mathcal{O}_{U_\alpha}^{\oplus r}$. The transition functions of a locally free sheaf can be used to define a vector bundle and vice versa, and hence the concepts of vector bundles and locally free sheaves can be used interchangeably. The open coverings $U_\alpha$ can be viewed either in the complex topology, or, if $M$ is an algebraic variety, in the Zariski topology, thus leading to either holomorphic vector bundles (locally free sheaves in the $\mathbb{C}$-topology) or algebraic vector bundles (locally free sheaves in the Zariski topology). Clearly, every algebraic vector bundle defines a holomorphic vector bundle. Conversely, on a projective variety $M$, Serre's GAGA theorem (géométrie algébriques et géométrie analytique), a vast generalization of Chow's theorem, states that there exists a bijection between the equivalence classes of algebraic and holomorphic vector bundles (locally free sheaves).

The Picard group $\mathrm{Pic}\, M$ is the set of all isomorphism classes of line bundles on $M$. The tensor product defines a group structure on $\mathrm{Pic}\, M$ where the neutral element is the trivial line bundle $\mathcal{O}_\mathcal{M}$ and the inverse of a line bundle $\mathcal{L}$ is its dual bundle $\mathcal{L}^*$, which is also denoted by $\mathcal{L}^{-1}$. For this reason, locally free sheaves of rank 1 are also called invertible sheaves.

We now return to the case of a compact Riemann surface (algebraic curve) $C$. The concept of line bundles and divisors can be translated into each other. If $D = \sum n_i P_i$ is a divisor on $C$ and $U$ an open set, then we denote by $D_U$ the restriction of $D$ to $U$, that is, the divisor consisting of all points $P_i \in U$ with multiplicity $n_i$. One then defines a locally free sheaf (line bundle) $\mathcal{L}(D)$ by

$$\mathcal{L}(D)(U) = \{f \in \mathcal{M}_C(U); (f) \geq -D_U\}$$

To see that this is locally free, it is enough to consider for each point $P_i$ a neighborhood $U_i$ on which a holomorphic function $t_i$ exists, which vanishes only at $P_i$ and there of order 1 (i.e., it is a local parameter near the point $P_i$). Then,

$$\mathcal{L}(D)(U_i) = t_i^{-n_i}\mathcal{O}_{U_i} \cong \mathcal{O}_{U_i}$$

This correspondence defines a map

$$\begin{aligned} \mathrm{Div}\, C &\to \mathrm{Pic}\, C \\ D &\mapsto \mathcal{L}(D) \end{aligned}$$

It is not hard to show that:

1. every line bundle $\mathcal{L} \in \operatorname{Pic} C$ is of the form $\mathcal{L} = \mathcal{L}(D)$ for some divisor $D$ on the curve C;
2. $D_1 \sim D_2 \Longleftrightarrow \mathcal{L}(D_1) \cong \mathcal{L}(D_2)$;
3. $\mathcal{L}(D_1) \otimes \mathcal{L}(D_2) \cong \mathcal{L}(D_1 + D_2)$; and
4. $\mathcal{L}(-D) \cong \mathcal{L}(D)^{-1}$.

Hence, there is an isomorphism of abelian groups

$$\mathrm{Cl}(C) \cong \operatorname{Pic} C$$

This correspondence allows to define the degree of a line bundle $\mathcal{L}$. In the complex analytic setting this can also be interpreted as follows. Let $\mathcal{O}_C^*$ be the sheaf of nowhere-vanishing functions. Using cocycles, one easily identifies

$$H^1(C, \mathcal{O}_C^*) \cong \operatorname{Pic} C$$

and the exponential sequence

$$0 \to \mathbb{Z} \to \mathcal{O}_C \overset{\exp}{\to} \mathcal{O}_C^* \to 0$$

induces an exact sequence

$$\begin{aligned} 0 &\to H^1(C, \mathbb{Z}) \to H^1(C, \mathcal{O}_C) \\ &\to H^1(C, \mathcal{O}_C^*) = \operatorname{Pic} C \to H^2(C, \mathbb{Z}) \end{aligned}$$

The last map in this exact sequence associates to each line bundle $\mathcal{L}$ its first Chern class $c_1(\mathcal{L}) \in H^2(C, \mathbb{Z}) \cong \mathbb{Z}$, which can be identified with the degree of $\mathcal{L}$. Hence, the subgroup $\operatorname{Pic}^0 C$ of degree 0 line bundles on $C$ is isomorphic to

$$\operatorname{Pic}^0 C \cong H^1(C, \mathcal{O}_C)/H^1(C, \mathbb{Z})$$

Altogether there are identifications

$$\operatorname{Pic}^0 C \cong \mathrm{Cl}^0 C \cong J(C)$$

## The Riemann–Roch Theorem and Applications

For every divisor $D$ on a compact Riemann surface $C$, the discussion of the preceding section shows that there is an identification of finite-dimensional vector spaces

$$L(D) = H^0(C, \mathcal{L}(D))$$

where $H^0(C, \mathcal{L}(D))$ is the space of global sections of the line bundle $\mathcal{L}(D)$. One defines

$$l(D) = \dim_{\mathbb{C}} L(D)$$

It is a crucial question in the theory of compact Riemann surfaces to study the dimension $l(D)$ as $D$ varies.

The canonical bundle $\omega_C$ of $C$ is defined as the dual of the tangent bundle of $C$. Its global sections are holomorphic 1-forms. Every divisor $K_C$ on $C$ with $\omega_C = \mathcal{L}(K_C)$ is called (a) canonical divisor. The canonical divisors are the divisors of the meromorphic 1-forms on C, whereas the effective canonical divisors correspond to the divisors of holomorphic 1-forms (here, we simply write a 1-form locally as $f(z)\,dz$ and define a divisor by taking the zeros, resp. poles of $f(z)$). By abuse of notation, we also denote the divisor class corresponding to canonical divisors by $K_C$. There is a natural identification

$$\mathbb{P}(H^0(C, \omega_C)) = |K_C|$$

For a divisor $D$, the index of speciality is defined by

$$i(D) = l(K_C - D) = \dim_{\mathbb{C}} L(K_C - D)$$

The linear system $|K_C - D|$ is called the adjoint system of $|D|$. A crucial role is played by the

**Theorem 4** (Riemann–Roch). *For any divisor D on a compact Riemann surface C of genus g, the equality*

$$l(D) - i(D) = \deg D + 1 - g \qquad [2]$$

*holds.*

This can also be written in terms of line bundles. If $\mathcal{L}$ is any line bundle, then we denote the dimension of the space of global sections by

$$h^0(\mathcal{L}) = \dim_{\mathbb{C}} H^0(C, \mathcal{L})$$

Then, the Riemann–Roch theorem can be written as

$$h^0(\mathcal{L}) - h^0(\omega_C \otimes \mathcal{L}^{-1}) = \deg \mathcal{L} + 1 - g \qquad [3]$$

This can be written yet again in a different way, if we use sheaf cohomology. By Serre duality, there is an isomorphism of cohomology groups

$$H^1(C, \mathcal{L}) \cong H^0(C, \omega_C \otimes \mathcal{L}^{-1})^*$$

and hence if we set

$$h^1(\mathcal{L}) = \dim_{\mathbb{C}} H^1(C, \mathcal{L})$$

then [3] reads

$$h^0(\mathcal{L}) - h^1(\mathcal{L}) = \deg \mathcal{L} + 1 - g \qquad [4]$$

Whereas [2] is the classical formulation of the Riemann–Roch theorem, formula [4] is the formulation which is more suitable for generalizations. From this point of view, the classical Riemann–Roch theorem is a combination of the cohomological formulation [4] together with Serre duality.

The Riemann–Roch theorem has been vastly generalized. This was first achieved by Hirzebruch who proved what is nowadays called the Hirzebruch–Riemann–Roch theorem for vector bundles on projective manifolds. A further generalization is due to Grothendieck, who proved a "relative" version involving maps between varieties. Nowadays, theorems like the Hirzebruch–Riemann–Roch theorem can be

viewed as special cases of the Atiyah–Singer index theorem for elliptic operators. The latter also contains the Gauss–Bonnet theorem from differential geometry as a special case. Moreover, Serre duality holds in much greater generality, namely for coherent sheaves on projective varieties.

Applying the Riemann–Roch theorem [3] to the zero divisor $D = 0$, resp. the trivial line bundle $\mathcal{O}_C$, one obtains

$$h^0(\omega_C) = g \qquad [5]$$

that is, the number of independent global holomorphic 1-forms equals the genus of the curve $C$. Similarly, for $D = K_C$, resp. $\mathcal{L} = \omega_C$, we find from [3] and [5] that

$$\deg K_C = 2g - 2$$

These relations show, how the Riemann–Roch theorem links analytic, resp. algebraic, invariants with the topology of the curve $C$.

Finally, if $\deg D > 2g - 2$, then $\deg(K_C - D) < 0$ and hence $i(D) = l(K_C - D) = 0$ and [2] becomes

$$l(D) = \deg D + 1 - g \quad \text{if } \deg D > 2g - 2$$

which is Riemann's original version of the theorem.

Classically, linear series arose in the study of projective embeddings of algebraic curves. For a nonzero effective divisor

$$D = \sum_{i=1}^{k} n_i P_i, \quad n_i > 0$$

the support of $D$ is defined by

$$\operatorname{supp}(D) = \{P_1, \ldots, P_k\}$$

A complete linear system $|D|$ is called base point free, if no point $P$ exists which is in the support of every divisor $D' \in |D|$. This is the same as saying that for every $P \in C$ a section $s \in H^0(C, \mathcal{L}(D))$ exists which does not vanish at $P$. Let $|D|$ be base point free and let $s_0, \ldots, s_n \in H^0(C, \mathcal{L}(D))$ be a basis of the space of sections. Then, one obtains a map

$$\varphi_{|D|} : C \to \mathbb{P}(H^0(C, \mathcal{L}(D))) = \mathbb{P}^n$$
$$P \mapsto (s_0(P) : \ldots : s_n(P))$$

The divisors $D' \in |D|$ are then exactly the pullbacks of the hyperplanes $H$ of $\mathbb{P}^n$ under the map $\varphi_{|D|}$. Note that the map $\varphi_{|D|}$ as defined here depends on the choice of the basis $s_0, \ldots, s_n$, but any two such choices only differ by an automorphism of $\mathbb{P}^n$. We say that $|D|$, resp. the associated line bundle $\mathcal{L} = \mathcal{L}(D)$, is very ample if $\varphi_{|D|}$ defines an embedding. Using the Riemann–Roch theorem, it is not difficult to prove:

**Proposition 1** *Let $D$ be a divisor of degree $d$ on the curve $C$. Then*

(i) *$|D|$ is base point free if $d \geq 2g$ and*
(ii) *$|D|$ is very ample if $d \geq 2g + 1$.*

If the genus $g(C) \geq 2$, then one can prove that $|K_C|$ is base point free and consider the canonical map

$$\varphi_{|K_C|} : C \to \mathbb{P}^{g-1}$$

A curve $C$ is called hyperelliptic if there exists a surjective map $f : C \to \mathbb{P}^1$ which is a covering of degree 2. In genus 2 every curve is hyperelliptic, whereas for genus $g \geq 3$ hyperelliptic curves are special. The connection with the canonical map is given by

**Theorem 5** (Clifford). *Let $C$ be a curve of genus $g \geq 2$. Then the canonical map is an embedding if and only if $C$ is not hyperelliptic.*

We end this section by stating Hurwitz's theorem: Let $f : C \to D$ be a surjective holomorphic map between compact Riemann surfaces (if $f$ is not constant then it is automatically surjective). Then, near a point $P \in C$ the map $f$ is given in local analytic coordinates by $f(t) = t^{n_P}$ and we call $f$ "ramified" of order $n_P$ if $n_P > 1$. The ramification divisor of $f$ is defined as

$$R = \sum_{P \in C} (n_P - 1)P$$

Note that this is a finite sum. If we define

$$f^*(Q) = \sum_{P \in f^{-1}(Q)} n_P P$$

then one can show that

$$\deg f = \deg f^*(Q) = \sum_{P \in f^{-1}(Q)} n_P$$

is independent of the point $Q$. This number is called the degree of the map $f$. (This should not be confused with the degree $\deg(f)$ of the principal divisor $(f)$ defined by $f$.) In fact, applying the above equality to the map $f : C \to \mathbb{P}^1$ associated to a nonconstant meromorphic function $f$ shows that the degree of the principal divisor $(f)$ is zero, since

$$\deg(f) = \deg f^*(0) - \deg f^*(\infty) = 0$$

**Theorem 6** (Hurwitz). *Let $f : C \to D$ be a surjective holomorphic map between compact Riemann surfaces of genus $g(C)$ and $g(D)$, respectively. Then,*

$$2g(C) - 2 = \deg f \cdot (2g(D) - 2) + \deg R$$

*where $R$ is the ramification divisor.*

## Brill–Noether Theory

In this section, we state the main results of Brill–Noether theory. For a divisor $D$ on a curve $C$ we denote by

$$r(D) = l(D) - 1$$

the projective dimension of the complete linear system $|D|$. The principal objects of Brill–Noether theory are the sets $W_d^r \subset \mathrm{Cl}^d(C) = \mathrm{Pic}^d(C)$ given by

$$W_d^r(C) = \{D; \deg D = d, r(D) \geq r\}$$

These sets are subvarieties of $\mathrm{Cl}^d(C) = \mathrm{Pic}^d(C)$.

We denote by $g_d^r$ a linear system (not necessarily complete) of degree $d$ and projective dimension $r$. Closely related to the varieties $W_d^r$ are the sets

$$G_d^r(C) = \{\delta; \delta \text{ is a } g_d^r \text{ on } C\}$$

These sets also have a natural structure as a projective variety. Clearly, there are maps $G_d^r(C) \to W_d^r(C)$.

If $g = g(C)$ is the genus of the curve $C$, then the Brill–Noether number is defined as

$$\rho(g, r, d) = g - (r + 1)(g - d + r)$$

Its significance is that it is the expected dimension of the varieties $G_d^r(C)$. The two basic results of Brill–Noether theory are:

**Theorem 7** (Existence Theorem). *Let $C$ be a curve of genus $g$. Let $d, r$ be integers such that $d \geq 1$, $r \geq 0$, and $\rho(g, r, d) \geq 0$. Then $G_d^r(C)$ and hence $W_d^r(C)$ are nonempty and every component of $G_d^r(C)$ has dimension at least $\rho$. If $r \geq d - g$, then the same is true for $W_d^r(C)$.*

**Theorem 8** (Connectedness Theorem). *Let $C$ be a curve of genus $g$ and $d, r$ integers such that $d \geq 1$, $r \geq 0$, and $\rho(g, r, d) \geq 1$. Then $G_d^r(C)$ and hence also $W_d^r(C)$ are connected.*

The above theorems hold for all curves $C$. There are other theorems which only hold for general curves (where general means outside a countable union of proper subvarieties in the moduli space, see the section "Moduli of compact Riemann surfaces").

**Theorem 9** (Dimension Theorem). *Let $C$ be a general curve of genus $g$ and $d \geq 1$, $r \geq 0$ integers. If $\rho(g, r, d) < 0$, then $G_d^r(C) = \emptyset$. If $\rho \geq 0$, then every component of $G_d^r(C)$ has dimension $\rho$.*

**Theorem 10** (Smoothness Theorem). *Let $C$ be a general curve of genus $g$ and $d \geq 1$, $r \geq 0$. Then, $G_d^r(C)$ is smooth of dimension $\rho$. If $\rho \geq 1$, then $G_d^r(C)$ and hence $W_d^r(C)$ are irreducible.*

Brill–Noether theory started with a paper of Brill and Noether in 1873. It was, however, only from the 1970s onwards that the main theorems could be proved rigorously, due to the work of Griffiths, Harris, Kleiman, Mumford, and many others. For an extensive treatment of the theory, as well as a list of references, the reader is referred to Arbarello *et al.* (1985).

## Green's Conjecture

In recent years, much progress was achieved in understanding the equations of canonical curves. If the curve $C$ is not hyperelliptic, then the canonical map $\varphi_{|K_C|} : C \to \mathbb{P}^{g-1}$ defines an embedding. We shall, in this case, identify $C$ with its image in $\mathbb{P}^{g-1}$ and call this a canonical curve. The Clifford index (for a precise definition see Lazarsfeld (1989)) is a first measure of how special a curve $C$ is with respect to the canonical map. Hyperelliptic curves, where the canonical map fails to be an embedding, have, by definition, Clifford index 0. The two next special cases are plane quintic curves (they have a $g_5^2$) and trigonal curves. A curve $C$ is called trigonal, if there is a $3:1$ map $C \to \mathbb{P}^1$, in which case $C$ has a $g_3^1$. More generally, the gonality of a curve $C$ is the minimal degree of a surjective map $C \to \mathbb{P}^1$. Plane quintics and trigonal curves are precisely the curves which have Clifford index 1.

**Theorem 11** (Enriques–Babbage). *If $C \subset \mathbb{P}^{g-1}$ is a canonical curve, then $C$ is either defined by quadratic equations, or it is trigonal or isomorphic to a plane quintic curve (i.e., it has Clifford index 1).*

One can now ask more refined questions about the equations defining canonical curves and the relations (syzygies) among these equations. This leads to looking at the minimal free resolution of a canonical curve $C$, which is of the form

$$0 \leftarrow \mathcal{I}_C \leftarrow \oplus_j \mathcal{O}_{\mathbb{P}^{g-1}}(-j)^{\beta_{0j}} \leftarrow \cdots \leftarrow \oplus_j \mathcal{O}_{\mathbb{P}^{g-1}}(-j)^{\beta_{kj}} \leftarrow 0$$

Here, $\mathcal{I}_C$ is the ideal sheaf of $C$ and $\mathcal{O}_{\mathbb{P}^{g-1}}(n)$ is the $n$th power of the dual of the Hopf bundle (or tautological sub-bundle) on $\mathbb{P}^{g-1}$ if $n \geq 0$, resp. the $|n|$th power of the Hopf bundle if $n < 0$. The $\beta_{ij}(C)$ are called the Betti numbers of $C$. The Green conjecture predicts a link between the nonvanishing of certain Betti numbers and geometric properties of the canonical curve, such as the existence of multisecants. Recently, C Voisin and M Teixidor have proved the Green conjecture for general curves of given gonality (see Beauville (2003)).

## Moduli of Compact Riemann Surfaces

As a set, the moduli space of compact Riemann surfaces of genus $g$ is defined as

$$\mathcal{M}_g = \{C; C \text{ is a compact Riemann surface of genus } g\}/\cong$$

For genus $g = 0$, the only Riemann surface is the Riemann sphere $\hat{\mathbb{C}} = \mathbb{P}^1$ and hence $\mathcal{M}_0$ consists of one point only. Every Riemann surface of genus 1 is a torus

$$E = \mathbb{C}/L$$

for some lattice $L$, which can be written in the form

$$L_\tau = \mathbb{Z}\tau + \mathbb{Z}, \quad \operatorname{Im}\tau > 0$$

Two elliptic curves $E_\tau = \mathbb{C}/L_\tau$ and $E_{\tau'} = \mathbb{C}/L_{\tau'}$ are isomorphic if and only if a matrix

$$M = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in \mathrm{SL}(2, \mathbb{Z})$$

exists with

$$\tau' = \frac{a\tau + b}{c\tau + d}$$

This proves that

$$\mathcal{M}_1 = \mathbb{H}_1/\mathrm{SL}(2, \mathbb{Z})$$

and this construction also shows that $\mathcal{M}_1$ can itself be given the structure of a Riemann surface. Using the $j$-function, one obtains that

$$\mathcal{M}_1 \cong \mathbb{C}$$

The situation is considerably more complicated for genus $g \geq 2$. The space of infinitesimal deformations of a curve $C$ is given by $H^1(C, T_C)$ where $T_C$ is the tangent bundle. By Serre duality

$$H^1(C, T_C) \cong H^0(C, \omega_C^{\otimes 2})^*$$

and by Riemann's theorem it then follows that

$$\dim H^1(C, T_C) = \dim H^0(C, \omega_C^{\otimes 2}) = 3g - 3$$

This shows that a curve of genus $g$ depends on $3g - 3$ parameters or moduli, a dimension count which was first performed by Riemann.

In genus 2 every curve has the hyperelliptic involution, and for a general curve of genus 2 this is the only automorphism. In genus $g \geq 3$ the general curve has no automorphisms, but some curves do. The order of the automorphism group is bounded by $84(g - 1)$. The existence of automorphism for some curves means that $\mathcal{M}_g$ is not a manifold, but has singularities. The singularities are, however, fairly mild. Locally, $\mathcal{M}_g$ always looks like $\mathbb{C}^{3g-3}/G$ near the origin, where $G$ is a finite group acting linearly on $\mathbb{C}^{3g-3}$. One expresses this by saying that $\mathcal{M}_g$ has only finite quotient singularities. A space with this property is also sometimes referred to as a $V$-manifold or an orbifold. Moreover, $\mathcal{M}_g$ is a quasiprojective variety, that is, a Zariski-open subset of a projective variety. As the above parameter count implies, the dimension of $\mathcal{M}_g$ is $3g - 3$. At this point it can also be clarified what is meant by a general curve in the context of Brill–Noether theory: a property is said to hold for the general curve in Brill–Noether theory if it holds outside a countable number of proper subvarieties of $\mathcal{M}_g$.

It is often useful to work with projective, rather than quasiprojective, varieties. This means that one wants to compactify $\mathcal{M}_g$ to a projective variety $\overline{\mathcal{M}}_g$, preferably in such a way that the points one adds still correspond to geometric objects. The crucial concept in this context is that of a stable curve. A stable curve of genus $g$ is a one-dimensional projective variety with the following properties:

1. $C$ is connected (but not necessarily irreducible),
2. $C$ has at most nodal singularities (i.e., two local analytic branches meet transversally),
3. the arithmetic genus $p_a(C) = h^1(C, \mathcal{O}_C) = g$, and
4. the automorphism group $\mathrm{Aut}(C)$ of $C$ is finite.

The last of these conditions is equivalent to the following: if a component of $C$ is an elliptic curve, then this must either meet another component or have a node, and if a component is a rational curve, then this component must either have at least two nodes or one node and intersect another component, or it is smooth and has at least three points of intersection with other components.

It should be noted that, in contrast to the previous illustrations, Figure 5 is drawn from the complex point of view, that is, the curves appear as one-dimensional objects.

The concept of stable curves leads to what is generally known as the Deligne–Mumford compactification of $\mathcal{M}_g$:

$$\overline{\mathcal{M}}_g = \{C; C \text{ is a stable curve of genus } g\}/\cong$$

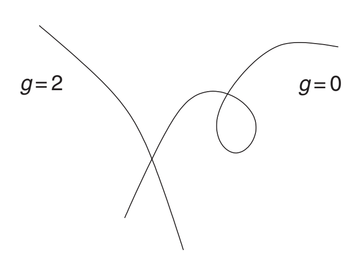


**Figure 5** An example of a stable curve of genus 3.

**Theorem 12** (Deligne–Mumford, Knudsen). *$\overline{\mathcal{M}}_g$ is an irreducible, projective variety of dimension $3g-3$ with only finite quotient singularities.*

The spaces $\overline{\mathcal{M}}_g$ have been studied intensively over the last 30 years. From the point of view of classification, an important question is to determine the Kodaira dimension of these spaces.

**Theorem 13** (Harris–Mumford, Eisenbud–Harris). *The moduli spaces $\overline{\mathcal{M}}_g$ are of general type for $g > 23$.*

On the other hand, it is known that $\overline{\mathcal{M}}_g$ is rational for $g \leq 6$, unirational for $g \leq 14$, and has negative Kodaira dimension for $g \leq 16$.

A further topic is to understand the cohomology of $\overline{\mathcal{M}}_g$, resp. the Chow ring, and to compute the intersection theory on $\overline{\mathcal{M}}_g$. For these topics we refer the reader to Vakil (2003).

Closely related is the moduli problem of stable $n$-pointed curves. A stable $n$-pointed curve (**Figure 6**) is an $(n+1)$-tuple $(C, x_1, \ldots, x_n)$, where $C$ is a connected nodal curve and $x_1, \ldots, x_n$ are smooth points of $C$ with the stability condition that the automorphism group of $(C, x_1, \ldots, x_n)$ is finite. These curves can be parametrized by a coarse moduli space $\overline{\mathcal{M}}_{g,n}$. These spaces share many properties of the spaces $\overline{\mathcal{M}}_g$: they are irreducible, projective varieties with finite quotient singularities and of dimension $3g-3+n$.

A further development, which has become very important in recent years, is that of moduli spaces of stable maps. These were introduced by Kontsevich in the context of quantum cohomology. To define stable maps, one first fixes a projective variety $X$ and then considers $(n+2)$-tuples $(C, x_1, \ldots, x_n, f)$ where $(C, x_1, \ldots, x_n)$ is an $n$-pointed curve of genus $g$ and $f: C \to X$ a map. The stability condition is, that this object allows only finitely many automorphisms $\varphi: C \to C$, fixing the marked points $x_1, \ldots, x_n$, such that $f \circ \varphi = f$. In order to obtain meaningful moduli spaces, one also fixes a class $\gamma \in H_2(X, \mathbb{Z})$. One then asks for a space parametrizing all stable $(n+2)$-tuples $(C, x_1, \ldots, x_n, f)$ with the additional property that $f_*[C] = \gamma$. This construction is best treated in the language of stacks, and one can show that this moduli problem gives rise to a proper Deligne–Mumford stack $\overline{\mathcal{M}}_{g,n}(X, \gamma)$. In general, this stack is very complicated, it need not be connected, can be very singular, and may have several components of different dimensions. Its expected dimension is

$$\begin{aligned}\exp.\dim \overline{\mathcal{M}}_{g,n}(X,\gamma) \\ = (\dim X - 3)(1-g) + n + \int_\gamma c_1(T_X)\end{aligned}$$

Quantum cohomology can now be rephrased as intersection theory on the stack $\overline{\mathcal{M}}_{g,n}(X, \gamma)$. In general, these stacks do not have the expected dimension. For this reason, Behrend and Fantechi (1997) have constructed a virtual fundamental class of the right dimension, which is the correct tool for the intersection theory which gives the algebro-geometric definition of quantum cohomology. In addition to this, there is also a symplectic formulation. It was shown by B Siebert that both approaches coincide.

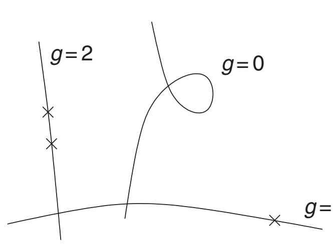

**Figure 6** An example of marked stable curve.

## Verlinde Formula and Conformal Blocks

The study of vector bundles (locally free sheaves) on a compact Riemann surface is an area of research in its own right. For a rank-$r$ bundle $\mathcal{E}$, the slope of $\mathcal{E}$ is defined by

$$\mu(\mathcal{E}) = \frac{\deg \mathcal{E}}{r}$$

where the degree of $\mathcal{E}$ is defined as the degree of the line bundle $\bigwedge^r \mathcal{E} = \det \mathcal{E}$. The bundle $\mathcal{E}$ is called stable, resp. semistable, if

$$\mu(\mathcal{F}) < \mu(\mathcal{E}), \quad \text{resp.} \quad \mu(\mathcal{F}) \leq \mu(\mathcal{E})$$

for every proper sub-bundle $\{0\} \subsetneq \mathcal{F} \subsetneq \mathcal{E}$. Let $C$ be a compact Riemann surface of genus $g \geq 2$ and let $\mathrm{SU}_C(r)$ be the moduli space of semistable rank-$r$ vector bundles with trivial determinant $\det \mathcal{E} = \mathcal{O}_C$. This is a projective variety of dimension $(r^2-1)(g-1)$. It contains a smooth open set, whose points correspond to the isomorphism classes of stable vector bundles. The complement of this set is in general the singular locus of $\mathrm{SU}_C(r)$ and its points correspond to direct sums of line bundles of degree 0. These are the so-called graded objects of the semistable, but not stable, bundles. By a theorem of Narasimhan and Seshadri, the points of $\mathrm{SU}_C(r)$ are also in one-to-one correspondence with the isomorphism classes of representations $\pi_1(C) \to \mathrm{SU}(r)$.

Let $L \in \mathrm{Pic}^{g-1}(C)$ be any line bundle of degree $g-1$ on C. Then, the set

$$\Theta_L = \left\{\mathcal{E} \in \mathrm{SU}_C(r); \dim H^0(C, \mathcal{E} \otimes L) > 0\right\}$$

is a Cartier divisor on $SU_C(r)$ and thus defines a line bundle $\mathcal{L}$ on $SU_C(r)$. This is a natural generalization of the construction of the classical theta divisor. The line bundle $\mathcal{L}$ generates the Picard group of the moduli space $SU_C(r)$.

**Theorem 14** (Verlinde Formula). *If C has genus g and k is a positive integer, then*

$$\dim H^0(SU_C(r), \mathcal{L}^k) = \left(\frac{r}{r+k}\right)^g \sum_{\substack{S \sqcup T = \{1,\ldots,r+k\} \\ |S|=r}} \prod_{\substack{s\in S \\ t \in T}} \left| \sin \pi \frac{s-t}{r+k} \right|^{g-1}$$

This formula was first found by Verlinde in the context of conformal field theory. Due to this relationship, the spaces $H^0(SU_C(r), \mathcal{L}^k)$ are also called conformal blocks. These spaces can also be defined for principal bundles. Rigorous proofs for the general case of the Verlinde formula are due to Beauville–Laszlo and Faltings. For a survey, see Beauville (1995).

# Riemann–Hilbert Methods in Integrable Systems

**D Shepelsky**, Institute for Low Temperature Physics and Engineering, Kharkov, Ukraine

## Introduction

The Riemann–Hilbert (RH) method in mathematical physics and analysis consists in reducing a particular problem to the problem of reconstruction of an analytic, scalar- or matrix-valued function in the complex plane from a prescribed jump across a given curve. More precisely, let an oriented contour $\Sigma$ be given in the complex $\lambda$-plane. The contour $\Sigma$ may have points of self-intersections, and it may consist of several connected components; typical contours appearing in applications to integrable systems are shown in Figure 1.

The orientation of an arc in $\Sigma$ defines the $+$ and the $-$ side of $\Sigma$. Suppose in addition that we are given a map $v : \Sigma \to GL(N, \mathbb{C})$ with $v, v^{-1} \in L^\infty(\Sigma)$. The (normalized) RH problem determined by the pair $(\Sigma, v)$ consists in finding an $N \times N$

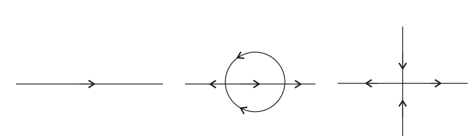

**Figure 1** Typical contours for RH problems.

matrix-valued function $m(\lambda)$ with the following properties:

$$m(\lambda) \text{ is analytic in } \mathbb{C}\backslash\Sigma \quad [1a]$$

$$m_+(\lambda) = m_-(\lambda)v(\lambda) \text{ for } \lambda \in \Sigma \text{ where } m_+(\lambda)(m_-(\lambda)) \text{ is the limit of } m \text{ from the } +(-) \text{ side of } \Sigma \quad [1b]$$

$$m(\lambda) \to I \text{ (identity matrix) as } \lambda \to \infty \quad [1c]$$

The precise sense in which the limit at $\infty$ and the boundary values $m_\pm$ are attained are technical matter that should be specified for each given RH problem $(\Sigma, v)$.

Concerning the name RH problem we note that in literature (particularly, in the theory of boundary values of analytic functions), the problem of reconstructing a function from its jump across a curve is often called the Hilbert boundary-value problem. The closely related problem of analytic matrix factorization (given $\Sigma$ and $v$, find $G(\lambda)$ analytic and nondegenerate in $\mathbb{C}\backslash\Sigma$ such that $G_+G_- = v$ on $\Sigma$) is sometimes called the Riemann problem. The name "RH problem" is also attributed to the reconstruction of a Fuchsian system with given poles and a given monodromy group.

In applications, the jump matrix $v$ also depends on certain parameters, in which the original problem at hand is naturally formulated (e.g., $v = v(\lambda; x, t)$ in applications to the integrable nonlinear differential equations in dimension $1 + 1$, with $x$ being the space variable and $t$ the time variable), and the main concern is the behavior of the solution of the RH problem, $m(\lambda; x, t)$, as a function of $x$ and $t$. Particular interest is in the behavior of $m(\lambda; x, t)$ as $x$ and $t$ become large.

In the scalar case, $N = 1$, rewriting the original multiplicative jump condition in the additive form

$$\log m_+(\lambda) = \log m_+(\lambda) + \log v(\lambda)$$

and using the Cauchy–Plemelj–Sokhotskii formula give an explicit integral representation for the solution

$$m(\lambda) = \exp\left\{\frac{1}{2\pi \mathrm{i}}\int_\Sigma \frac{\log v(\mu)}{\mu - \lambda}\mathrm{d}\mu\right\} \quad [2]$$

(in the case of nonzero index, $\Delta \log v|_\Sigma \neq 0$, formula [2] admits a suitable modification).

A generic (nonabelian) matrix RH problem cannot be solved explicitly in terms of contour integrals; however, it can always be reduced to a system of linear singular-integral equations, thus linearizing an originally nonlinear system.

The main benefit of reducing an originally nonlinear problem to the analytic factorization of a given matrix function arises in asymptotic analysis. Typically, the dependence of the jump matrix on the external parameters (say, $x$ and $t$) is oscillatory. In analogy of asymptotic evaluation of oscillatory contour integrals via the classical method of steepest descent, in the asymptotic evaluation of the solution $m(\lambda; x, t)$ of the matrix RH problem as $x, t \to \infty$, the nonlinear steepest-descent method examines the analytic structure of the jump matrix $v(\lambda; x, t)$ in order to deform the contour $\Sigma$ to contours where the oscillatory factors become exponentially small as $x, t \to \infty$, and hence the original RH problem reduces to a collection of local RH problems associated with the relevant points of stationary phase. Although the method has (in the matrix case) noncommutative and nonlinear elements, the final result of the analysis is as efficient as the asymptotic evaluation of the oscillatory integrals.

## Dressing Method

The RH method allows describing the solution of a differential system independently of the theory of differential equations. The solution might be explicit, that is, given in terms of elementary or elliptic or abelian functions and contour integrals of such functions. In general (transcendental) case, the solution can be represented in terms of the solution of certain linear singular integral equations.

In the modern theory of integrable systems, a system of nonlinear differential equations is often called integrable if it can be represented as a compatibility condition of an auxiliary overdetermined linear system of differential equations called a Lax pair of the given nonlinear system (actually it might involve more than two linear equations). In order that the compatibility condition represents a nontrivial nonlinear system of equations, the Lax pair is required to depend rationally on an auxiliary parameter (called a spectral parameter). The RH problem formulated in the complex plane of the spectral parameter allows, given a particular solution of the compatibility equations, to construct directly new solutions of the compatibility system by "dressing" the initial one.

For example, let $D(x, \lambda), x \in \mathbb{R}^n, \lambda \in \mathbb{C}$ be an $N \times N$ diagonal, polynomial in $\lambda$ with smooth coefficients, function such that $a_j := \partial D/\partial x_j$ are polynomials in $\lambda$ of degree $d_j$. Then $\Psi_0 := \exp D(x, \lambda)$ solves the system of linear equations $\partial\Psi_0/\partial x_j = a_j\Psi_0$, whose compatibility conditions $\partial^2\Psi_0/\partial x_j\partial x_k = \partial^2\Psi_0/\partial x_k\partial x_j$ are trivially satisfied. Given a contour $\Sigma$ and a smooth function $v$, consider the matrix RH problem [1]

with the jump matrix $\tilde{v}(\lambda; x) := \exp D(x, \lambda) v(\lambda) \exp -D(x, \lambda)$. Let $m(\lambda; x)$ be the solution of this RH problem. Then $(D_j m)_+ = (D_j m)_- \tilde{v}$, where $D_j f := \partial f / \partial x_j + [a_j, f]$ with $[a, b] := ab - ba$. The Liouville theorem implies that $(D_j m) m^{-1}$ is an entire function which is $o(\lambda^{d_j})$ as $\lambda \to \infty$. Setting $\Psi(x, \lambda) := m(\lambda; x) \exp D(x, \lambda)$ gives the system of linear equations

$$\frac{\partial \Psi}{\partial x_j} = a_j + \sum_{k<d_j} \lambda^k q_{jk}(x) \equiv R_j(x, \lambda)\Psi \qquad [3]$$

the compatibility conditions for which are

$$\frac{\partial R_k}{\partial x_j} - \frac{\partial R_j}{\partial x_k} = [R_j, R_k] \qquad [4]$$

Equating coefficients of various powers of $\lambda$ in [4] gives a (generally) nonlinear system of partial differential equations for the coefficient matrices $q_{jk}$. Thus, given $D(x, \lambda)$, the RH problem, if it is solvable, maps the pair $(\Sigma, v)$ to solutions of [4].

Specializing to $n = 2$ with variables $(x, t) \in \mathbb{R}^2$, the overdetermined system of linear equations and the corresponding compatibility conditions are

$$\Psi_x = U\Psi, \qquad \Psi_t = V\Psi \qquad [5]$$

and

$$U_t - V_x + [U, V] = 0 \qquad [6]$$

respectively. Conditions [6] are sometimes called the zero-curvature conditions.

Equations [5] and [6] with $U$ and $V$ depending rationally on the spectral parameter $\lambda$ represents the integrable nonlinear systems in $1 + 1$ dimension. A typical example of such a system is the (defocusing) nonlinear Schrödinger (NLS) equation

$$\mathrm{i}q_t + q_{xx} - 2|q|^2 q = 0 \qquad [7]$$

Starting from the RH problem with the $2 \times 2$ jump matrix

$$v(\lambda; x, t) = \mathrm{e}^{\mathrm{i}\theta\sigma_3/2} v(\lambda) \mathrm{e}^{-\mathrm{i}\theta\sigma_3/2} \qquad [8]$$

where $\theta(\lambda; x, t) = -t\lambda^2 + x\lambda$, $\sigma_3 = \mathrm{diag}\{1, -1\}$, and $v(\lambda)$ satisfies the involution $\sigma_3 v^*(\lambda)\sigma_3 = v(\bar{\lambda})$, expanding out the limit of the solution of the RH problem as $\lambda \to \infty$

$$m(\lambda; x, t) = I + \frac{m_1(x, t)}{\lambda} + o\left(\frac{1}{\lambda}\right) \qquad [9]$$

and arguing as above gives [5], with

$$U = \frac{\mathrm{i}\lambda\sigma_3}{2} + \begin{pmatrix} 0 & q \\ \bar{q} & 0 \end{pmatrix} \qquad [10]$$

and $q = -\mathrm{i}(m_1)_{12}$, whereas the compatibility condition [6] reduces to [7].

The relation between the RH problem and the differential equations [5] is local in $x$ and $t$; it is based only on the unique solvability of the RH problem, the Liouville theorem, and the explicit dependence of the jump matrix in $x$ and $t$. The uniqueness of the solution of an RH problem is basically provided by the Liouville theorem: the ratio $m^{(1)}(m^{(2)})^{-1}$ of any two solutions is analytic in $\mathbb{C}\backslash\Sigma$ and continuous across $\Sigma$ and is therefore identically equal to $I$ by the normalization condition [1c].

On the other hand, there are no completely general effective criteria for the solvability. Nevertheless, many RH problems seen in applications to integrable systems satisfy the following sufficient condition: if $\Sigma$ is symmetric with respect to $\mathbb{R}$ and contains $\mathbb{R}$, and if, in addition, $v^*(\lambda) = v(\bar{\lambda})$ for $\lambda \in \Sigma\backslash\mathbb{R}$ and $\mathrm{Re}\, v(\lambda) > 0$ for $\lambda \in \mathbb{R}$, then the RH problem is solvable.

For nonlinear equations supporting solitons, the RH problem appears naturally in a more general setting, as a meromorphic factorization problem, where $m$ in [1] is sought to be a (piecewise) meromorphic function, with additionally prescribed poles and respective residue conditions. Alternatively, in the Riemann factorization problem $G_+ G_- = v$, one assumes that $G$ degenerates at some given points $\lambda_1, \ldots, \lambda_n \in \Omega^+$ and $\mu_1, \ldots, \mu_n \in \Omega^-$, where $\mathbb{C} = \Omega^+ \cup \Omega^- \cup \Sigma$, and prescribes two sets of subspaces, $\mathrm{Im}\, G|_{\lambda=\lambda_j}$ and $\mathrm{Ker}\, G|_{\lambda=\mu_j}$. In the case $v \equiv I$, the solution of the factorization problem with zeros (meromorphic RH problem) is purely algebraic, and gives formulas describing multisoliton solutions. In the general case, $v \not\equiv I$, the meromorphic RH problem can be algebraically converted to a holomorphic RH problem, by subsequently removing the poles with the help of the Blaschke–Potapov factors.

Alternatively, a meromorphic RH problem can be converted to a holomorphic one by adding to $\Sigma$ an additional contour $\Sigma_{\mathrm{aux}}$ enclosing all the poles, interpolating the constants involved in the residue conditions inside the region surrounded by $\Sigma_{\mathrm{aux}}$, and defining a new jump matrix on $\Sigma_{\mathrm{aux}}$ using the interpolant and the Blaschke–Potapov factors.

RH problems formulated on the complex plane $\mathbb{C}$ correspond typically to solutions of relevant nonlinear problems decaying at infinity. For other types of boundary conditions (e.g., nonzero constants or periodic or quasiperiodic boundary conditions), the corresponding RH problem is naturally formulated on a Riemann surface. For example, the RH problem associated with finite density conditions $q(x, t) \to \rho \mathrm{e}^{\mathrm{i}\phi_\pm}$ as $x \to \pm\infty$ for the NLS equation [7] is naturally formulated on the two-sheet Riemann surface of the function $k(\lambda) = \sqrt{\lambda^2 - 4\rho^2}$ with

the contour $\Sigma$ consisting of the points $(\lambda, \varepsilon)$, where $|\lambda| \geq 2\rho$ and $\varepsilon = \pm 1$ marks the surface sheet.

## Inverse-Scattering Transform

The inverse-scattering transform method for solving initial-value problems for integrable nonlinear equations written as the compatibility conditions [6] for linear equations [5] consists in the following: starting from the given initial data, solve the direct problem, that is, determine appropriate eigenfunctions (solutions of the differential $x$-equation in the Lax pair [5]) having well-controlled analytic properties as functions of the auxiliary (spectral) parameter $\lambda$ and the associated spectral functions of $\lambda$; then, by virtue of the $t$-equations in the Lax pair [5], the associated functions evolve in a simple, explicit way. Finally, using the explicit evolution of the spectral functions, solve the inverse problem of finding the associated coefficients in the $x$-equation, which, by [5], evolve according to the given nonlinear equation and thus solve the Cauchy problem for this equation. The last step in this procedure, the inverse-scattering problem, can be effectively solved by reformulating it as an RH problem, which in turn can be related to a system of singular integral equations. The classical Gelfand–Levitan–Marchenko integral equation of the inverse-scattering problem is the Fourier transform of some special cases of these singular integral equations.

To fix ideas, consider the initial-value problem for the NLS equation [7], where the data $q(x, t=0) = q_0(x)$ have sufficient smooth and decay as $|x| \to \infty$. For each $\lambda \in \mathbb{C}\backslash\mathbb{R}$, one constructs solutions $\Psi(x, \lambda)$ of $\Psi_x = U\Psi$ with $U$ given by [10], having the properties

$$m(x, \lambda) := \Psi(x, \lambda) \exp\left(\frac{-\mathrm{i}x\lambda\sigma_3}{2}\right) \to I \quad \text{as } x \to -\infty$$

and $m(x, \lambda)$ is bounded as $x \to \infty$. For each fixed $x$, the $2 \times 2$ matrix function $m(x, \lambda)$ solves the RH problem in $\lambda$, where $\Sigma = \mathbb{R}$ and the jump matrix is

$$v = v(\lambda; x) = \begin{pmatrix} 1 - |r(\lambda)|^2 & r(\lambda)\,\mathrm{e}^{\mathrm{i}\lambda x} \\ -\bar{r}(\lambda)\,\mathrm{e}^{-\mathrm{i}\lambda x} & 1 \end{pmatrix} \qquad [11]$$

Here $r(\lambda)$ is the reflection coefficient of $q_0(x)$.

The direct scattering map $\mathcal{R}$ is described by mapping $q \mapsto r$,

$$q \mapsto m(x, \lambda) = m(x, \lambda; q) \mapsto v(\lambda; x) \mapsto r = \mathcal{R}(q)$$

By virtue of the $t$-equations in [5], if $q(t) = q(x, t)$ solves the NLS equation, then $r(t) = \mathcal{R}(q(\,\cdot\,, t))$ evolves as $r(t) = r(t, \lambda) = \mathrm{e}^{-\mathrm{i}t\lambda^2} r_0(\lambda)$, where $r_0 = \mathcal{R}(q_0)$. Given $r$, the inverse-scattering map $\mathcal{R}^{-1}$ is obtained by solving the normalized RH problem (RHP) with the jump matrix [11] and evaluating its solution $m(x, \lambda)$ as $\lambda \to \infty$ [9]:

$$\begin{aligned} r \mapsto v \mapsto \mathrm{RHP} &\mapsto m(x, \lambda) \\ &= m(x, \lambda; r) \mapsto m_1(x) \mapsto q(x) \\ &= -\mathrm{i}(m_1(x))_{12} \end{aligned}$$

and thus

$$q(x, t) = \mathcal{R}^{-1}\left(\mathrm{e}^{\mathrm{i}x(\cdot) - \mathrm{i}t(\cdot)^2} r(\cdot)\right) \qquad [12]$$

The mathematical rigor to this scheme is provided by the general theory of analytic matrix factorization making use of the relation between the factorization problem and certain singular integral equations; this relation can be established with the help of the Cauchy operators

$$Ch(\lambda) = \int_\Sigma \frac{h(\mu)}{\mu - \lambda} \frac{\mathrm{d}\mu}{2\pi\mathrm{i}}, \quad \lambda \in \mathbb{C}\backslash\Sigma$$

and

$$C^{\pm}h(\lambda) = \lim_{\substack{\lambda' \to \lambda \\ \lambda' \in (\pm)-\text{side of } \Sigma}} (Ch)(\lambda')$$

For a very general class of contours, the Cauchy operators $C^{\pm} : L^p \to L^p, 1 < p < \infty$, are bounded, $C^+ - C^- = I$, and $C^+ + C^- = -H$, where

$$Hh(\lambda) := \lim_{\varepsilon \to 0} \int_{\substack{\Sigma \\ |\mu - \lambda| > \varepsilon}} \frac{h(\mu)}{\lambda - \mu} \frac{\mathrm{d}\mu}{\pi\mathrm{i}}$$

is the Hilbert transform.

The map $\mathcal{R}$ is often considered as a nonlinear Fourier-type map; this point of view is supported by the fact that $\mathcal{R}$ is a bijection between the corresponding Schwartz spaces of functions. Making use of the $L^p$ or Hölder theory of the Cauchy operators and the related factorization problems, it is possible to analyze the action of $\mathcal{R}$ and $\mathcal{R}^{-1}$ in various functional spaces. This also requires making more precise the definition of the RH problem: for fixed $1 < p < \infty$, given $\Sigma$ and $v$ such that $v, v^{-1} \in L^\infty(\Sigma \to GL(N, \mathbb{C}))$, we say that $m_\pm$ solves an RH $L^p$-problem if $m_\pm \in I + \partial C(L^p)$ and $m_+(\lambda) = m_-(\lambda)v(\lambda)$ for $\lambda \in \Sigma$. Here a pair of $L^p(\Sigma)$-functions $f_\pm \in \partial C(L^p)$ if there exists a unique function $h \in L^p(\Sigma)$ such that $f_\pm(\lambda) = (C^\pm h)(\lambda)$. Then $f(\lambda) = Ch(\lambda)$, $\lambda \in \mathbb{C}\backslash\Sigma$, is called the extension of $f_\pm$ off $\Sigma$.

Given a factorization of $v = (v^-)^{-1}v^+ = (I - w^-)^{-1}(I + w^+)$ on $\Sigma$ with $v^\pm, (v^\pm)^{-1} \in L^p$, the basic associated singular integral operator is defined by

$$C_w h := C^+(hw^-) + C^-(hw^+)$$

If the operator $I - C_w$ is invertible on $L^p(\Sigma)$, with $\mu \in I + L^p(\Sigma)$, solving $(I - C_w)m = I$, then $m(\lambda) = I + (C(\mu(w_+ + w^-)))(\lambda)$ is the unique solution of the

RH problem $(\Sigma, v)$. Although the operator $C_w$ need not be compact, in many cases it is Fredholm with zero index. Then the existence of $(I - C_w)^{-1}$ is equivalent to the solvability of the RH problem $(\Sigma, v)$, and the normalized RH problem ($m \to I$ as $\lambda \to \infty$) has a unique solution if and only if the corresponding homogeneous RH problem (with $m \to 0$ as $\lambda \to \infty$) has only the trivial solution (vanishing lemma).

The most complete theory for RH problem relative to simple contours is the theory when $v$ is in an inverse, closed, decomposing Banach algebra $\mathcal{A}$, that is, the algebra of continuous functions with the Hilbert transform bounded in it such that if $f \in \mathcal{A}$, then $f^{-1} \in \mathcal{A}$. For contours with self-intersections, the RH factorization theory is formulated in terms of a pair of decomposing algebras: choosing the orientation of the contour in such a way that it divides the $\lambda$-plane into two disjoint regions, $\Omega^+$ and $\Omega^-$, and each arc of $\Sigma$ forms part of the positively oriented boundary of $\Omega^+$, the functions in the $+(-)$ algebra are continuous up to the boundary in each connected component of $\Omega^+$ $(\Omega^-)$.

The choice of functional spaces in the RH problem should be based on the integrable system at hand. For example, an integrable flow connected to the scattering problem for $\Psi_x = U\Psi$, with $U$ defined by [10], has in general the form $e^{it\lambda^p\sigma_3}v(\lambda)e^{-it\lambda^p\sigma_3}$ (Ablowitz–Kaup–Newell–Segur (AKNS) hierarchy) in the scattering space (for the NLS equation, $p=2$), so that appropriate spaces are $L^2((1+x^2)\,dx) \cap H^{p-1}$ for $q(\cdot, t)$ and $L^2((1+|\lambda|^{2p-2})|d\lambda|) \cap H^1$ as the scattering space. Deift and Zhou showed that in this case the scattering map $\mathcal{R}$ and the inverse-scattering map $\mathcal{R}^{-1}$ indeed involve no "loss" of smoothness or decay.

A generalization of the inverse-scattering transform method to the initial boundary-value problems for integrable nonlinear equations (on the half-line or on a finite interval with respect to the space variable $x$) can be also developed on the basis of the RH problem formalism. It this case, the construction of the corresponding RH problem involves simultaneous spectral analysis of the both linear equations in the Lax pair [5]. The boundary values generate an additional set of spectral functions, which generally makes the construction of the associated RH problem more complicated than in the case of the corresponding initial-value problem (particularly, the contour is to be enhanced by adding the part coming from the spectral analysis of the $t$-equation); however, this RH problem again depends explicitly on $x$ and $t$, which makes it possible to develop relevant techniques (such as the nonlinear steepest-descent method for the asymptotic analysis) in the same spirit as in the case of initial-value problems.

An RH problem may be viewed as a special case in a more general setting of problems of reconstructing an analytic function from the known structure of its singularities. The departure from analyticity of a function $m$ of the complex variable $\lambda$ can be described in terms of the "d-bar" derivative, $\partial m/\partial\bar{\lambda}$. If $\partial m/\partial\bar{\lambda}$ can be linearly related to $m$ itself, then the use of the extension of Cauchy's formula

$$m(\lambda) = \frac{1}{2\pi i}\int_D d\mu \wedge d\bar{\mu}\frac{1}{\mu-\lambda}\frac{\partial m}{\partial\bar{\mu}} + \frac{1}{2\pi i}\int_{\partial D} d\mu\frac{m(\mu)}{\mu-\lambda}$$

leads to a linear integral equation for $m$. This is the case for some multidimensional $(2+1)$ nonlinear integrable equations. For example, for the Kadomtsev–Petviashvili-I equation (the two-dimensional generalization of the Korteweg–de Vries equation) $(q_t + 6qq_x + q_{xxx})_x = 3q_{yy}$, the appropriate eigenfunctions are still sectionally meromorphic, but their jumps across a contour are connected nonlocally to $m$ on the contour, which leads to nonlocal RH problem of the type

$$m_+(\lambda) = m_-(\lambda) + \int_\Sigma d\mu m_-(\mu)f(\mu,\lambda), \quad \lambda \in \Sigma$$

with given $f(\mu,\lambda)$ (analogue of scattering data). Contrarily, the eigenfunctions for the Kadomtsev–Petviashvili-II equation $(q_t + 6qq_x + q_{xxx})_x = -3q_{yy}$ are nowhere analytic, with $\partial m/\partial\bar{\lambda}$ related to $m$ by

$$\frac{\partial m}{\partial\bar{\lambda}}(\lambda) = F(\operatorname{Re}\lambda, \operatorname{Im}\lambda)m(-\bar{\lambda}), \quad \lambda \in \mathbb{C}$$

## Nonlinear Steepest-Descent Method

The nonlinear steepest-descent method is based on a direct asymptotic analysis of the relevant RH problem; it is general and algorithmic in the sense that it does not require *a priori* information (anzatz) about the form of the solution of the asymptotic problem. However, the noncommutativity of the matrix setting requires developing rather sophisticated technical ideas, which, in particular, enable an explicit solution of the associated local RH problems.

To fix ideas, let us again consider the NLS equation. The dependence of the jump matrix $v(\lambda; x, t)$ on $x$ and $t$ is oscillatory; it is the same as in the integral

$$q(x,t) = \frac{1}{\sqrt{2\pi}}\int_{\mathbb{R}} e^{i(x\lambda - t\lambda^2)}\hat{q}_0(\lambda)d\lambda \qquad [13]$$

which solves the initial-value problem for the linearized version of [7]:

$$iq_t + q_{xx} = 0, \quad q(x,0) = q_0(x) \qquad [14]$$

(here $\hat{q}_0(\lambda)$ is the Fourier transform of the initial data $q_0$). The main contribution to [13] as $|x|$ and $t$ tend to $\infty$ comes from the point of stationary phase of $e^{i(x\lambda - t\lambda^2)}$, that is, the point $\lambda = \lambda_0 = x/2t$, for which

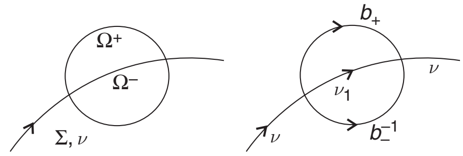
$$\frac{d}{d\lambda}(x\lambda - t\lambda^2) = 0$$

If $\hat{q}_0(\lambda)$ is analytic in a strip $|\mathrm{Im}\,\lambda| < \varepsilon$, then one can use Cauchy's theorem to deform [13] to an integral on a contour $\Sigma_\varepsilon$ such that $|e^{i(x\lambda - t\lambda^2)}|$ decreases rapidly on $\Sigma_\varepsilon$ away from $\lambda = \lambda_0$. Hence, as $t \to \infty$, the problem localizes to a neighborhood of $\lambda = \lambda_0$; this constitutes the standard method of steepest descent.

In the spirit of the oscillatory contour integral case, the nonlinear steepest-descent method for an oscillatory RH problem introduced by Deift and Zhou consists in the following: deform the contour and (rationally) approximate the jump matrix in order to obtain an RH problem with a jump matrix that decays to the identity away from stationary phase points; then, rescaling the problem near the stationary phase points, obtain a (local) RH problem with a piecewise constant jump matrix, which can be solved in closed form, usually in terms of certain special functions.

The contour deformation means the following. Suppose that the jump matrix of an RH problem $(\Sigma, v)$ has a factorization $v = b_-^{-1} v_1 b_+$ between two points on $\Sigma$, where $b_+(b_-)$ has holomorphic and nondegenerating continuation to the part $\Omega^+(\Omega^-)$ of a disk $\Omega$ supported by these points, see Figure 2a. Then the contour $\Sigma$ may be deformed to the contour $\Sigma' = \Sigma \cup \partial\Omega$, and the jump matrices across $\Sigma'$ may be defined as indicated in Figure 2b. If $m$ solves the RH problem $(\Sigma, v)$, then $m'$ defined by $m' = m b_\pm^{-1}$ in $\Omega^\pm$ and $m' = m$ outside $\Omega$ solves the deformed RH problem associated with $\Sigma'$.

The appropriate factorization of $v$ given by [8] and the contour deformation are to be chosen in accordance with signature table; for the NLS equation, it is given in Figure 3. The key step is to move algebraically the factors $e^{\pm i\theta}$ in $v(\lambda; x, t)$ into regions of the complex plane, where they are exponentially decreasing as $t \to \infty$. The jump matrix admits two algebraic factorizations:



(a) (b)

**Figure 2** Deformation of an RH problem.

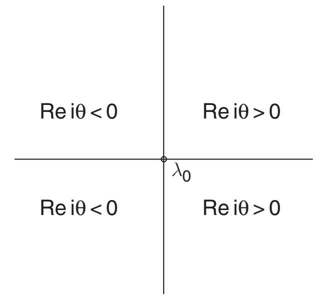


**Figure 3** Signature table.

$$\begin{aligned} v &= \begin{pmatrix} 1 - |r|^2 & r e^{i\theta} \\ -\bar{r} e^{-i\theta} & 1 \end{pmatrix} \\ &= \begin{pmatrix} 1 & r e^{i\theta} \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ -\bar{r} e^{-i\theta} & 1 \end{pmatrix} \quad (\lambda > \lambda_0) \\ &= \begin{pmatrix} 1 & 0 \\ -\dfrac{\bar{r} e^{-i\theta}}{1 - |r|^2} & 1 \end{pmatrix} \begin{pmatrix} 1 - |r|^2 & 0 \\ 0 & \dfrac{1}{1 - |r|^2} \end{pmatrix} \\ &\quad \times \begin{pmatrix} 1 & \dfrac{r e^{i\theta}}{1 - |r|^2} \\ 0 & 1 \end{pmatrix} \quad (\lambda < \lambda_0) \end{aligned}$$

The diagonal factors $(1 - |r|^2)^{\pm 1}$ can be removed by conjugating $v$ by $\delta_\pm^{\sigma_3}$, where $\delta(\lambda)$ solves the scalar, normalized RH problem on $\mathbb{R}: \delta_+ = \delta_-(1 - |r|^2)$ for $\lambda < \lambda_0$ and $\delta_+ = \delta_-$ for $\lambda > \lambda_0$; the solution of the latter can be written in a closed form:

$$\delta(\lambda) = \exp\left\{ \frac{1}{2\pi i} \int_{-\infty}^{\lambda_0} \frac{\log(1 - |r(\mu)|^2)}{\mu - \lambda} \, d\mu \right\}$$

Then $\tilde{m} := m \delta^{-\sigma_3}$ solves the RH problem across $\Sigma = \mathbb{R}$, with the jump matrix

$$\begin{aligned} \tilde{v} &= \begin{pmatrix} 1 & r\delta^2 e^{i\theta} \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ -\bar{r}\delta^{-2} e^{-i\theta} & 1 \end{pmatrix} \quad (\lambda > \lambda_0) \\ &= \begin{pmatrix} 1 & 0 \\ -\dfrac{\bar{r}\delta_-^{-2} e^{-i\theta}}{1 - |r|^2} & 1 \end{pmatrix} \begin{pmatrix} 1 & \dfrac{r\delta_+^2 e^{i\theta}}{1 - |r|^2} \\ 0 & 1 \end{pmatrix} \quad (\lambda < \lambda_0) \end{aligned}$$

Replacing $r, \bar{r}$, etc., by appropriate rational approximations $[r], [\bar{r}]$, matching at $\lambda = \lambda_0$,

$$\tilde{m}_+ \begin{pmatrix} 1 & 0 \\ -[\bar{r}]\delta^{-2} e^{-i\theta} & 1 \end{pmatrix}$$

can be continued to the sector above $\mathbb{R}_+ + \lambda_0$ and

$$\tilde{m}_- \begin{pmatrix} 1 & [r]\delta^2 e^{i\theta} \\ 0 & 1 \end{pmatrix}$$

can be continued to the sector below $\mathbb{R}_+ + \lambda_0$, where the factors $e^{\pm i\theta}$ are exponentially decreasing. Doing the same for the appropriate factors on $\mathbb{R}_- + \lambda_0$, we obtain an RH problem on a cross, say, $(\lambda_0 + e^{i\pi/4}\mathbb{R}) \cup (\lambda_0 + e^{-i\pi/4}\mathbb{R})$. As $t \to \infty$, the RH problem then localizes at $\lambda_0$.

Performing an appropriate scaling, a straightforward computation shows that, as $t \to \infty$, the problem reduces to an RH problem with the jump matrix that does not depend on $\lambda$ (it is determined by $r(\lambda_0)$), which make it possible to solve this problem explicitly (in terms of the parabolic cylinder functions, in the case of the NLS equation). Using explicit asymptotics for these functions and controlling the error terms, it is possible to obtain the uniform (for all $x \in \mathbb{R}$) asymptotics for the solution of the initial-value problem for the NLS equation with $q_0 \in L^2((1+x^2)\,dx) \cap H^1$ of the form

$$q(x,t) = t^{-1/2}\alpha(\lambda_0)\exp(ix^2/(4t) - i\nu(\lambda_0)\log 2t) + O(t^{-(1/2+\kappa)})$$

for any fixed $0 < \kappa < 1/4$, where $\alpha$ and $\nu$ are given in terms of $r = \mathcal{R}(q_0)$:

$$\nu(\lambda) = -\frac{1}{2\pi}\log(1 - |r(\lambda)|^2)$$

$$|\alpha(\lambda)|^2 = \frac{\nu(\lambda)}{2}$$

and

$$\arg\alpha(\lambda) = \frac{1}{\pi}\int_{-\infty}^{\lambda}\log(\lambda-\mu)\,d(\log(1-|r(\mu)|^2)) + \frac{\pi}{4} + \arg\Gamma(i\nu(\lambda)) + \arg r(\lambda)$$

The method can be used to obtain asymptotic expansions to all orders. Also, for nonlinear equations supporting solitons, the soliton part of the asymptotics can be incorporated via the dressing method.

Further applications include long-time asymptotics for near-integrable systems, such as the perturbed NLS equation $iq_t + q_{xx} - 2|q|^2q - \varepsilon|q|^l q = 0$ for $l > 2$ and $\varepsilon > 0$, and the small-dispersion limits of integrable equations (e.g., for the Korteweg–de Vries equation $q_t - 6qq_x + \varepsilon^2 q_{xxx} = 0$ with small dispersion $\varepsilon \searrow 0$).

The RH formalism makes possible a comprehensive global asymptotic analysis of the Painlevé transcendents (which, due to their increasing role in the modern mathematical physics, should be considered as new nonlinear special functions), including explicit connection formulas, as $x$ approaches relevant critical points along different directions in the complex plane.

The development of the RH method in the theory of integrable systems caused emerging new analytic and algebraic ideas for other branches of mathematics and theoretical physics. The recent examples are the study of the asymptotics in the theory of orthogonal polynomials and random matrices and in combinatories (random permutations).

## Regular and Fuchsian Linear Systems on the Riemann Sphere

Consider a system of ordinary linear differential equations with time belonging to the Riemann sphere $CP^1 = \mathbf{C} \cup \infty$:

$$dX/dt = A(t)X \qquad [1]$$

The $n \times n$ matrix $A$ is meromorphic on $CP^1$, with poles at $a_1, \ldots, a_{p+1}$; the dependent variables $X$ form an $n \times n$ matrix. One can assume that $\infty$ is not among the poles $a_j$ and it is not a pole of the 1-form $A(t)dt$ (this can be achieved by a fractionally-linear transformation of $t$).

P Deligne has introduced a terminology of meromorphic connections and sections which is often preferred in modern literature to the one of meromorphic linear systems and their solutions, and there is a one-to-one correspondence between the two languages.

**Definition 1** System [1] is regular at the pole $a_j$ if its solutions have a moderate (or polynomial) growth rate there, that is, for every sector $S$ centered at $a_j$ and not containing other poles of the system and for every solution $X$ restricted to $S$ there exists $N_j \in \mathbf{R}$ such that $\|X(t - a_j)\| = O(|t - a_j|^{N_j})$ for all $t \in S$. System [1] is regular if it is regular at all poles $a_j$. System [1] is Fuchsian if its poles are logarithmic (i.e., of first order). Every Fuchsian system is regular.

**Remark 2** The opening of the sector $S$ might be $> 2\pi$. Restricting to a sector is necessary because the solutions are, in general, ramified at the poles $a_j$ and by turning around the poles much faster than approaching them one can obtain any growth rate.

A Fuchsian system can be presented in the form

$$dX/dt = \left(\sum_{j=1}^{p+1} A_j/(t - a_j)\right)X, \quad A_j \in \mathrm{gl}(n, \mathbf{C}) \qquad [2]$$

The sum of its *matrices-residua* $A_j$ is 0, that is,

$$A_1 + \cdots + A_{p+1} = 0 \qquad [3]$$

(recall that $\infty$ is not a pole of the system).

**Remark 3** The linear equation (with meromorphic coefficients) $\sum_{j=0}^{n} a_j(t)x^{(j)} = 0$ is Fuchsian if $a_j$ has poles of order only $\leq n - j$. A linear equation is Fuchsian if and only if it is regular. The best-studied Fuchsian equations are the hypergeometric one and its generalizations and the Jordan–Pochhammer equation.

The linear change of the dependent variables

$$X \mapsto W(t)X \qquad [4]$$

(where $W$ is meromorphic on $CP^1$) makes system [2] undergo the gauge transformation

$$A \to -W^{-1}(dW/dt) + W^{-1}AW \qquad [5]$$

(Most often one requires $W$ to be holomorphic and holomorphically invertible for $t \neq a_j, j = 1, \ldots, p+1$, so that no new singular points appear in the system.) This transformation preserves regularity but not necessarily being Fuchsian. The only invariant under the group of linear transformations [4] is the monodromy group of the system.

**Definition 4** Set $\Sigma = CP^1 \backslash \{a_1, \ldots, a_{p+1}\}$. Fix a base point $a_0 \in \Sigma$ and a matrix $B \in \mathrm{GL}(n, \mathbf{C})$. Consider a closed contour $\gamma$ with base point $a_0$ and bypassing the poles of the system. The monodromy operator of system [1] defined by this contour is the linear operator $M$ acting on the solution space of the system which maps the solution $X$ with $X|_{t=a_0} = B$ into the value of its analytic continuation along $\gamma$. Notation: $X \overset{\gamma}{\mapsto} XM$. The monodromy operator depends only on the class of homotopy equivalence of $\gamma$.

The monodromy group is the subgroup of $\mathrm{GL}(n, \mathbf{C})$ generated by all monodromy operators. It is defined only up to conjugacy due to the freedom to choose $a_0$ and $B$.

**Definition 5** Define the product (concatenation) $\gamma_1\gamma_2$ of two paths $\gamma_1, \gamma_2$ in $\Sigma$ (where the end of $\gamma_1$ coincides with the beginning of $\gamma_2$) as the path obtained by running $\gamma_1$ first and $\gamma_2$ next.

**Remark 6** The monodromy group is an antirepresentation of the fundamental group $\pi_1(\Sigma)$ into $\mathrm{GL}(n, \mathbf{C})$ because one has

$$X \overset{\gamma_1}{\mapsto} XM_1 \overset{\gamma_2}{\mapsto} XM_2M_1 \qquad [6]$$

that is, the concatenation $\gamma_1\gamma_2$ of the two contours defines the monodromy operator $M_2M_1$. In the text, the monodromy group is referred to as to a representation, not an antirepresentation.

One usually chooses a standard set of generators of $\pi_1(\Sigma)$ (see Figure 1) defined by contours $\gamma_j, j = 1, \ldots, p+1$, where $\gamma_j$ consists of a segment

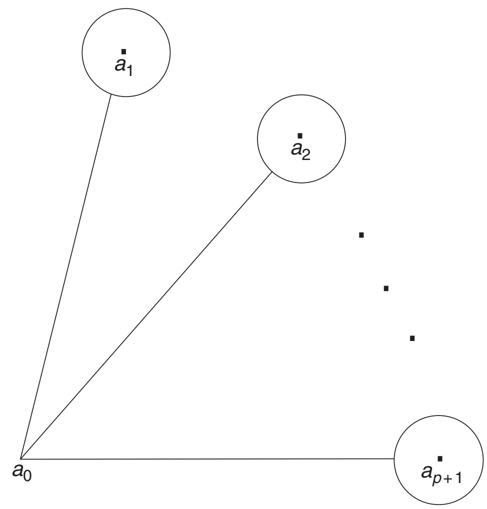

**Figure 1** The standard set of generators.

$[a_0, a'_j]$ ($a'_j$ being a point close to $a_j$), of a small circumference run counterclockwise (centered at $a_j$, passing through $a'_j$ and containing inside no pole of the system other than $a_j$), and of the segment $[a'_j, a_0]$. Thus, $\gamma_j$ is freely homotopic to a small loop circumventing counterclockwise $a_j$ (and no other pole $a_i$). The indices of the poles are chosen such that the indices of the contours increase from 1 to $p+1$ when one turns around $a_0$ clockwise.

For the standard choice of the contours the generators $M_j$ satisfy the relation

$$M_1 \ldots M_{p+1} = I \qquad [7]$$

Indeed, the concatenation of contours $\gamma_{p+1} \ldots \gamma_1$ is homotopy equivalent to 0 and equality [7] results from Remark 6.

**Remarks 7**

(i) If the matrix-residuum $A_j$ of a Fuchsian system has no eigenvalues differing by a nonzero integer, then the monodromy operator $M_j$ defined as above is conjugate to $\exp(2\pi i A_j)$. It is always true that the eigenvalues $\sigma_{k,j}$ of $M_j$ equal $\exp(2\pi i \lambda_{k,j})$, where $\lambda_{k,j}$ are the eigenvalues of $A_j$.

(ii) If the generators $M_j$ of the monodromy group are defined after a standard set of contours $\gamma_j$, then they are conjugate to the corresponding operators $L_j$ of local monodromy, that is, when the poles $a_j$ are circumvented counterclockwise along small loops. The operators $L_j$ of a regular system can be computed (up to conjugacy) algorithmically – one first makes the system Fuchsian at $a_j$ by means of a change [4] and then carries out the computation. Thus, $M_j = Q_j^{-1} L_j Q_j$ for some $Q_j \in GL(n, \mathbf{C})$ and the difficulty when computing the monodromy group of system [1] consists in computing the matrices $Q_j$ which is a transcendental problem.

(iii) As will be noted in Theorem 9, every component of every solution to a regular linear system is a function of the class of Nilsson, that is, representable as a convergent (on sectors) series $\sum_{k \in \mathbf{N},\, 1 \le i \le n,\, 0 \le \nu \le n-1} a_{i,k,\nu} t^{\alpha_i + k} \ln^\nu t$, $\alpha_i \in \mathbf{C}$, $a_{i,k,\nu} \in \mathbf{C}$.

**Example 8** The Fuchsian system $dX/dt = (A/t)X$, $A \in \mathrm{gl}(n, \mathbf{C})$, has two poles – at 0 and at $\infty$, with matrices-residua $A$ and $-A$. Any solution is of the form $X = \exp(A \ln t)G$, $G \in \mathrm{GL}(n, \mathbf{C})$. To compute the local monodromy around 0, change the argument of $t$ by $2\pi i$. This results in $\ln t \mapsto \ln t + 2\pi i$ and $X \mapsto XG^{-1}\exp(2\pi i A)G$, that is the monodromy operator at 0 equals $G^{-1}\exp(2\pi i A)G$ (and in the same way the one at $\infty$ equals $G^{-1}\exp(-2\pi i A)G$).

## Formulation and History of the Problem

The Riemann–Hilbert problem (or Hilbert's twenty-first problem) is formulated as follows:

*Prove that for any set of points $a_1, \ldots, a_{p+1} \in \mathbf{C}P^1$ and for any set of matrices $M_1, \ldots, M_p \in \mathrm{GL}(n, \mathbf{C})$ there exists a Fuchsian linear system with poles at and only at $a_1, \ldots, a_{p+1}$ for which the corresponding monodromy operators are $M_1, \ldots, M_p$, $M_{p+1} = (M_1 \ldots M_p)^{-1}$.*

Historically, the Riemann–Hilbert problem was first stated for Fuchsian equations, not for systems – Riemann mentions in a note at the end of the 1850s the problem how to reconstruct a Fuchsian equation from its monodromy representation and Hilbert includes it in 1900 as the twenty-first problem on his list in a formulation mentioning equations and not systems. However, the number of parameters necessary to parametrize a Fuchsian equation is, in general, smaller than the one necessary to parametrize a monodromy group generated by $p$ matrices. Therefore, one has to allow the presence of additional apparent singularities in the equation, that is, singularities the monodromy around which is trivial.

It had been believed for a long time that the Riemann–Hilbert problem has a positive solution for any $n \in \mathbf{N}$, after J. Plemelj in 1908 gave a proof with a gap. In his proof, Plemelj tries to reduce the Riemann–Hilbert problem to the so-called homogeneous Hilbert boundary-value problem of the theory of singular integral equations. It follows from the correct part of the proof that if one of

the monodromy operators of system [1] is diagonalizable, then system [1] is equivalent to a Fuchsian one; this is due to Yu S Il'yashenko. (In particular, if one allows just one additional apparent singularity, then the Riemann–Hilbert problem is positively solvable. The author has shown that the result still holds if one of the monodromy operators has one Jordan block of size 2 and $n-2$ Jordan blocks of size 1. The result is sharp – it would be false if one allows one Jordan block of size $\geq 3$ or two blocks of size 2.) It also follows that any finitely generated subgroup of $GL(n, \mathbf{C})$ is the monodromy group of a regular system with prescribed poles which is Fuchsian at all the poles with the possible exception of one (where the system is regular) which can be chosen among them at random.

After the publication of Plemelj's result, the interest shifted basically towards the question how to construct a Fuchsian system given the monodromy operators $M_j$. At the end of the 1920s IA Lappo-Danilevskii expressed the solutions to a Fuchsian system as series of the monodromy operators. These series are convergent for monodromy operators close to the identity matrix and for such operators one can express the residua $A_j$ of the Fuchsian system as convergent series of the monodromy operators.

In 1956 BL Krylov proved that the Riemann–Hilbert problem is solvable for $n=p=2$ by constructing a Fuchsian system after its monodromy group. In 1983 NP Erugin did the same in the case $n=2, p=3$, and established a connection between the Riemann–Hilbert problem and Painlevé's equations.

In 1957 H Röhrl reformulated the problem in terms of fibre bundles. His approach is more geometric; however, it does not require the system realizing a given monodromy group to be Fuchsian, but only regular.

In 1978 W Dekkers considered the particular case $n=2$ of the Riemann–Hilbert problem, and gave a positive answer to it. The gap in Plemelj's proof was detected in the 1980s by AT Kohn and YuS Il'yashenko.

It was proved by AA Bolibrukh in 1989 that, for $n \geq 3$, the problem has a negative answer. For $n=3$, the answer is negative precisely for those couples (monodromy group, set of poles) for which each monodromy operator $M_1, \ldots, M_{p+1}$ is conjugate to a Jordan block of size 3, the monodromy group is reducible, with an invariant subspace or factor-space of dimension 2, the monodromy sub- or factor-representation corresponding to it is irreducible and cannot be realized by a Fuchsian system having all its matrices-residua conjugate to Jordan blocks of size 2. In Bolibrukh's work, the last condition is formulated in a different (but equivalent) way using the notion of Fuchsian weight.

## The New Setting of the Problem

After the negative answer to the Riemann–Hilbert problem for $n \geq 3$, it is reasonable to reformulate it as follows:

*Find necessary and/or sufficient conditions for the choice of the monodromy operators $M_1, \ldots, M_p$ and the points $a_1, \ldots, a_{p+1}$ so that there should exist a Fuchsian system with poles at and only at the given points and whose monodromy operators $M_j$ should be the given ones.*

In the new setting of the Riemann–Hilbert problem, the answer is positive if the monodromy group is irreducible (for any positions of the poles $a_j$). This has been first proved by Bolibrukh for $n=3$ and then independently by the author and by him for any $n$.

Bolibrukh found many examples of couples (reducible monodromy group, poles) for which the answer to the Riemann–Hilbert problem is negative. For $n=3$, the negative answer is due to possible "bad position" of the poles and a small shift from this position while keeping the same monodromy group leads to a couple for which the answer is positive. For $n \geq 4$, there are couples where the negative answer is due to arithmetic properties of the eigenvalues of the matrices-residua and the corresponding monodromy groups are not realizable by Fuchsian systems for any position of the poles. During the last years of his life, Bolibrukh studied upper-triangular monodromy representations and found other examples with negative answer to the Riemann–Hilbert problem.

Bolibrukh also found some sufficient conditions for the positive resolvability of the Riemann–Hilbert problem in the case of a reducible monodromy group. For example, suppose that the monodromy group is a semidirect sum:

$$M_j = \begin{pmatrix} M_j^1 & * \\ 0 & M_j^2 \end{pmatrix}$$

where the matrices $M_j^i$ (of size $l_i \times l_i, i=1,2$) define the representations $\chi_i$. Suppose that the representation $\chi_2$ is realizable by a Fuchsian system, that the representation $\chi_1$ is irreducible, and that one of the matrices $M_j$ is block-diagonal, with left upper block of size $s \times s$, where $s \leq l_1$. Then for any choice of the poles $a_j$ the monodromy group can be realized by some Fuchsian system.

Bolibrukh also gave an estimation upon the number $m$ of additional apparent singularities in a Fuchsian equation which are sufficient to realize a given irreducible monodromy group. It follows from his result that

$$m \leq \frac{n(n-1)(p-1)}{2} + 1 - n$$

One can ask the question what the codimension of the subset in the space (monodromy group, poles) is which provides the negative answer to the Riemann–Hilbert problem in its initial setting. The (author's) answer for $p \geq 3$ is $2p(n-1)$, and for $n \geq 7$ this codimension is attained only at couples (monodromy group, poles) for which every monodromy operator $M_j$ is conjugate to a Jordan block of size $n$, the group has an invariant subspace or factor-space of dimension $n-1$, the corresponding sub- or factor-representation is irreducible and cannot be realized by a Fuchsian system in which all matrices-residua are conjugate to Jordan blocks of size $n-1$. For $n \leq 6$ there are examples where the same codimension is attained (but cannot be decreased) on other couples as well.

## Levelt's Result and Bolibrukh's Method

In 1961, AHM Levelt described the form of the solution to a regular system at its pole. His result is in the core of Bolibrukh's method for solving the Riemann–Hilbert problem.

**Theorem 9** *In the neighborhood of a pole, the solution to a regular linear system is representable in the form*

$$X = U_j(t-a_j)(t-a_j)^{D_j}(t-a_j)^{E_j}G_j \qquad [8]$$

*where the matrix* $U_j$ *is holomorphic in a neighborhood of* 0, $D_j = \mathrm{diag}(\varphi_{1,j}, \ldots, \varphi_{n,j}), \varphi_{n,j} \in \mathbf{Z}$, $\det G_j \neq 0$. *The matrix* $E_j$ *is in upper-triangular form and the real parts of its eigenvalues belong to* $[0,1)$ (*by definition*, $(t-a_j)^{E_j} = \mathrm{e}^{E_j \ln(t-a_j)}$). *The numbers* $\varphi_{k,j}$ *satisfy the condition* [10] *formulated below. They are valuations in the eigenspaces of the monodromy operator* $M_j$ (*i.e., in the maximal subspaces invariant for* $M_j$ *on which it acts as an operator with a single eigenvalue*).

*A regular system is Fuchsian at* $a_j$ *if and only if*

$$\det U_j(0) \neq 0 \qquad [9]$$

*The condition on* $\varphi_{k,j}$ *can be formulated as follows: let* $E_j$ *have one and the same eigenvalue in the rows with indices* $s_1 < s_2 < \cdots < s_q$. *Then one has*

$$\varphi_{s_1,j} \geq \varphi_{s_2,j} \geq \cdots \geq \varphi_{s_q,j} \qquad [10]$$

**Remark 10** Denote by $\beta_{k,j}$ the diagonal entries (i.e., the eigenvalues) of the matrix $E_j$. Then the sums $\beta_{k,j} + \varphi_{k,j}$ are the eigenvalues of the matrix-residuum $A_j$ at $a_j$.

In proving that the Riemann–Hilbert problem is positively solved in the case of an irreducible monodromy group, Bolibrukh (or the author) uses the correct part of Plemelj's proof – namely, that the given monodromy group can be realized by a regular system which is Fuchsian at all poles but one. After this, a suitable change [4] is sought which makes the system Fuchsian at the last pole. The criterium to be Fuchsian is provided by the above theorem; one checks how the matrices $D_j$, that is, the exponents $\varphi_{k,j}$ and the matrices $U_j$ change as a result of the transformation [4]. This is easier (one has only to multiply to the left by $W(t)$) than to see how the matrix $A(t)$ of system [1] changes because one has conjugation in rule [5]. This idea is also due to Bolibrukh.

When Bolibrukh obtains the negative answer to the Riemann–Hilbert problem in some case of reducible monodromy group, he often uses the following two propositions:

**Proposition 11** *The sum* $\sum \beta_{k,j} + \varphi_{k,j}$ *relative to a subspace of the solution space invariant for all monodromy operators is a non-positive integer.*

In particular, the sum of all exponents $\beta_{k,j} + \varphi_{k,j}$ is a non-positive integer which is 0 if and only if the system is Fuchsian.

**Proposition 12** *If some component of some column of some matrix solution to a regular system is identically equal to* 0, *then the monodromy group of the system is reducible.*

A reducible monodromy group can be conjugated to a block upper-triangular form, with the diagonal blocks defining irreducible representations. Thus, the Riemann–Hilbert problem for reducible monodromy groups makes necessary the answer to the question "given the set of poles $a_j$, for which sets of exponents $\varphi_{k,j}$ can a given irreducible monodromy group be realized by such a Fuchsian system?" For $n \geq 2$, an irreducible monodromy group can be *a priori* realized by infinitely many Fuchsian systems, with different sets of exponents $\varphi_{k,j}$. Consider the case when these exponents are fixed for $j \neq 1$; suppose that $a_1 = 0$. The author has shown that then infinitely many of the *a priori* possible choices of the exponents $\varphi_{k,1}$ cannot be realized by Fuchsian systems if and only if the given monodromy group is realized by a Fuchsian system which is obtained from another one via the change of time $t \mapsto t^k/(b_k t^k + b_{k-1}t^{k-1} + \cdots + b_0)$, $b_i \in \mathbf{C}, b_0 \neq 0, k \in \mathbf{N}^*, k > 1$. This change increases the number of poles.

## Further Developments – The Deligne–Simpson Problem

The Riemann–Hilbert problem can be generalized for irregular systems as follows. One asks whether for given poles $a_j$ there exists a linear system of ordinary differential equations on the Riemann sphere with these and only these poles which is Fuchsian at the regular singular points, which has prescribed formal normal forms, formal monodromies and Stokes multipliers at the irregular singular points, and which has a prescribed global monodromy.

The Riemann–Hilbert problem has been considered in some papers (of H Esnault, E Vieweg, and C Hertling) in the context of algebraic curves of higher genus instead of $CP^1$.

The study of the so-called Riemann–Hilbert correspondence between the category of holonomic $\mathcal{D}$-modules and the one of perverse sheaves with constructible cohomology has been initiated in the works of J Bernstein in the algebraic aspect and of M Sato, T Kawai, and M Kashiwara in the analytic one. This has been done in the case of a variety of arbitrary dimension (not necessarily $CP^1$), with codimension one pole divisor. Perversity has been defined by P Deligne, M Goresky, and R MacPherson. Regularity has been defined by M Kashiwara in the analytic aspect and by Z Mebkhout in the geometric one. Important contributions in the domain are due to Ph Maisonobe, M Merle, N Nitsure, C Sabbah, and the list is far from being exhaustive. The Riemann–Hilbert correspondence plays an important role in other trends of mathematics as well.

The Deligne–Simpson problem is formulated like this: *Give necessary and sufficient conditions upon the choice of the conjugacy classes* $c_j \subset \mathrm{gl}(n, \mathbf{C})$ *or* $C_j \subset \mathrm{GL}(n, \mathbf{C})$ *so that there should exist an irreducible* (*i.e., without proper invariant subspace*) $(p+1)$*-tuple of matrices* $A_j \in c_j$ *satisfying* [3] *or of matrices* $M_j$ *satisfying* [7].

The problem was stated in the 1980s by P Deligne for matrices $M_j$ and in the 1990s by the author for matrices $A_j$. C Simpson was the first to obtain results towards its resolution in the case of matrices $M_j$. The problem admits the following geometric interpretation in the case of matrices $M_j$: *For which* $(p+1)$*-tuples of local monodromies does there exist an irreducible global monodromy with such local monodromies?*

For generic eigenvalues the problem has found a complete solution in the author's papers in the form of a criterium upon the Jordan normal forms defined by the conjugacy classes. The author has treated the case of nilpotent matrices $A_j$ and the one of unipotent matrices $M_j$ as well. For matrices $A_j$, the problem has been completely solved (for any eigenvalues) by W Crawley-Boevey. The case of matrices $A_j$ with $p = 2$ has been treated by O Gleizer using results of A Klyachko. The case when the matrices $M_j$ are unitary is considered in papers of S Agnihotri, P Belkale, I Biswas, C Teleman, and C Woodward. Several cases of finite groups have been considered by M Dettweiler, S Reiter, K Strambach, J Thompson, and H Völklein. The important rigid case has been studied by NM Katz. Y Haraoka has considered the problem in the context of linear systems in Okubo's normal form. One can find details in an author's survey on the Deligne–Simpson problem (Kostov, 2004).

# Riemannian Holonomy Groups and Exceptional Holonomy

**D D Joyce**, University of Oxford, Oxford, UK

## Riemannian Holonomy Groups

Let $(M, g)$ be a Riemannian $n$-manifold. The holonomy group $\mathrm{Hol}(g)$ is a Lie subgroup of $\mathrm{O}(n)$, a global invariant of $g$ which measures the constant tensors $S$ on $M$ preserved by the Levi-Civita connection $\nabla$ of $g$. The most well-known examples of metrics with special holonomy are Kähler metrics, with $\mathrm{Hol}(g) \subseteq U(m) \subset \mathrm{O}(2m)$. A Kähler manifold $(M, g)$ also carries a complex structure $J$ and Kähler 2-form $\omega$ with $\nabla J = \nabla\omega = 0$.

The classification of Riemannian holonomy groups gives a list of interesting special Riemannian geometries such as Calabi–Yau manifolds and the exceptional holonomy groups $G_2$ and Spin(7), all of which are important in physics. These geometries have many features in common with Kähler geometry, and are characterized by the existence of constant exterior forms.

### General Properties of Holonomy Groups

Let $M$ be a connected manifold of dimension $n$ and $g$ a Riemannian metric on $M$, with Levi-Civita connection $\nabla$, regarded as a connection on the tangent bundle $TM$ of $M$. Suppose $\gamma : [0,1] \to M$ is a smooth path, with $\gamma(0) = x$ and $\gamma(1) = y$. Let $s$ be a smooth section of $\gamma^*(TM)$, so that $s : [0,1] \to TM$ with $s(t) \in T_{\gamma(t)}M$ for each $t \in [0,1]$. Then we say that $s$ is parallel if $\nabla_{\dot\gamma(t)} s(t) = 0$ for all $t \in [0,1]$, where $\dot\gamma(t)$ is

$$\frac{\mathrm{d}}{\mathrm{d}t}\gamma(t) \in T_{\gamma(t)}M$$

For each $v \in T_xM$, there is a unique parallel section $s$ of $\gamma^*(TM)$ with $s(0) = v$. Define a map $P_\gamma : T_xM \to T_yM$ by $P_\gamma(v) = s(1)$. Then $P_\gamma$ is well defined and linear, and is called the parallel transport map along $\gamma$. This easily generalizes to continuous, piecewise-smooth paths $\gamma$. As $\nabla g = 0$, we see that $P_\gamma : T_xM \to T_yM$ is orthogonal with respect to the metric $g$ on $T_xM$ and $T_yM$.

**Definition 1** Fix a point $x \in M$. $\gamma$ is said to be loop based at $x$ if $\gamma : [0,1] \to M$ is a continuous, piecewise-smooth path with $\gamma(0) = \gamma(1) = x$. If $\gamma$ is a loop based at $x$, then the parallel transport map $P_\gamma$ lies in $\mathrm{O}(T_xM)$, the group of orthogonal linear transformations of $T_xM$. Define the (Riemannian) holonomy group $\mathrm{Hol}_x(g)$ of $g$ based at $x$ to be

$$\mathrm{Hol}_x(g) = \{P_\gamma : \gamma \text{ is a loop based at } x\} \subseteq \mathrm{O}(T_xM) \qquad [1]$$

Here are some elementary properties of $\mathrm{Hol}_x(g)$. The only difficult part is showing that $\mathrm{Hol}_x(g)$ is a (closed) Lie subgroup.

**Theorem 2** $\mathrm{Hol}_x(g)$ *is a Lie subgroup of* $\mathrm{O}(T_xM)$, *which is closed and connected if* $M$ *is simply connected, but need not be closed or connected otherwise. Let* $x, y \in M$, *and suppose* $\gamma : [0,1] \to M$ *is a continuous, piecewise-smooth path with* $\gamma(0) = x$ *and* $\gamma(1) = y$, *so that* $P_\gamma : T_xM \to T_yM$. *Then*

$$P_\gamma \, \mathrm{Hol}_x(g) P_\gamma^{-1} = \mathrm{Hol}_y(g) \qquad [2]$$

By choosing an orthonormal basis for $T_xM$ we can identify $\mathrm{O}(T_xM)$ with the Lie group $\mathrm{O}(n)$, and so identify $\mathrm{Hol}_x(g)$ with a Lie subgroup of $\mathrm{O}(n)$. Changing the basis changes the subgroups by conjugation by an element of $\mathrm{O}(n)$. Thus, $\mathrm{Hol}_x(g)$ may be regarded as a Lie subgroup of $\mathrm{O}(n)$ defined up to conjugation. Equation [2] shows that in this sense, $\mathrm{Hol}_x(g)$ is independent of the base point $x$. Therefore, we omit the subscript $x$ and write $\mathrm{Hol}(g)$ for the holonomy group of $g$, regarded as a subgroup of $\mathrm{O}(n)$ defined up to conjugation.

It is significant that $\mathrm{Hol}(g)$ is a global invariant of $g$, that is, it does not vary from point to point like local invariants of $g$ such as the curvature. Generic metrics $g$ on $M$ have $\mathrm{Hol}(g) = \mathrm{SO}(n)$ if $M$ is orientable, and $\mathrm{Hol}(g) = \mathrm{O}(n)$ otherwise. But some special metrics $g$ can have $\mathrm{Hol}(g)$ a proper

subgroup of SO($n$) or O($n$). Then $M$ carries some extra geometric structures compatible with $g$.

Broadly, the smaller Hol($g$) is as a subgroup of O($n$), the more special $g$ is, and the more extra geometric structures there are. Therefore, understanding and classifying the possible holonomy groups gives a family of interesting special Riemannian geometries, such as Kähler geometry. All of these special geometries have cropped up in physics.

Define the holonomy algebra $\mathfrak{hol}(g)$ to be the Lie algebra of Hol($g$), regarded as a Lie subalgebra of $\mathfrak{o}(n)$, defined up to the adjoint action of O($n$). Define $\mathfrak{hol}_x(g)$ to be the Lie algebra of $\mathrm{Hol}_x(g)$, as a Lie subalgebra of $\mathfrak{o}(T_xM) \cong \Lambda^2 T_x^* M$. The holonomy algebra $\mathfrak{hol}(g)$ is intimately connected with the Riemann curvature tensor $R_{abcd} = g_{ae}R^e{}_{bcd}$ of $g$.

**Theorem 3** *The Riemann curvature tensor $R_{abcd}$ lies in $S^2\mathfrak{hol}_x(g)$ at $x$, where $\mathfrak{hol}_x(g)$ is regarded as a subspace of $\Lambda^2 T_x^* M$. It also satisfies the first and second Bianchi identities*

$$R_{abcd} + R_{adbc} + R_{acdb} = 0 \qquad [3]$$

$$\nabla_e R_{abcd} + \nabla_c R_{abde} + \nabla_d R_{abec} = 0 \qquad [4]$$

A related result is the Ambrose–Singer holonomy theorem, which, roughly speaking, says that $\mathfrak{hol}_x(g)$ may be reconstructed from $R_{abcd}|_y$ for all $y \in M$, moved to $x$ by parallel transport.

If $(M, g)$ and $(N, h)$ are Riemannian manifolds, the product $M \times N$ carries a product metric $g \times h$. It is easy to show that $\mathrm{Hol}(g \times h) = \mathrm{Hol}(g) \times \mathrm{Hol}(h)$. A Riemannian manifold $(M, g)$ is called reducible if every point has an open neighborhood isometric to a Riemannian product and irreducible otherwise.

**Theorem 4** *Let $(M, g)$ be Riemannian $n$-manifold. Then the natural representation of* Hol($g$) *on $\mathbb{R}^n$ is reducible if and only if $g$ is reducible.*

There is a class of Riemannian manifolds called the "Riemannian symmetric spaces" which are important in the theory of Riemannian holonomy groups. A Riemannian symmetric space is a special kind of Riemannian manifold with a transitive isometry group. The theory of symmetric spaces was worked out by Élie Cartan in the 1920s, who classified them completely, using his own classification of Lie groups and their representations.

A Riemannian metric $g$ is called "locally symmetric" if $\nabla_e R_{abcd} \equiv 0$, and "nonsymmetric" otherwise. Every locally symmetric metric is locally isometric to a Riemannian symmetric space. The relevance of symmetric spaces to holonomy groups is that many possible holonomy groups are the holonomy group of a Riemannian symmetric space, but are not realized by any nonsymmetric metric. Therefore, by restricting attention to nonsymmetric metrics, one considerably reduces the number of possible Riemannian holonomy groups.

A tensor $S$ on $M$ is constant if $\nabla S = 0$. An important property of Hol($g$) is that it determines the constant tensors on $M$.

**Theorem 5** *Let $(M, g)$ be a Riemannian manifold, with Levi-Civita connection $\nabla$. Fix $x \in M$, so that* $\mathrm{Hol}_x(g)$ *acts on $T_xM$, and so on the tensor powers $\bigotimes^k T_xM \otimes \bigotimes^l T_x^*M$. Suppose $S \in C^\infty(\bigotimes^k TM \otimes \bigotimes^l T^*M)$ is a constant tensor. Then $S|_x$ is fixed by the action of* $\mathrm{Hol}_x(g)$. *Conversely, if $S|_x \in \bigotimes^k T_xM \otimes \bigotimes^l T_x^*M$ is fixed by* $\mathrm{Hol}_x(g)$, *it extends to a unique constant tensor $S \in C^\infty(\bigotimes^k TM \otimes \bigotimes^l T^*M)$.*

The main idea in the proof is that if $S$ is a constant tensor and $\gamma : [0,1] \to M$ is a path from $x$ to $y$, then $P_\gamma(S|_x) = S|_y$, that is, "constant tensors are invariant under parallel transport." In particular, they are invariant under parallel transport around closed loops based at $x$, and so under elements of $\mathrm{Hol}_x(g)$.

### Berger's Classification of Holonomy Groups

Berger classified Riemannian holonomy groups in 1955.

**Theorem 6** *Let $M$ be a simply connected, $n$-dimensional manifold, and $g$ an irreducible, nonsymmetric Riemannian metric on $M$. Then*

(i) $\mathrm{Hol}(g) = \mathrm{SO}(n)$,
(ii) $n = 2m$ *and* $\mathrm{Hol}(g) = \mathrm{SU}(m)$ *or* $\mathrm{U}(m)$,
(iii) $n = 4m$ *and* $\mathrm{Hol}(g) = \mathrm{Sp}(m)$ *or* $\mathrm{Sp}(m)\mathrm{Sp}(1)$,
(iv) $n = 7$ *and* $\mathrm{Hol}(g) = G_2$, *or*
(v) $n = 8$ *and* $\mathrm{Hol}(g) = \mathrm{Spin}(7)$.

To simplify the classification, Berger makes three assumptions: $M$ is simply connected, $g$ is irreducible, and $g$ is nonsymmetric. We can make $M$ simply connected by passing to the "universal cover." The holonomy group of a reducible metric is a product of holonomy groups of irreducible metrics, and the holonomy groups of locally symmetric metrics follow from Cartan's classification of Riemannian symmetric spaces. Thus, these three assumptions can easily be removed.

Here is a sketch of Berger's proof of Theorem 6. As $M$ is simply connected, Theorem 2 shows Hol($g$) is a closed, connected Lie subgroup of SO($n$), and since $g$ is irreducible, Theorem 4 shows the representation of Hol($g$) on $\mathbb{R}^n$ is irreducible. So, suppose that $H$ is a closed, connected subgroup of

SO($n$) acting irreducibly on $\mathbb{R}^n$, with Lie algebra $\mathfrak{h}$. The classification of all such $H$ follows from the classification of Lie groups (and is of considerable complexity). Berger's method was to take the list of all such groups $H$, and to apply two tests to each possibility to find out if it could be a holonomy group. The only groups $H$ which passed both tests are those in the theorem.

Berger's tests are algebraic and involve the curvature tensor. Suppose that $R_{abcd}$ is the Riemann curvature of a metric $g$ with $\mathrm{Hol}(g) = H$. Then Theorem 3 gives $R_{abcd} \in S^2\mathfrak{h}$, and the first Bianchi identity [3] applies. But if $\mathfrak{h}$ has large codimension in $\mathfrak{o}(n)$, then the vector space $\mathfrak{R}^H$ of elements of $S^2\mathfrak{h}$ satisfying [3] will be small, or even zero. However, the "Ambrose–Singer holonomy theorem" shows that $\mathfrak{R}^H$ must be big enough to generate $\mathfrak{h}$. For many of the candidate groups $H$, this does not hold, and so $H$ cannot be a holonomy group. This is the first test.

Now $\nabla_e R_{abcd}$ lies in $(\mathbb{R}^n)^* \otimes \mathfrak{R}^H$, and also satisfies the second Bianchi identity, eqn [4]. Frequently, these imply that $\nabla R = 0$, so that $g$ is locally symmetric. Therefore, we may exclude such $H$, and this is Berger's second test.

Berger's proof does not show that the groups on his list actually occur as Riemannian holonomy groups – only that no others do. It is now known, though this took another thirty years to find out, that all possibilities in Theorem 6 do occur.

### The Groups on Berger's List

Here are some brief remarks about each group on Berger's list.

(i) SO($n$) is the holonomy group of generic Riemannian metrics.

(ii) Riemannian metrics $g$ with $\mathrm{Hol}(g) \subseteq \mathrm{U}(m)$ are called "Kähler metrics." Kähler metrics are a natural class of metrics on complex manifolds, and generic Kähler metrics on a given complex manifold have holonomy U($m$).

Metrics $g$ with $\mathrm{Hol}(g) = \mathrm{SU}(m)$ are called Calabi–Yau metrics. Since SU($m$) is a subgroup of U($m$), all Calabi–Yau metrics are Kähler. If $g$ is Kähler and $M$ is simply connected, then $\mathrm{Hol}(g) \subseteq \mathrm{SU}(m)$ if and only if $g$ is Ricci-flat. Thus, Calabi–Yau metrics are locally more or less the same as Ricci-flat Kähler metrics.

If $(M, J)$ is a compact complex manifold with trivial canonical bundle admitting Kähler metrics, then Yau's solution of the Calabi conjecture gives a unique Ricci-flat Kähler metric in each canonical class. This gives a way to construct many examples of Calabi–Yau manifolds, and explains why these have been named after them.

(iii) Metrics $g$ with $\mathrm{Hol}(g) = \mathrm{Sp}(m)$ are called "hyper-Kähler." As $\mathrm{Sp}(m) \subseteq \mathrm{SU}(2m) \subset \mathrm{U}(2m)$, hyper-Kähler metrics are Ricci-flat and Kähler.

Metrics $g$ with holonomy group Sp($m$)Sp(1) for $m \geq 2$ are called "quaternionic Kähler." (Note that quaternionic Kähler metrics are not in fact Kähler.) They are Einstein, but not Ricci-flat.

(iv), (v) $G_2$ and Spin(7) are the exceptional cases, so they are called the "exceptional holonomy groups." Metrics with these holonomy groups are Ricci-flat.

The groups can be understood in terms of the four division algebras: the real numbers $\mathbb{R}$, the complex numbers $\mathbb{C}$, the quaternions $\mathbb{H}$, and the octonions or Cayley numbers $\mathbb{O}$.

- SO($n$) is a group of automorphisms of $\mathbb{R}^n$.
- U($m$) and SU($m$) are groups of automorphisms of $\mathbb{C}^m$.
- Sp($m$) and Sp($m$) Sp(1) are automorphism groups of $\mathbb{H}^m$.
- $G_2$ is the automorphism group of $\mathrm{Im}\,\mathbb{O} \cong \mathbb{R}^7$. Spin(7) is a group of automorphisms of $\mathbb{O} \cong \mathbb{R}^8$, preserving part of the structure on $\mathbb{O}$.

## The Exceptional Holonomy Groups

For some time after Berger's classification, the exceptional holonomy groups remained a mystery. In 1987, Bryant used the theory of exterior differential systems to show that locally there exist many metrics with these holonomy groups, and gave some explicit, incomplete examples. Then in 1989, Bryant and Salamon found explicit, complete metrics with holonomy $G_2$ and Spin(7) on noncompact manifolds. In 1994–95, the author constructed the first examples of metrics with holonomy $G_2$ and Spin(7) on compact manifolds. For more information on exceptional holonomy, see Joyce (2000, 2002).

### The Holonomy Group $G_2$

Let $(x_1, \ldots, x_7)$ be coordinates on $\mathbb{R}^7$. Write $\mathrm{d}\boldsymbol{x}_{ij\ldots l}$ for the exterior form $\mathrm{d}x_i \wedge \mathrm{d}x_j \wedge \cdots \wedge \mathrm{d}x_l$ on $\mathbb{R}^7$. Define a metric $g_0$, a 3-form $\varphi_0$, and a 4-form $*\varphi_0$ on $\mathbb{R}^7$ by

$$\begin{aligned} g_0 &= \mathrm{d}x_1^2 + \cdots + \mathrm{d}x_7^2 \\ \varphi_0 &= \mathrm{d}\boldsymbol{x}_{123} + \mathrm{d}\boldsymbol{x}_{145} + \mathrm{d}\boldsymbol{x}_{167} + \mathrm{d}\boldsymbol{x}_{246} \\ &\quad - \mathrm{d}\boldsymbol{x}_{257} - \mathrm{d}\boldsymbol{x}_{347} - \mathrm{d}\boldsymbol{x}_{356} \\ *\varphi_0 &= \mathrm{d}\boldsymbol{x}_{4567} + \mathrm{d}\boldsymbol{x}_{2367} + \mathrm{d}\boldsymbol{x}_{2345} + \mathrm{d}\boldsymbol{x}_{1357} \\ &\quad - \mathrm{d}\boldsymbol{x}_{1346} - \mathrm{d}\boldsymbol{x}_{1256} - \mathrm{d}\boldsymbol{x}_{1247} \end{aligned} \qquad [5]$$

The subgroup of $\mathrm{GL}(7, \mathbb{R})$ preserving $\varphi_0$ is the exceptional Lie group $G_2$. It also preserves $g_0, *\varphi_0$,

and the orientation on $\mathbb{R}^7$. It is a compact, semisimple, 14-dimensional Lie group, a subgroup of SO(7).

A $G_2$-structure on a 7-manifold $M$ is a principal sub-bundle of the frame bundle of $M$, with structure group $G_2$. Each $G_2$-structure gives rise to a 3-form $\varphi$ and a metric $g$ on $M$, such that every tangent space of $M$ admits an isomorphism with $\mathbb{R}^7$ identifying $\varphi$ and $g$ with $\varphi_0$ and $g_0$, respectively. By an abuse of notation, $(\varphi, g)$ can be referred to as a $G_2$-structure.

**Proposition 7** *Let $M$ be a 7-manifold and $(\varphi, g)$ a $G_2$-structure on $M$. Then the following are equivalent*:

(i) $\mathrm{Hol}(g) \subseteq G_2$, *and $\varphi$ is the induced 3-form*;
(ii) $\nabla\varphi = 0$ *on $M$, where $\nabla$ is the Levi-Civita connection of $g$; and*
(iii) $d\varphi = d(*\varphi) = 0$ *on $M$.*

The equations $d\varphi = d(*\varphi) = 0$ look like linear partial differential equations on $\varphi$. However, it is better to consider them as nonlinear, for the following reason. The 3-form $\varphi$ determines the metric $g$, and $g$ gives the Hodge star $*$ on $M$. So $*\varphi$ is a nonlinear function of $\varphi$, and $d(*\varphi) = 0$ a nonlinear equation. Thus, constructing and studying $G_2$-manifolds come down to studying solutions of nonlinear elliptic partial differential equations.

Note that $\mathrm{Hol}(g) \subseteq G_2$ if and only if $\nabla\varphi = 0$ follows from Theorem 5. We call $\nabla\varphi$ the "torsion" of the $G_2$-structure $(\varphi, g)$, and when $\nabla\varphi = 0$ the $G_2$-structure is "torsion-free." A triple $(M, \varphi, g)$ is called a $G_2$-manifold if $M$ is a 7-manifold and $(\varphi, g)$ a torsion-free $G_2$-structure on $M$. If $g$ has holonomy $\mathrm{Hol}(g) \subseteq G_2$, then $g$ is Ricci-flat.

**Theorem 8** *Let $M$ be a compact 7-manifold, and suppose that $(\varphi, g)$ is a torsion-free $G_2$-structure on $M$. Then $\mathrm{Hol}(g) = G_2$ if and only if $\pi_1(M)$ is finite. In this case, the moduli space of metrics with holonomy $G_2$ on $M$, up to diffeomorphisms isotopic to the identity, is a smooth manifold of dimension $b^3(M)$.*

### The Holonomy Group Spin(7)

Let $\mathbb{R}^8$ have coordinates $(x_1, \ldots, x_8)$. Define a 4-form $\Omega_0$ on $\mathbb{R}^8$ by

$$\begin{aligned}\Omega_0 = {}& dx_{1234} + dx_{1256} + dx_{1278} + dx_{1357} - dx_{1368} \\ & - dx_{1458} - dx_{1467} - dx_{2358} - dx_{2367} - dx_{2457} \\ & + dx_{2468} + dx_{3456} + dx_{3478} + dx_{5678}\end{aligned} \qquad [6]$$

The subgroup of $\mathrm{GL}(8, \mathbb{R})$ preserving $\Omega_0$ is the holonomy group Spin(7). It also preserves the orientation on $\mathbb{R}^8$ and the Euclidean metric $g_0 = dx_1^2 + \cdots + dx_8^2$. It is a compact, semisimple, 21-dimensional Lie group, a subgroup of SO(8).

A Spin(7)-structure on an 8-manifold $M$ gives rise to a 4-form $\Omega$ and a metric $g$ on $M$, such that each tangent space of $M$ admits an isomorphism with $\mathbb{R}^8$ identifying $\Omega$ and $g$ with $\Omega_0$ and $g_0$, respectively. By an abuse of notation, the pair $(\Omega, g)$ is referred to as a Spin(7)-structure.

**Proposition 9** *Let $M$ be an 8-manifold and $(\Omega, g)$ a* Spin(7)*-structure on $M$. Then the following are equivalent*:

(i) $\mathrm{Hol}(g) \subseteq \mathrm{Spin}(7)$ *and $\Omega$ is the induced 4-form*;
(ii) $\nabla\Omega = 0$ *on $M$, where $\nabla$ is the Levi-Civita connection of $g$; and*
(iii) $d\Omega = 0$ *on $M$.*

We call $\nabla\Omega$ the torsion of the Spin(7)-structure $(\Omega, g)$, and $(\Omega, g)$ torsion free if $\nabla\Omega = 0$. A triple $(M, \Omega, g)$ is called a Spin(7)-manifold if $M$ is an 8-manifold and $(\Omega, g)$ a torsion-free Spin(7)-structure on $M$. If $g$ has holonomy $\mathrm{Hol}(g) \subseteq \mathrm{Spin}(7)$, then $g$ is Ricci-flat.

Here is a result on compact 8-manifolds with holonomy Spin(7).

**Theorem 10** *Let $(M, \Omega, g)$ be a compact* Spin(7)*-manifold. Then, $\mathrm{Hol}(g) = \mathrm{Spin}(7)$ if and only if $M$ is simply connected, and $b^3(M) + b^4_+(M) = b^2(M) + 2b^4_-(M) + 25$. In this case, the moduli space of metrics with holonomy* Spin(7) *on $M$, up to diffeomorphisms isotopic to the identity, is a smooth manifold of dimension $1 + b^4_-(M)$.*

The inclusions between the holonomy groups $\mathrm{SU}(m)$, $G_2$, Spin(7) are

$$\begin{array}{ccccc} \mathrm{SU}(2) & \longrightarrow & \mathrm{SU}(3) & \longrightarrow & G_2 \\ \downarrow & & \downarrow & & \downarrow \\ \mathrm{SU}(2)\times\mathrm{SU}(2) & \longrightarrow & \mathrm{SU}(4) & \longrightarrow & \mathrm{Spin}(7) \end{array} \qquad [7]$$

The meaning of the above equation is illustrated by using the inclusion $\mathrm{SU}(3) \hookrightarrow G_2$. As SU(3) acts on $\mathbb{C}^3$, it also acts on $\mathbb{R} \oplus \mathbb{C}^3 \cong \mathbb{R}^7$, taking the SU(3)-action on $\mathbb{R}$ to be trivial. Thus, we embed SU(3) as a subgroup of $\mathrm{GL}(7, \mathbb{R})$. It turns out that SU(3) is contained in the subgroup $G_2$ of $\mathrm{GL}(7, \mathbb{R})$ defined in the section "The holonomy group $G_2$."

### Constructing Compact $G_2$- and Spin(7)-Manifolds

The author's method of constructing compact 7-manifolds with holonomy $G_2$ is based on the

Kummer construction for Calabi–Yau metrics on the $K3$ surface and may be divided into four steps.

*Step* 1. Let $T^7$ be the 7-torus and $(\varphi_0, g_0)$ a flat $G_2$-structure on $T^7$. Choose a finite group $\Gamma$ of isometries of $T^7$ preserving $(\varphi_0, g_0)$. Then the quotient $T^7/\Gamma$ is a singular, compact 7-manifold, an orbifold.

*Step* 2. For certain special groups $\Gamma$, there is a method to resolve the singularities of $T^7/\Gamma$ in a natural way, using complex geometry. We get a nonsingular, compact 7-manifold $M$, together with a map $\pi : M \to T^7/\Gamma$, the resolving map.

*Step* 3. On $M$, we explicitly write down a one-parameter family of $G_2$-structures $(\varphi_t, g_t)$ depending on $t \in (0, \epsilon)$. They are not torsion free, but have small torsion when $t$ is small. As $t \to 0$, the $G_2$-structure $(\varphi_t, g_t)$ converges to the singular $G_2$-structure $\pi^*(\varphi_0, g_0)$.

*Step* 4. We prove using analysis that for sufficiently small $t$, the $G_2$-structure $(\varphi_t, g_t)$ on $M$, with small torsion, can be deformed to a $G_2$-structure $(\varphi_t, \tilde{g}_t)$, with zero torsion. Finally, it is shown that $\tilde{g}_t$ is a metric with holonomy $G_2$ on the compact 7-manifold $M$.

We explain the first two steps in greater detail. For Step 1, an example of a suitable group $\Gamma$ is given here.

**Example 11** Let $(x_1, \ldots, x_7)$ be coordinates on $T^7 = \mathbb{R}^7/\mathbb{Z}^7$, where $x_i \in \mathbb{R}/\mathbb{Z}$. Let $(\varphi_0, g_0)$ be the flat $G_2$-structure on $T^7$ defined by [5]. Let $\alpha, \beta$, and $\gamma$ be the involutions of $T^7$ defined by

$$\alpha : (x_1, \ldots, x_7) \mapsto (x_1, x_2, x_3, -x_4, -x_5, -x_6, -x_7) \qquad [8]$$

$$\beta : (x_1, \ldots, x_7) \mapsto (x_1, -x_2, -x_3, x_4, x_5, \tfrac{1}{2} - x_6, -x_7) \qquad [9]$$

$$\gamma : (x_1, \ldots, x_7) \mapsto (-x_1, x_2, -x_3, x_4, \tfrac{1}{2} - x_5, x_6, \tfrac{1}{2} - x_7) \qquad [10]$$

By inspection, $\alpha$, $\beta$, and $\gamma$ preserve $(\varphi_0, g_0)$, because of the careful choice of exactly which signs to change. Also, $\alpha^2 = \beta^2 = \gamma^2 = 1$, and $\alpha$, $\beta$, and $\gamma$ commute. Thus, they generate a group $\Gamma = \langle \alpha, \beta, \gamma \rangle \cong \mathbb{Z}_2^3$ of isometries of $T^7$ preserving the flat $G_2$-structure $(\varphi_0, g_0)$.

Having chosen a lattice $\Lambda$ and finite group $\Gamma$, the quotient $T^7/\Gamma$ is an orbifold, a singular manifold with only quotient singularities. The singularities of $T^7/\Gamma$ come from the fixed points of nonidentity elements of $\Gamma$. We now describe the singularities in the example.

**Lemma 12** *In Example 11, $\beta\gamma$, $\gamma\alpha$, $\alpha\beta$, and $\alpha\beta\gamma$ have no fixed points on $T^7$. The fixed points of $\alpha, \beta, \gamma$ are each 16 copies of $T^3$. The singular set $S$ of $T^7/\Gamma$ is a disjoint union of 12 copies of $T^3$, 4 copies from each of $\alpha, \beta, \gamma$. Each component of $S$ is a singularity modeled on that of $T^3 \times \mathbb{C}^2/\{\pm 1\}$.*

The most important consideration in choosing $\Gamma$ is that we should be able to resolve the singularities of $T^7/\Gamma$ within holonomy $G_2$, in Step 2. We have no idea how to resolve general orbifold singularities of $G_2$-manifolds. However, after fifty years of hard work we understand well how to resolve orbifold singularities of Calabi–Yau manifolds, with holonomy SU($m$). This is done by a combination of algebraic geometry, which produces the underlying complex manifold by a crepant resolution, and Calabi–Yau analysis, which produces the Ricci-flat Kähler metric on this complex manifold.

Now the holonomy groups SU(2) and SU(3) are subgroups of $G_2$, as in [7]. Our tactic in Step 2 is to ensure that all of the singular set $S$ of $T^7/\Gamma$ can locally be resolved with holonomy SU(2) or SU(3), and then use Calabi–Yau geometry to do this. In particular, suppose each connected component of $S$ is isomorphic to either

1. $T^3 \times \mathbb{C}^2/G$, for $G$ a finite subgroup of SU(2); or
2. $\mathcal{S}^1 \times \mathbb{C}^3/G$, for $G$ a finite subgroup of SU(3) acting freely on $\mathbb{C}^3 \setminus \{0\}$.

One can use complex algebraic geometry to find a crepant resolution $X$ of $\mathbb{C}^2/G$ or $Y$ of $\mathbb{C}^3/G$. Then $T^3 \times X$ or $\mathcal{S}^1 \times Y$ gives a local model for how to resolve the corresponding component of $S$ in $T^7/\Gamma$. Thus we construct a nonsingular, compact 7-manifold $M$ by using the patches $T^3 \times X$ or $\mathcal{S}^1 \times Y$ to repair the singularities of $T^7/\Gamma$. In the case of Example 11, this means gluing 12 copies of $T^3 \times X$ into $T^7/\Gamma$, where $X$ is the blow-up of $\mathbb{C}^2/\{\pm 1\}$ at its singular point.

By considering different groups $\Gamma$ acting on $T^7$, and also by finding topologically distinct resolutions $M_1, \ldots, M_k$ of the same orbifold $T^7/\Gamma$, we can construct many compact Riemannian 7-manifolds with holonomy $G_2$. A good number of examples are given in Joyce (2000, chapter 12). **Figure 1** displays the 252 different sets of Betti numbers of compact, simply connected 7-manifolds with holonomy $G_2$ constructed there together with 5 more sets from Kovalev. It seems likely to the author that the Betti numbers given in **Figure 1** are only a small proportion of

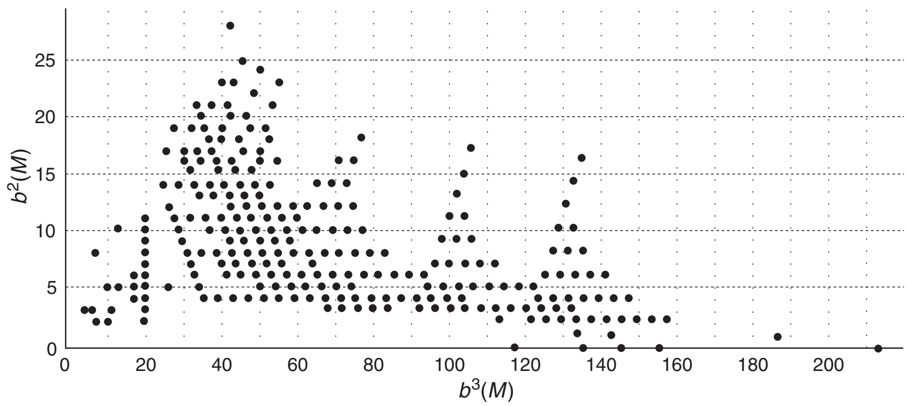

**Figure 1** Betti numbers $(b^2, b^3)$ of compact $G_2$-manifolds. (From Joyce (2000) and Kovalev (2003).)

the Betti numbers of all compact 7-manifolds with holonomy $G_2$.

A different construction of compact 7-manifolds with holonomy $G_2$ was given by Kovalev (2003), involving gluing together asymptotically cylindrical Calabi–Yau 3-folds. Compact 8-manifolds with holonomy Spin(7) were constructed by the author using two different methods: first, by resolving singularities of torus orbifolds $T^8/\Gamma$ in a similar way to the $G_2$ case (though the details are different and more difficult), and second, by resolving $Y/\langle\sigma\rangle$ for $Y$ a Calabi–Yau 4-orbifold with singularities of a special kind, and $\sigma$ an antiholomorphic isometric involution of $Y$. Details can be found in Joyce (2000).

## Saddle Point Problems

**M Schechter**, University of California at Irvine, Irvine, CA, USA

### Introduction

Many problems arising in science and engineering call for the solving of the Euler equations of functionals, that is, equations of the form

$$G'(u) = 0 \qquad [1]$$

where $G(u)$ is a $C^1$-functional (usually representing the energy) arising from the given data. As an illustration, the equation

$$-\Delta u(x) = f(x, u(x))$$

is the Euler equation of the functional

$$G(u) = \frac{1}{2}\|\nabla u\|^2 - \int F(x, u(x))\,\mathrm{d}x$$

on an appropriate space, where

$$F(x,t) = \int_0^t f(x,s)\,\mathrm{d}s \qquad [2]$$

and the norm is that of $L^2$. The solving of the Euler equations is tantamount to finding critical points of the corresponding functional. The classical approach was to look for maxima or minima. If one is looking for a minimum, it is not sufficient to know that the functional is bounded from below, as is easily checked. However, one can show that there is a sequence satisfying

$$G(u_k) \to a, \qquad G'(u_k) \to 0 \qquad [3]$$

for $a = \inf G$. If the sequence has a convergent subsequence, this will produce a minimum.

However, when extrema do not exist, there is no clear way of obtaining critical points. In particular, this happens when the functional is not bounded from either above or below. Until recently, there was no organized procedure for producing critical points which are not extrema. We shall describe an approach which is very useful in such cases.

To illustrate the technique, we consider the problem of finding a solution of

$$-u''(x) + u(x) = f(x, u(x)) \qquad [4]$$

$x \in I = [0, 2\pi]$, under the conditions

$$u(0) = u(2\pi), \qquad u'(0) = u'(2\pi) \qquad [5]$$

We assume that the function $f(x,t)$ is continuous in $I \times \mathbb{R}$ and is periodic in $x$ with period $2\pi$. The approach begins by asking the question, "does there exist a differentiable function $G$ from a space $H$ to $\mathbb{R}$ such that [4], [5] are equivalent to [1]?" It is hoped that one can mimic the methods of calculus to find critical points and thus solve [1].

Actually, we are asking the following: does there exist a mapping $G$ from a space $H$ to $\mathbb{R}$ such that $G$ has a critical point $u$ satisfying $G'(u) = -u'' + u - f(x, u(x))$?

In order to solve the problem one has to

1. find $G(u)$ such that
$$(G'(u), v)_H = (u, v)_H - (f(\cdot, u), v) \qquad [6]$$
holds for each $u, v \in H$,
2. show that there is a function $u(x)$ such that $G'(u) = 0$,
3. show that $u''$ exists in $I$,
4. show that [1] implies [4].

We used the notation

$$(u, v) = \int_0^{2\pi} u(x)v(x)\,\mathrm{d}x$$

In order to carry out the procedure, we assume that for each $R > 0$ there is a constant $C_R$ such that

$$|f(x,t)| \le C_R, \quad x \in I, \ t \in \mathbb{R}, \ |t| \le R \qquad [7]$$

This assumption is used to carry out step (1). We define

$$G(u) = \frac{1}{2}\|u\|_H^2 - \int_0^{2\pi} F(x, u(x))\,\mathrm{d}x \qquad [8]$$

where $F(x,t)$ is given by [2] and we take $H$ to be the completion of $C^1(I)$ with respect to the norm

$$\|u\|_H = (\|u'\|^2 + \|u\|^2)^{1/2} \qquad [9]$$

where $\|u\|^2 = (u, u)$. We have

**Theorem 1** *If $f(x,t)$ satisfies [7], then $G(u)$ given by [8] is continuously differentiable and satisfies [6].*

Once we have reduced the problem to solving [1], we can search for critical points. The easiest type to locate are "saddle points" which are local minima in some directions and local maxima in all others. For instance, we obtain theorems such as

**Theorem 2** *Assume that*

$$\begin{aligned} &|f(x,t)| \le C(|t|+1), \quad x \in I,\ t \in \mathbb{R} \\ &2F(x,t)/t^2 \to \beta(x) \quad \text{a.e. as } |t| \to \infty \end{aligned} \qquad [10]$$

*with $\beta(x)$ satisfying*

$$\begin{aligned} &1+n^2 \le \beta(x) \le 1+(n+1)^2 \\ &1+n^2 \not\equiv \beta(x) \not\equiv 1+(n+1)^2 \end{aligned} \qquad [11]$$

*and $n$ an integer $\ge 0$. If $G(u)$ is given by [8], then there is a $u_0 \in H$ such that*

$$G'(u_0) = 0 \qquad [12]$$

*In particular, $u_0$ is a solution of [4] and [5] in the usual sense.*

In proving this theorem, we shall make use of

**Theorem 3** *Let $M, N$ be closed subspaces of a Hilbert space $E$ such that $M = N^\perp$. Assume that at least one of these subspaces is finite dimensional. Let $G$ be a continuously differentiable functional on $E$ satisfying*

$$m_0 = \sup_{v\in N} \inf_{w \in M} G(v+w) \ne -\infty \qquad [13]$$

*and*

$$m_1 = \inf_{w\in M} \sup_{v \in N} G(v+w) \ne \infty \qquad [14]$$

*Then there is a sequence $\{u_k\} \subset E$ such that*

$$G(u_k) \to c, \quad m_0 \le c \le m_1, \qquad G'(u_k) \to 0 \qquad [15]$$

Theorem 3 allows us to obtain solutions if we can find subspaces of $H$ such that [13] and [14] hold. We use it to give the proof of Theorem 2.

**Proof.** Note that

$$\|u\|_H^2 = \sum (1+k^2)|\alpha_k|^2, \quad u \in H \qquad [16]$$

where the $\alpha_k$ are given by

$$\alpha_k = (u, \bar{\varphi}_k), \quad k = 0, \pm 1, \pm 2, \ldots \qquad [17]$$

and

$$\varphi_k(x) = \frac{1}{\sqrt{2\pi}} e^{ikx}, \quad k = 0, \pm 1, \pm 2, \ldots \qquad [18]$$

Let

$$N = \{u \in H : \alpha_k = 0 \text{ for } |k| > n\}$$

Thus,

$$\begin{aligned} \|u\|_H^2 &= \sum_{|k|\le n} (1+k^2)|\alpha_k|^2 \\ &\le (1+n^2)\|u\|^2, \quad u \in N \end{aligned} \qquad [19]$$

Let

$$M = \{u \in H : \alpha_k = 0 \text{ for } |k| \le n\}$$

In this case,

$$\begin{aligned} \|u\|_H^2 &= \sum_{|k|\ge n+1} (1+k^2)|\alpha_k|^2 \\ &\ge (1+(n+1)^2)\|u\|^2, \quad u \in M \end{aligned} \qquad [20]$$

Note that $M, N$ are closed subspaces of $H$ and that $M = N^\perp$. Note also that $N$ is finite dimensional. If we consider the functional [8], it is not difficult to show that [11] implies

$$\inf_M G > -\infty; \qquad \sup_N G < \infty \qquad [21]$$

We are now in a position to apply Theorem 3. This produces a saddle point satisfying [1]. □

## Minimax

Theorem 3 is very useful when extrema do not exist, but it is not always applicable. One is then forced to search for other ways of obtaining critical points. Again, one is faced with the fact that there is no systematic method of finding them. A useful idea is to try to find sets that separate the functional. By this we mean the following:

**Definition 1** Two sets $A, B$ separate the functional $G(u)$ if

$$a_0 := \sup_A G \le b_0 := \inf_B G \qquad [22]$$

We would like to find sets $A$ and $B$ such that [22] will imply

$$\exists u : G(u) \ge b_0, \quad G'(u) = 0 \qquad [23]$$

This is too much to expect since even semiboundedness does not imply the existence of an extremum. Consequently, we weaken our requirements and look for sets $A, B$ such that [22] implies

$$G(u_k) \to a, \qquad G'(u_k) \to 0 \qquad [24]$$

with $a \ge b_0$. This leads to

**Definition 2** We shall say that the set $A$ links the set $B$ if [22] implies [24] with $a \ge b_0$ for every $C^1$ functional $G(u)$.

Of course, [24] is a far cry from [23], but if, for example, the sequence [24] has a convergent subsequence, then [24] implies [23]. Whether or not [24] implies [23] is a property of the functional $G(u)$. We state this as

**Definition 3** We say that $G(u)$ satisfies the Palais–Smale (PS) condition if [24] always implies [23].

The usual way of verifying this is to show that every sequence satisfying [24] has a convergent subsequence (there are other ways).

All of this leads to

**Theorem 4** *If G satisfies the PS condition and is separated by a pair of linking sets, then it has a critical point satisfying* [23].

This theorem cannot be applied until one knows if there are linking sets and functionals that satisfy the PS condition. Fortunately, they exist. Examples and sufficient conditions for $A$ to link $B$ are found in the literature. Obviously, the weaker the conditions, the more pairs will qualify. To date, the conditions described in the next section allow all known examples.

## The Details

Let $E$ be a Banach space, and let $\Phi$ be the set of all continuous maps $\Gamma = \Gamma(t)$ from $E \times [0,1]$ to $E$ such that

1. $\Gamma(0) = I$, the identity map;
2. for each $t \in [0,1), \Gamma(t)$ is a homeomorphism of $E$ onto $E$ and $\Gamma^{-1}(t) \in C(E \times [0,1), E)$;
3. $\Gamma(1)E$ is a single point in $E$ and $\Gamma(t)A$ converges uniformly to $\Gamma(1)E$ as $t \to 1$ for each bounded set $A \subset E$; and
4. for each $t_0 \in [0,1)$ and each bounded set $A \subset E$,

$$\sup_{0 \le t \le t_0, u \in A} \{\|\Gamma(t)u\| + \|\Gamma^{-1}(t)u\|\} < \infty \qquad [25]$$

We have the following

**Theorem 5** *A sufficient condition for A to link B is*

(i) $A \cap B = \phi$ and
(ii) *for each* $\Gamma \in \Phi$ *there is a* $t \in (0,1]$ such that

$$\Gamma(t)A \cap B \neq \phi$$

**Theorem 6** *Let G be a* $C^1$*-functional on E, and let A, B be subsets of E such that A, B satisfy* [22] *and the hypotheses of* Theorem 5. *Assume that*

$$a := \inf_{\Gamma \in \Phi} \sup_{0 \le s \le 1, u \in A} G(\Gamma(s)u) \qquad [26]$$

*is finite. Let* $\psi(t)$ *be a positive, locally Lipschitz continuous function on* $[0,\infty)$ *such that*

$$\int_0^\infty \psi(r)\,\mathrm{d}r = \infty \qquad [27]$$

*Then there is a sequence* $\{u_k\} \subset E$ *such that*

$$G(u_k) \to a, \qquad G'(u_k)/\psi(\|u_k\|) \to 0 \qquad [28]$$

*If* $a = b_0$*, then we can also require that*

$$\mathrm{d}(u_k, B) \to 0 \qquad [29]$$

**Corollary 1** *Under the hypotheses of* Theorem 6 *there is a sequence* $\{u_k\} \subset E$ *such that*

$$G(u_k) \to a, \qquad (1 + \|u_k\|)G'(u_k) \to 0 \qquad [30]$$

**Proof.** We merely take $\psi(u) = 1/(1 + \|u\|)$ in Theorem 6. □

A useful criterion for finding linking subsets is

**Theorem 7** *Let F be a continuous map from a Banach space E to* $\mathbb{R}^n$*, and let* $Q \subset E$ *be such that* $F_0 = F|_Q$ *is a homeomorphism of Q onto the closure of a bounded open subset* $\Omega$ *of* $\mathbb{R}^n$*. If* $p \in \Omega$*, then* $F_0^{-1}(\partial\Omega)$ *links* $F^{-1}(p)$.

## Some Examples

The following are examples of sets that link.

**Example 1** Let $M, N$ be closed subspaces such that $E = M \oplus N$ (with one finite dimensional). Let

$$B_R = \{u \in E : \|u\| < R\}$$

and take $A = \partial B_R \cap N, B = M$. Then $A$ links $B$. To see this, we identify $N$ with some $\mathbb{R}^n$ and take $\Omega = B_R \cap N, Q = \bar{\Omega}$. For $u \in E$, we write

$$u = v + w, \quad v \in N, \ w \in M \qquad [31]$$

and take $F$ to be the projection

$$Fu = v$$

Since $F|_Q = I$ and $M = F^{-1}(0)$, we see from Theorem 7 that $A$ links $B$.

**Example 2** We take $M, N$ as in Example 1. Let $w_0 \neq 0$ be an element of $M$, and take

$$\begin{aligned} A &= \{v \in N : \|v\| \le R\} \\ &\quad \cup \{sw_0 + v : v \in N, s \ge 0, \|sw_0 + v\| = R\} \\ B &= \partial B_\delta \cap M, \quad 0 < \delta < R. \end{aligned}$$

Then $A$ links $B$. Again we identify $N$ with some $\mathbb{R}^n$, and we may assume $\|w_0\| = 1$. Let

$$Q = \{sw_0 + v : v \in N, s \ge 0, \|sw_0 + v\| \le R\}$$

Then $A = \partial Q$ in $\mathbb{R}^{n+1}$. If $u$ is given by [31], we define

$$Fu = v + \|w\|w_0$$

Then $F|_Q = I$ and $B = F^{-1}(\delta w_0)$. We can now apply Theorem 7 to conclude that $A$ links $B$.

**Example 3** Take $M, N$ as before and let $v_0 \neq 0$ be an element of $N$. We write $N = \{v_0\} \oplus N'$. We take

$$A = \{v' \in N' : \|v'\| \le R\}$$
$$\cup \{sv_0 + v' : v' \in N', s \ge 0, \|sv_0 + v'\| = R\}$$
$$B = \{w \in M : \|w\| \ge \delta\}$$
$$\cup \{sv_0 + w : w \in M, s \ge 0, \|sv_0 + w\| = \delta\}$$

where $0 < \delta < R$. Then $A$ links $B$. To see this, we let

$$Q = \{sv_0 + v' : v' \in N', s \ge 0, \|sv_0 + v'\| \le R\}$$

and reason as before. For simplicity, we assume that $\|v_0\| = 1$, $E$ is a Hilbert space and that the splitting $E = N' \oplus \{v_0\} \oplus M$ is orthogonal. If

$$u = v' + w + sv_0, \quad v' \in N',\ w \in M,\ s \in \mathbb{R} \qquad [32]$$

we define

$$F(u) = v' + \left(s + \delta - \sqrt{\delta^2 - \|w\|^2}\right)v_0, \quad \|w\| \le \delta$$
$$= v' + (s + \delta)v_0, \quad \|w\| > \delta$$

Note that $F|_Q = I$ while $F^{-1}(\delta v_0)$ is precisely the set $B$. Hence we can conclude via Theorem 7 that $A$ links $B$.

**Example 4** This is the same as Example 3 with $A$ replaced by $A = \partial B_R \cap N$. The proof is the same with $Q$ replaced by $Q = \bar{B}_R \cap N$.

**Example 5** Let $M, N$ be as in Example 1. Take $A = \partial B_\delta \cap N$, and let $v_0$ be any element in $\partial B_1 \cap N$. Take $B$ to be the set of all $u$ of the form

$$u = w + sv_0, \quad w \in M$$

satisfying any of the following:

(i) $\|w\| \le R, s = 0$,
(ii) $\|w\| \le R, s = 2R_0$, and
(iii) $\|w\| = R, 0 \le s \le 2R_0$

where $0 < \delta < \min(R, R_0)$. Then $A$ links $B$. To see this, take $N = \{v_0\} \oplus N'$. Then any $u \in E$ can be written in the form [32]. Define

$$F(u) = v' + \left(R_0 - \max\left\{\frac{R_0}{R}\|w\|, |s - R_0|\right\}\right)v_0$$

and $Q = \bar{B}_\delta \cap N$. Again we may identify $N$ with some $\mathbb{R}^n$. Then $F \in C(E, N)$ and $F|_Q = I$. Moreover, $A = F^{-1}(0)$. Hence, $A$ links $B$ by Theorem 7.

**Example 6** Let $M, N$ be as in Example 1. Let $v_0$ be in $\partial B_1 \cap N$ and write $N = \{v_0\} \oplus N'$. Let $A = \partial B_\delta \cap N$, $Q = \bar{B}_\delta \cap N$, and

$$B = \{w \in M : \|w\| \le R\}$$
$$\cup \{w + sv_0 : w \in M, s \ge 0, \|w + sv_0\| = R\}$$

where $0 < \delta < R$. Then $A$ links $B$. To see this, write $u = w + v' + sv_0$, $w \in M$, $v' \in N'$, $s \in \mathbb{R}$ and take

$$F(u) = (cR - \max\{c\|w + sv_0\|, |cR - s|\})v_0 + v'$$

where $c = \delta/(R - \delta)$. Then $F$ is the identity operator on $Q$, and $F^{-1}(0) = B$. Apply Theorem 7.

## Some Applications

Many elliptic semilinear problems can be described in the following way. Let $\Omega$ be a domain in $\mathbb{R}^n$, and let $A$ be a self-adjoint operator on $L^2(\Omega)$. We assume that $A \ge \lambda_0 > 0$ and that

$$C_0^\infty(\Omega) \subset D := D(A^{1/2}) \subset H^{m,2}(\Omega) \qquad [33]$$

for some $m > 0$, where $C_0^\infty(\Omega)$ denotes the set of test functions in $\Omega$ (i.e., infinitely differentiable functions with compact supports in $\Omega$), and $H^{m,2}(\Omega)$ denotes the Sobolev space. If $m$ is an integer, the norm in $H^{m,2}(\Omega)$ is given by

$$\|u\|_{m,2} := \left(\sum_{|\mu| \le m} \|D^\mu u\|^2\right)^{1/2} \qquad [34]$$

Here $D^\mu$ represents the generic derivative of order $|\mu|$ and the norm on the right-hand side of [34] is that of $L^2(\Omega)$. We shall not assume that $m$ is an integer.

Let $q$ be any number satisfying

$$2 \le q \le 2n/(n - 2m), \quad 2m < n$$
$$2 \le q < \infty, \qquad n \le 2m$$

and let $f(x, t)$ be a continuous function on $\Omega \times \mathbb{R}$. We make the following assumptions.

**Assumption A** The function $f(x, t)$ satisfies

$$|f(x, t)| \le V_0(x)^q |t|^{q-1} + V_0(x) W_0(x) \qquad [35]$$

and

$$f(x, t)/V_0(x)^q = o(|t|^{q-1}) \text{ as } |t| \to \infty \qquad [36]$$

where $V_0(x) > 0$ is a function in $L^q(\Omega)$ such that

$$\|V_0 u\|_q \le C\|u\|_D, \quad u \in D \qquad [37]$$

and $W_0$ is a function in $L^{q'}(\Omega)$. Here

$$\|u\|_q := \left(\int_\Omega |u(x)|^q \, dx\right)^{1/q} \quad [38]$$

$$\|u\|_D := \|A^{1/2}u\| \quad [39]$$

and $q' = q/(q-1)$. With the norm [39], $D$ becomes a Hilbert space. Define $G$ and $F$ by [8] and [2]. It follows that $G$ is a continuously differentiable functional on the whole of $D$.

We assume further that

$$H(x,t) = 2F(x,t) - tf(x,t) \geq -W_1(x) \in L^1(\Omega), \quad x \in \Omega, t \in \mathbb{R} \quad [40]$$

and

$$H(x,t) \to \infty \quad \text{a.e. as } |t| \to \infty \quad [41]$$

Moreover, we assume that there are functions $V(x), W(x) \in L^2(\Omega)$ such that multiplication by $V(x)$ is a compact operator from $D$ to $L^2(\Omega)$ and

$$F(x,t) \leq C(V(x)^2|t|^2 + V(x)W(x)|t|) \quad [42]$$

We wish to obtain a solution of

$$Au = f(x,u), \quad u \in D \quad [43]$$

By a solution of [43] we shall mean a function $u \in D$ such that

$$(u,v)_D = (f(\cdot,u),v), \quad v \in D \quad [44]$$

If $f(x,u)$ is in $L^2(\Omega)$, then a solution of [44] is in $D(A)$ and solves [43] in the classical sense. Otherwise we call it a weak or semistrong solution. We have

**Theorem 8** *Let $A$ be a self-adjoint operator in $L^2(\Omega)$ such that $A \geq \lambda_0 > 0$ and [33] holds for some $m > 0$. Assume that $\lambda_0$ is an eigenvalue of $A$ with eigenfunction $\varphi_0$. Assume also*

$$2F(x,t) \leq \lambda_0 t^2, \quad |t| \leq \delta \text{ for some } \delta > 0 \quad [45]$$

*and*

$$2F(x,t) \geq \lambda_0 t^2 - W_0(x), \quad t > 0, x \in \Omega \quad [46]$$

*where $W_0 \in L^1(\Omega)$. Assume that $f(x,t)$ satisfies [35], [36], [40], [41], and [42]. Then [43] has a solution $u \neq 0$.*

**Proof.** Under the hypotheses of the theorem, it is known that the following alternative holds: either

(i) there is an infinite number of $y(x) \in D(A)\backslash\{0\}$ such that

$$Ay = f(x,y) = \lambda_0 y \quad [47]$$

or

(ii) for each $\rho > 0$ sufficiently small, there is an $\varepsilon > 0$ such that

$$G(u) \geq \varepsilon, \|u\|_D = \rho \quad [48]$$

We may assume that option (ii) holds, for otherwise we are done. By [46] we have

$$G(R\varphi_0) \leq R^2(\|\varphi_0\|_D^2 - \lambda_0\|\varphi_0\|^2) + \int_\Omega W_0(x)\, dx = \int_\Omega W_0(x)\, dx$$

By Theorem 6, there is a sequence satisfying [28]. Taking $\psi(r) = 1/(r+1)$, we conclude that there is a sequence $\{u_k\} \subset D$ such that

$$G(u_k) \to c, \quad m_0 \leq c \leq m_1, \quad (1 + \|u_k\|_D)G'(u_k) \to 0 \quad [49]$$

In particular, we have

$$\|u_k\|_D^2 - 2\int_\Omega F(x,u_k)\, dx \to c \quad [50]$$

and

$$\|u_k\|_D^2 - (f(\cdot,x_k),u_k) \to 0 \quad [51]$$

Consequently,

$$\int_\Omega H(x,u_k)\, dx \to -c \quad [52]$$

These imply

$$\int_\Omega H(x,u_k)\, dx \leq K \quad [53]$$

If $\rho_k = \|u_k\|_D \to \infty$, let $\tilde{u}_k = u_k/\rho_k$. Then $\|\tilde{u}_k\|_D = 1$. Consequently, there is a renamed subsequence such that $\tilde{u}_k \to \tilde{u}$ weakly in $D$, strongly in $L^2(\Omega)$, and a.e. in $\Omega$. We have from [42]

$$1 \leq (m_1 + \delta)/\rho_k^2 + 2C\int_\Omega \{V(x)^2\tilde{u}_k^2 + V(x)W(x)|\tilde{u}_k|\rho_k^{-1}\}\, dx$$

Consequently,

$$1 \leq 2C\int_\Omega V(x)^2\tilde{u}^2\, dx \quad [54]$$

This shows that $\tilde{u} \not\equiv 0$. Let $\Omega_0$ be the subset of $\Omega$ on which $\tilde{u} \neq 0$. Then

$$|u_k(x)| = \rho_k|\tilde{u}_k(x)| \to \infty, \quad x \in \Omega_0 \quad [55]$$

If $\Omega_1 = \Omega \backslash \Omega_0$, then we have

$$\int_{\Omega} H(x, u_k)\,\mathrm{d}x = \int_{\Omega_0} + \int_{\Omega_1} \geq \int_{\Omega_0} H(x, u_k)\,\mathrm{d}x - \int_{\Omega_1} W_1(x)\,\mathrm{d}x \to \infty \qquad [56]$$

This contradicts [53], and we see that $\rho_k = \|u_k\|_D$ is bounded. Once we know that the $\rho_k$ are bounded, we can apply well-known theorems to obtain the desired conclusion. □

**Remark 1** It should be noted that the crucial element in the proof of Theorem 8 was [51]. If we had been dealing with an ordinary Palais–Smale sequence, we could only conclude that

$$\|u_k\|_D^2 - (f(\cdot, u_k), u_k) = o(\rho_k)$$

which would imply only

$$\int_{\Omega} H(x, u_k)\,\mathrm{d}x = o(\rho_k)$$

This would not contradict [56], and the argument would not go through.

As another application, we wish to solve

$$-x''(t) = \nabla_x V(t, x(t)) \qquad [57]$$

where

$$x(t) = (x_1(t), \ldots, x_n(t)) \qquad [58]$$

is a map from $I = [0, 2\pi]$ to $\mathbb{R}^n$ such that each component $x_j(t)$ is a periodic function in $H^1$ with period $2\pi$, and the function

$$V(t, x) = V(t, x_1, \ldots, x_n)$$

is continuous from $\mathbb{R}^{n+1}$ to $\mathbb{R}$ with a gradient

$$\nabla_x V(t, x) = (\partial V/\partial x_1, \ldots, \partial V/\partial x_n) \in C(\mathbb{R}^{n+1}, \mathbb{R}^n) \qquad [59]$$

For each $x \in \mathbb{R}^n$, the function $V(t, x)$ is periodic in $t$ with period $2\pi$. We shall study this problem under the following assumptions:

1. $$0 \leq V(t, x) \leq C(|x|^2 + 1)$$
$$t \in I, x \in \mathbb{R}^n$$
2. There are constants $m > 0, \alpha \leq 3m^2/2\pi^2$ such that
$$V(t, x) \leq \alpha, \quad |x| \leq m, t \in I, x \in \mathbb{R}^n$$
3. There are constants $\beta > 1/2$ and $C$ such that
$$V(t, x) \geq \beta |x|^2$$
when
$$|x| > C, t \in I, x \in \mathbb{R}^n$$
4. The function given by
$$H(t, x) = 2V(t, x) - \nabla_x V(t, x) \cdot x \qquad [60]$$
satisfies
$$H(t, x) \leq W(t) \in L^1(I), \quad |x| \geq C \qquad [61]$$
$t \in I$, $x \in \mathbb{R}^n$, and
$$H(t, x) \to -\infty \quad \text{as } |x| \to \infty \qquad [62]$$

We have

**Theorem 9** *Under the above hypotheses, the system [57] has a nonconstant solution.*

**Proof.** Let $X$ be the set of vector functions $x(t)$ described above. It is a Hilbert space with norm satisfying

$$\|x\|_X^2 = \sum_{j=1}^{n} \|x_j\|_{H^1}^2$$

We also write

$$\|x\|^2 = \sum_{j=1}^{n} \|x_j\|^2$$

where $\|\cdot\|$ is the $L^2(I)$ norm. Let

$$N = \{x(t) \in X : x_j(t) \equiv \text{constant}, 1 \leq j \leq n\}$$

and $M = N^{\perp}$. The dimension of $N$ is $n$, and $X = M \oplus N$. The following is easily proved.

**Lemma 1** *If $x \in M$, then*

$$\|x\|_\infty^2 \leq \frac{\pi}{6} \|x'\|^2$$

*and*

$$\|x\| \leq \|x'\|$$

We define

$$G(x) = \|x'\|^2 - 2\int_I V(t, x(t))\,\mathrm{d}t, \quad x \in X \qquad [63]$$

For each $x \in X$ write $x = v + w$, where $v \in N$, $w \in M$. For convenience, we shall use the following equivalent norm for $X$:

$$\|x\|_X^2 = \|w'\|^2 + \|v\|^2$$

If $x \in M$ and

$$\|x'\|^2 = \rho^2 = \frac{6}{\pi} m^2$$

then Lemma 1 implies that $\|x\|_\infty \leq m$, and we have by Hypothesis 2 that $V(t, x) \leq \alpha$.

Hence,

$$G(x) \geq \|x'\|^2 - 2\int_{|x|<m} \alpha \, dt \geq \rho^2 - 2\alpha(2\pi) \geq 0 \qquad [64]$$

Note that Hypothesis 3 is equivalent to

$$V(t,x) \geq \beta|x|^2 - C, \quad t \in I, \ x \in \mathbb{R}^n \qquad [65]$$

for some constant $C$. Next, let

$$y(t) = v + sw_0$$

where $v \in N$, $s \geq 0$, and

$$w_0 = (\sin t, 0, \ldots, 0)$$

Then $w_0 \in M$, and

$$\|w_0\|^2 = \|w_0'\|^2 = \pi$$

Note that

$$\|y\|^2 = \|v\|^2 + s^2\pi = 2\pi|v|^2 + \pi s^2$$

Consequently,

$$\begin{aligned} G(y) &= s^2\|w_0'\|^2 - 2\int_I V(t, y(t))\, dt \\ &\leq \pi s^2 - 2\beta\int_I |y(t)|^2 \, dt + 2\pi C \\ &= \pi s^2 - 2\beta(\|v\|^2 + \pi s^2) + 2\pi C \\ &\leq (1-2\beta)\pi s^2 - 4\beta\pi|v|^2 + 2\pi C \\ &\to -\infty \text{ as } s^2 + |v|^2 \to \infty \end{aligned}$$

We also note that Hypothesis 1 implies

$$G(v) \leq 0, \quad v \in N \qquad [66]$$

Take

$$\begin{aligned} A &= \{v \in N : \|v\| \leq R\} \\ &\quad \cup \{sw_0 + v : v \in N, s \geq 0, \|sw_0 + v\|_X = R\} \\ B &= \partial B_\rho \cap M, 0 < \rho = 6m^2/\pi < R \end{aligned}$$

where

$$B_\sigma = \{x \in X : \|x\|_X < \sigma\}$$

By Example 2, $A$ links $B$. Moreover, if $R$ is sufficiently large,

$$\sup_A G = 0 \leq \inf_B G \qquad [67]$$

Hence, we may conclude that there is a sequence $\{x^{(k)}\} \subset X$ such that

$$G(x^{(k)}) \to c \geq 0, \quad (1 + \|x^{(k)}\|_X)\, G'(x^{(k)}) \to 0$$

Hence,

$$G(x^{(k)}) = \|[x^{(k)}]'\|^2 - 2\int_I V(t, x^{(k)}(t))\, dt \to c \geq 0 \qquad [68]$$

$$(G'(x^{(k)}), z)/2 = ([x^{(k)}]', z') - \int_I \nabla_x V(t, x^{(k)}) \cdot z(t)\, dt \to 0, \quad z \in X \qquad [69]$$

and

$$(G'(x^{(k)}), x^{(k)})/2 = \|[x^{(k)}]'\|^2 - \int_I \nabla_x V(t, x^{(k)}) \cdot x^{(k)}\, dt \to 0 \qquad [70]$$

If

$$\rho_k = \|x^{(k)}\|_X \leq C$$

then there is a renamed subsequence such that $x^{(k)}$ converges to a limit $x \in X$ weakly in $X$ and uniformly on $I$. From [69] we see that

$$(G'(x), z)/2 = (x', z') - \int_I \nabla_x V(t, x(t)) \cdot z(t)\, dt = 0, \quad z \in X$$

from which we conclude easily that $x$ is a solution of [57]. From [68], we see that

$$G(x) \geq c \geq 0$$

showing that $x(t)$ is not a constant. For if $c > 0$ and $x \in N$, then

$$G(x) = -2\int_I V(t, x(t))\, dt \leq 0$$

If $c = 0$, we see that $x \in B$ by Theorem 6. Hence, $x \in M$. If

$$\rho_k = \|x^{(k)}\|_X \to \infty$$

let $\tilde{x}^{(k)} = x^{(k)}/\rho_k$. Then, $\|\tilde{x}^{(k)}\|_X = 1$. Let $\tilde{x}^{(k)} = \tilde{w}^{(k)} + \tilde{v}^{(k)}$, where $\tilde{w}^{(k)} \in M$ and $\tilde{v}^{(k)} \in N$. There is a renamed subsequence such that $\tilde{x}^{(k)}$ converges uniformly in $I$ to a limit $\tilde{x}$ and $\|[\tilde{x}^{(k)}]'\| \to r$ and $\|\tilde{x}^{(k)}\| \to \tau$, where $r^2 + \tau^2 = 1$. From [68] and [70], we obtain

$$\|[\tilde{x}^{(k)}]'\|^2 - 2\int_I V(t, x^{(k)}(t))\, dt/\rho_k^2 \to 0$$

and

$$\|[\tilde{x}^{(k)}]'\|^2 - \int_I \nabla_x V(t, x^{(k)}) \cdot x^{(k)}\, dt/\rho_k^2 \to 0$$

Thus,

$$2\int_I V(t, x^{(k)}(t))\, dt/\rho_k^2 \to r^2 \qquad [71]$$

and

$$\int_I \nabla_x V(t, x^{(k)}) \cdot x^{(k)}\, dt/\rho_k^2 \to r^2 \qquad [72]$$

Hence,

$$\int_I H(t, x^{(k)}(t))\, dt/\rho_k^2 \to 0 \qquad [73]$$

By Hypothesis 3, the left-hand side of [71] is

$$\geq 2\beta \|\tilde{x}^{(k)}\|^2 - 4\pi C/\rho_k^2$$

Thus,

$$r^2 \geq 2\beta\tau^2 = 2\beta(1 - r^2)$$

showing that $r > 0$. Hence, $\tilde{x}(t) \not\equiv 0$. Let $\Omega_0 \subset I$ be the set on which $[\tilde{x}(t)] \neq 0$. The measure of $\Omega_0$ is positive. Thus, $|x^{(k)}(t)| \to \infty$ as $k \to \infty$ for $t \in \Omega_0$. Hence,

$$\int_I H(t, x^{(k)}(t))\, dt \leq \int_{\Omega_0} H(t, x^{(k)}(t))\, dt + \int_{I\setminus\Omega_0} W(t)\, dt \to -\infty$$

contrary to Hypothesis 4. Thus, the $\rho_k$ are bounded, and the proof is complete. □

## Superlinear Problems

Consider the problem

$$-\Delta u = f(x, u), \quad x \in \Omega;\ u = 0 \text{ on } \partial\Omega \qquad [74]$$

where $\Omega \subset \mathbb{R}^n$ is a bounded domain whose boundary is a smooth manifold, and $f(x, t)$ is a continuous function on $\bar{\Omega} \times \mathbb{R}$. This semilinear Dirichlet problem has been studied by many authors. It is called "sublinear" if there is a constant $C$ such that

$$|f(x, t)| \leq C(|t| + 1), \quad x \in \Omega, t \in \mathbb{R}$$

Otherwise, it is called "superlinear". Assume

($a_1$) There are constants $c_1, c_2 \geq 0$ such that

$$|f(x, t)| \leq c_1 + c_2|t|^s$$

where $0 \leq s < (n + 2)/(n - 2)$ if $n > 2$.

($a_2$) $f(x, t) = o(|t|)$ as $t \to 0$.

($a_3$) Either

$$F(x, t)/t^2 \to \infty \text{ as } t \to \infty$$

or

$$F(x, t)/t^2 \to \infty \text{ as } t \to -\infty.$$

We have

**Theorem 10** *Under hypotheses* ($a_1$)–($a_3$) *the boundary-value problem*

$$-\Delta u = \beta f(x, u),\ x \in \Omega; \quad u = 0 \text{ on } \partial\Omega \qquad [75]$$

*has a nontrivial solution for almost every positive* $\beta$.

Unfortunately, this theorem does not give any information for any specific $\beta$. It still leaves open the problem of solving [74]. For this purpose, we add the assumption

($a_4$) There are constants $\mu > 2, r \geq 0$ such that

$$\mu F(x, t) - tf(x, t) \leq C(t^2 + 1), \quad |t| \geq r \qquad [76]$$

We have

**Theorem 11** *Under hypotheses* ($a_1$)–($a_4$) *problem* [74] *has a nontrivial solution.*

We also have

**Theorem 12** *If we replace hypothesis* ($a_4$) *with*

($a_4'$) *The function* $-H(x, t)$ *is convex in* $t$,

*then the problem* [74] *has at least one nontrivial solution.*

## Weak Linking

It is not clear if it is possible for $A$ to link $B$ if neither is contained in a finite-dimensional manifold. For instance, if $E = M \oplus N$, where $M, N$ are closed infinite-dimensional subspaces of $E$ and $B_R$ is the ball centered at the origin of radius $R$ in $E$, it is unknown if the set $A = M \cap \partial B_R$ links $B = N$. (If either $M$ or $N$ is finite dimensional, then $A$ does link $B$.) Unfortunately, this is the situation which arises in some important applications including Hamiltonian systems, the wave equation and elliptic systems, to name a few.

We now consider linking when both $M$ and $N$ are infinite dimensional and $G'$ has some additional continuity property. A property that is very useful is that of weak-to-weak continuity:

$$u_k \to u \text{ weakly in } E \implies G'(u_k) \to G'(u) \text{ weakly} \qquad [77]$$

We make the following definition:

**Definition 3** A subset $A$ of a Banach space $E$ links a subset $B$ of $E$ "weakly" if for every $G \in C^1(E, \mathbb{R})$ satisfying [77] and

$$a_0 := \sup_A G \leq b_0 := \inf_B G \qquad [78]$$

there is a sequence $\{u_k\} \subset E$ and a constant $c$ such that

$$b_0 \leq c < \infty \qquad [79]$$

and

$$G(u_k) \to c, \qquad G'(u_k) \to 0 \qquad [80]$$

We have the following counterpart of Theorem 7.

**Theorem 13** *Let $E$ be a separable Hilbert space, and let $G$ be a continuous functional on $E$ with a continuous derivative satisfying [77]. Let $N$ be a closed subspace of $E$, and let $Q$ be a bounded open subset of $N$ containing the point $p$. Let $F$ be a continuous map of $E$ onto $N$ such that*

(i) $F|_Q = I$, *and*
(ii) *For each finite-dimensional subspace $S \neq \{0\}$ of $E$ containing $p$, there is a finite-dimensional subspace $S_0 \neq \{0\}$ of $N$ containing $p$ such that*

$$v \in \bar{Q} \cap S_0, \qquad w \in S \Longrightarrow F(v+w) \in S_0 \qquad [81]$$

*Set $A = \partial Q, B = F^{-1}(p)$. If*

$$a_1 = \sup_{\bar{Q}} G < \infty \qquad [82]$$

*and [22] holds, then there is a sequence $\{u_k\} \subset E$ such that [24] holds with $a \le a_1$.*

Theorem 13 states that if $Q, F, p$ satisfy the hypotheses of that theorem, then $A = \partial Q$ links $B = F^{-1}(p)$ weakly. It follows from this theorem that all sets $A, B$ known to link when one of the subspaces $M, N$ is finite dimensional will link weakly even when $M, N$ are both infinite dimensional.

Now we give some applications of Theorem 13 to semilinear boundary-value problems. Let $\Omega$ be a domain in $\mathbb{R}^n$ and let $A$ be a self–adjoint operator in $L^2(\Omega)$ having 0 in its resolvent set (thus, there is an interval $(a, b)$ in its resolvent set satisfying $a < 0 < b$). Let $f(x,t)$ be a continuous function on $\Omega \times \mathbb{R}$ such that

$$|f(x,t)| \le V(x)^2|t| + W(x)V(x) \qquad [83]$$

$x \in \Omega$, $t \in \mathbb{R}$, and

$$f(x,t)/t \to \alpha_\pm(x) \quad \text{as } t \to \pm\infty \qquad [84]$$

where $V, W \in L^2(\Omega)$, and multiplication by $V(x) > 0$ is a compact operator from $D = D(|A|^{1/2})$ to $L^2(\Omega)$. Let

$$M = \int_b^\infty \mathrm{d}E(\lambda)D, \qquad N = \int_{-\infty}^a \mathrm{d}E(\lambda)D$$

where $\{E(\lambda)\}$ is the spectral measure of $A$. Then $M, N$ are invariant subspaces for $A$ and $D = M \oplus N$. If

$$\alpha(u,v) = \int_\Omega (\alpha_+ u^+ - \alpha_- u^-)v\,\mathrm{d}x \qquad [85]$$

$\alpha(u) = \alpha(u,u)$, then we assume that

$$\alpha(v) \ge (Av, v), \quad v \in N \qquad [86]$$

$$(Aw, w) \ge \alpha(w), \quad w \in M \qquad [87]$$

We also assume that the only solution of

$$Au = \alpha_+ u^+ - \alpha_- u^- \qquad [88]$$

is $u \equiv 0$, where $u^\pm = \max\{\pm u, 0\}$. We have

**Theorem 14** *Under the above hypotheses there is at least one solution of*

$$Au = f(x,u), \quad u \in D(A) \qquad [89]$$

Next, we consider an application concerning radially symmetric solutions for the problem

$$u_{tt} - \Delta u = f(t,x,u), \quad t \in \mathbb{R},\ x \in B_R \qquad [90]$$

$$u(t,x) = 0, \quad t \in \mathbb{R},\ x \in \partial B_R \qquad [91]$$

$$u(t+T,x) = u(t,x), \quad t \in \mathbb{R},\ x \in B_R \qquad [92]$$

where $B_R = \{x \in \mathbb{R}^n : |x| < R\}$. We assume that the ratio $R/T$ is rational. Let

$$8R/T = a/b \qquad [93]$$

where $a, b$ are relatively prime positive integers. It can be shown that

$$n \not\equiv 3 \ (\mathrm{mod}(4,a)) \qquad [94]$$

implies that the linear problem corresponding to [90]–[92] has no essential spectrum. If

$$n \equiv 3 \ (\mathrm{mod}(4,a)) \qquad [95]$$

then the essential spectrum of the linear operator consists of precisely one point

$$\lambda_0 = -(n-3)(n-1)/4R^2 \qquad [96]$$

Consider the case

$$f(t,r,s) = \mu s + p(t,r,s) \qquad [97]$$

where $\mu$ is a point in the resolvent set, $r = |x|$, and

$$|p(t,r,s)| \le C(|s|^\theta + 1), \quad s \in \mathbb{R} \qquad [98]$$

for some number $\theta < 1$. We then have

**Theorem 15** *If [94] holds, then [90]–[92] have a weak rotationally invariant solution. If [95] holds and $\lambda_0 < \mu$, assume in addition that $p(t,r,s)$ is nondecreasing in $s$. If $\mu < \lambda_0$, assume that $p(t,r,s)$ is nonincreasing in $s$. Then [90]–[92] have a weak rotationally invariant solution.*

# Scattering in Relativistic Quantum Field Theory: Fundamental Concepts and Tools

**D Buchholz**, Universität Göttingen, Göttingen, Germany
**S J Summers**, University of Florida, Gainesville, FL, USA

## Physical Motivation and Mathematical Setting

The primary connection of relativistic quantum field theory to experimental physics is through scattering theory, that is, the theory of the collision of elementary (or compound) particles. It is therefore a central topic in quantum field theory and has attracted the attention of leading mathematical physicists. Although a great deal of progress has been made in the mathematically rigorous understanding of the subject, there are important matters which are still unclear, some of which will be indicated below.

In the paradigmatic scattering experiment, several particles, which are initially sufficiently distant from each other that the idealization that they are not mutually interacting is physically reasonable, approach each other and interact (collide) in a region of microscopic extent. The products of this collision then fly apart until they are sufficiently well separated that the approximation of noninteraction is again reasonable. The initial and final states of the objects in the scattering experiment are therefore to be modeled by states of noninteracting, that is, free, fields, which are mathematically represented on Fock space. Typically, what is measured in such experiments is the probability distribution (cross section) for the transitions from a specified state of the incoming particles to a specified state of the outgoing particles.

It should be mentioned that until the late 1950s, the scattering theory of relativistic quantum particles relied upon ideas from nonrelativistic quantum-mechanical scattering theory (interaction representation, adiabatic limit, etc.), which were invalid in the relativistic context. Only with the advent of axiomatic quantum field theory did it become possible to properly formulate the concepts and mathematical techniques which will be outlined here.

Scattering theory can be rigorously formulated either in the context of quantum fields satisfying the Wightman axioms (Streater and Wightman 1964) or in terms of local algebras satisfying the Haag–Kastler–Araki axioms (Haag 1992). In brief, the relation between these two settings may be described as follows: in the Wightman setting, the theory is formulated in terms of operator-valued distributions $\phi$ on Minkowski space, the quantum fields, which act on the physical state space. These fields, integrated with test functions $f$ having support in a given region $\mathcal{O}$ of spacetime (only four-dimensional Minkowski space $\mathbb{R}^4$ will be treated here), $\phi(f) = \int d^4x\, f(x)\phi(x)$, form under the operations of addition, multiplication, and Hermitian conjugation a polynomial $^*$-algebra $\mathcal{P}(\mathcal{O})$ of unbounded operators. In the Haag–Kastler–Araki setting, one proceeds from these algebras to algebras $\mathcal{A}(\mathcal{O})$ of bounded operators which, roughly speaking, are formed by the bounded functions $A$ of the operators $\phi(f)$. This step requires some mathematical care, but these subtleties will not be discussed here. As the statements and proofs of the results in these two frameworks differ only in technical details, the theory is presented here in the more convenient setting of algebras of bounded operators ($C^*$-algebras).

Central to the theory is the notion of a particle, which, in fact, is a quite complex concept, the full nature of which is not completely understood, cf.

below. In order to maintain the focus on the essential points, we consider in the subsequent sections primarily a single massive particle of integer spin $s$, that is, a boson. In standard scattering theory based upon Wigner's characterization, this particle is simply identified with an irreducible unitary representation $U_1$ of the identity component $\mathcal{P}_+^\uparrow$ of the Poincaré group with spin $s$ and mass $m > 0$. The Hilbert space $\mathcal{H}_1$ upon which $U_1(\mathcal{P}_+^\uparrow)$ acts is called the one-particle space and determines the possible states of a single particle, alone in the universe. Assuming that configurations of several such particles do not interact, one can proceed by a standard construction to a Fock space describing freely propagating multiple particle states,

$$\mathcal{H}_\mathrm{F} = \bigoplus_{n\in\mathbb{N}_0} \mathcal{H}_n$$

where $\mathcal{H}_0 = \mathbb{C}$ and $\mathcal{H}_n$ is the $n$-fold symmetrized direct product of $\mathcal{H}_1$ with itself. This space is spanned by vectors $\Phi_1 \otimes \cdots \otimes \Phi_n$, where $\otimes$ denotes the symmetrized tensor product, representing an $n$-particle state wherein the $k$th particle is in the state $\Phi_k \in \mathcal{H}_1$, $k = 1, \ldots, n$. The representation $U_1(\mathcal{P}_+^\uparrow)$ induces a unitary representation $U_\mathrm{F}(\mathcal{P}_+^\uparrow)$ on $\mathcal{H}_\mathrm{F}$ by

$$U_\mathrm{F}(\lambda)(\Phi_1 \otimes \cdots \otimes \Phi_n) \doteq U_1(\lambda)\Phi_1 \otimes \cdots \otimes U_1(\lambda)\Phi_n \quad [1]$$

In interacting theories, the states in the corresponding physical Hilbert space $\mathcal{H}$ do not have such an *a priori* interpretation in physical terms, however. It is the primary goal of scattering theory to identify in $\mathcal{H}$ those vectors which describe, at asymptotic times, incoming, respectively, outgoing, configurations of freely moving particles. Mathematically, this amounts to the construction of certain specific isometries (generalized Møller operators), $\Omega^\mathrm{in}$ and $\Omega^\mathrm{out}$, mapping $\mathcal{H}_\mathrm{F}$ onto subspaces $\mathcal{H}^\mathrm{in} \subset \mathcal{H}$ and $\mathcal{H}^\mathrm{out} \subset \mathcal{H}$, respectively, and intertwining the unitary actions of the Poincaré group on $\mathcal{H}_\mathrm{F}$ and $\mathcal{H}$. The resulting vectors

$$(\Phi_1 \otimes \cdots \otimes \Phi_n)^\mathrm{in/out} \doteq \Omega^\mathrm{in/out}(\Phi_1 \otimes \cdots \otimes \Phi_n) \in \mathcal{H} \quad [2]$$

are interpreted as incoming and outgoing particle configurations in scattering processes wherein the $k$th particle is in the state $\Phi_k \in \mathcal{H}_1$.

If, in a theory, the equality $\mathcal{H}^\mathrm{in} = \mathcal{H}^\mathrm{out}$ holds, then every incoming scattering state evolves, after the collision processes at finite times, into an outgoing scattering state. It is then physically meaningful to define on this space of states the scattering matrix, setting $S = \Omega^\mathrm{in}\Omega^{\mathrm{out}*}$. Physical data such as collision cross sections can be derived from $S$ and the corresponding transition amplitudes $\langle(\Phi_1 \otimes \cdots \otimes \Phi_m)^\mathrm{in}, (\Phi'_1 \otimes \cdots \otimes \Phi'_n)^\mathrm{out}\rangle$, respectively, by a standard procedure. It should be noted, however, that neither the above physically mandatory equality of state spaces nor the more stringent requirement that every state has an interpretation in terms of incoming and outgoing scattering states, that is, $\mathcal{H} = \mathcal{H}^\mathrm{in} = \mathcal{H}^\mathrm{out}$ (asymptotic completeness), has been fully established in any interacting relativistic field theoretic model so far. This intriguing problem will be touched upon in the last section of this article.

Before going into details, let us state the few physically motivated postulates entering into the analysis. As discussed, the point of departure is a family of algebras $\mathcal{A}(\mathcal{O})$, more precisely a net, associated with the open subregions $\mathcal{O}$ of Minkowski space and acting on $\mathcal{H}$. Restricting attention to the case of bosons, we may assume that this net is local in the sense that if $\mathcal{O}_1$ is spacelike separated from $\mathcal{O}_2$, then all elements of $\mathcal{A}(\mathcal{O}_1)$ commute with all elements of $\mathcal{A}(\mathcal{O}_2)$. (In the presence of fermions, these algebras contain also fermionic operators which anticommute.) This is the mathematical expression of the principle of Einstein causality. The unitary representation $U$ of $\mathcal{P}_+^\uparrow$ acting on $\mathcal{H}$ is assumed to satisfy the relativistic spectrum condition (positivity of energy in all Lorentz frames) and, in the sense of equality of sets, $U(\lambda)\mathcal{A}(\mathcal{O})U(\lambda)^{-1} = \mathcal{A}(\lambda\mathcal{O})$ for all $\lambda \in \mathcal{P}_+^\uparrow$ and regions $\mathcal{O}$, where $\lambda\mathcal{O}$ denotes the Poincaré transformed region. It is also assumed that the subspace of $U(\mathcal{P}_+^\uparrow)$-invariant vectors is spanned by a single unit vector $\Omega$, representing the vacuum, which has the Reeh–Schlieder property, that is, each set of vectors $\mathcal{A}(\mathcal{O})\Omega$ is dense in $\mathcal{H}$. These standing assumptions will subsequently be amended by further conditions concerning the particle content of the theory.

## Haag–Ruelle Theory

Haag and Ruelle were the first to establish the existence of scattering states within this general framework (Jost 1965); further substantial improvements are due to Araki and Hepp (Araki 1999). In all of these investigations, the arguments were given for quantum field theories with associated particles (in the Wigner sense) which have strictly positive mass $m > 0$ and for which $m$ is an isolated eigenvalue of the mass operator (upper and lower mass gap). Moreover, it was assumed that states of a single particle can be created from the vacuum by local operations. In physical terms, these assumptions allow only for theories with short-range interactions and particles carrying strictly localizable charges.

In view of these limitations, Haag–Ruelle theory has been developed in a number of different directions. By now, the scattering theory of massive particles is under complete control, including also

particles carrying nonlocalizable (gauge or topological) charges and particles having exotic statistics (anyons, plektons) which can appear in theories in low spacetime dimensions. Due to constraints of space, these results must go without further mention; we refer the interested reader to the articles Buchholz and Fredenhagen (1982) and Fredenhagen *et al.* (1996). Theories of massless particles and of particles carrying charges of electric or magnetic type (infraparticles) will be discussed in subsequent sections.

We outline here a recent generalization of Haag–Ruelle scattering theory presented in Dybalski (2005), which covers massive particles with localizable charges without relying on any further constraints on the mass spectrum. In particular, the scattering of electrically neutral, stable particles fulfilling a sharp dispersion law in the presence of massless particles is included (e.g., neutral atoms in their ground states). Mathematically, this assumption can be expressed by the requirement that there exists a subspace $\mathcal{H}_1 \subset \mathcal{H}$ such that the restriction of $U(\mathcal{P}_+^\uparrow)$ to $\mathcal{H}_1$ is a representation of mass $m > 0$. We denote by $P_1$ the projection in $\mathcal{H}$ onto $\mathcal{H}_1$.

To establish notation, let $\mathcal{O}$ be a bounded spacetime region and let $A \in \mathcal{A}(\mathcal{O})$ be any operator such that $P_1 A\Omega \neq 0$. The existence of such localized (in brief, local) operators amounts to the assumption that the particle carries a localizable charge. That the particle is stable, that is, completely decouples from the underlying continuum states, can be cast into a condition first stated by Herbst: for all sufficiently small $\mu > 0$

$$\|E_\mu(1 - P_1)A\Omega\| \leq c\mu^\eta \qquad [3]$$

for some constants $c, \eta > 0$, where $E_\mu$ is the projection onto the spectral subspace of the mass operator corresponding to spectrum in the interval $(m - \mu, m + \mu)$. In the case originally considered by Haag and Ruelle, where $m$ is isolated from the rest of the mass spectrum, this condition is certainly satisfied.

Setting $A(x) \doteq U(x)AU(x)^{-1}$, where $U(x)$ is the unitary implementing the spacetime translation $x = (x_0, \boldsymbol{x})$ (the velocity of light and Planck's constant are set equal to 1 in what follows), one puts, for $t \neq 0$,

$$A_t(f) = \int \mathrm{d}^4x\, g_t(x_0) f_{x_o}(\boldsymbol{x}) A(x) \qquad [4]$$

Here $x_0 \mapsto g_t(x_0) \doteq g((x_0 - t)/|t|^\kappa)/|t|^\kappa$ induces a time averaging about $t$, $g$ being any test function which integrates to 1 and whose Fourier transform has compact support, and $1/(1+\eta) < \kappa < 1$ with $\eta$ as above. The Fourier transform of $f_{x_0}$ is given by $\widetilde{f_{x_0}}(\boldsymbol{p}) \doteq \widetilde{f}(\boldsymbol{p})\, \mathrm{e}^{-\mathrm{i}x_0\omega(\boldsymbol{p})}$, where $f$ is some test function on $\mathbb{R}^3$ with $\widetilde{f}(\boldsymbol{p})$ having compact support, and $\omega(\boldsymbol{p}) = (\boldsymbol{p}^2 + m^2)^{1/2}$. Note that $(x_0, \boldsymbol{x}) \mapsto f_{x_0}(\boldsymbol{x})$ is a solution of the Klein–Gordon equation of mass $m$.

With these assumptions, it follows by a straightforward application of the harmonic analysis of unitary groups that in the sense of strong convergence $A_t(f)\Omega \to P_1 A(f)\Omega$ and $A_t(f)^*\Omega \to 0$ as $t \to \pm\infty$, where $A(f) = \int \mathrm{d}^3x\, f(\boldsymbol{x}) A(0, \boldsymbol{x})$. Hence, the operators $A_t(f)$ may be thought of as creation operators and their adjoints as annihilation operators. These operators are the basic ingredients in the construction of scattering states. Choosing local operators $A_k$ as above and test functions $f^{(k)}$ with disjoint compact supports in momentum space, $k = 1, \ldots, n$, the scattering states are obtained as limits of the Haag–Ruelle approximants

$$A_{1t}(f^{(1)}) \cdots A_{nt}(f^{(n)})\Omega \qquad [5]$$

Roughly speaking, the operators $A_{kt}(f^{(k)})$ are localized in spacelike separated regions at asymptotic times $t$, due to the support properties of the Fourier transforms of the functions $f^{(k)}$. Hence they commute asymptotically because of locality and, by the clustering properties of the vacuum state, the above vector becomes a product state of single-particle states. In order to prove convergence, one proceeds, in analogy to Cook's method in quantum-mechanical scattering theory, to the time derivatives,

$$\begin{aligned} &\partial_t A_{1t}(f^{(1)}) \cdots A_{nt}(f^{(n)})\Omega \\ &\quad = \sum_{k \neq l} A_{1t}(f^{(1)}) \cdots [\partial_t A_{kt}(f^{(k)}), A_{lt}(f^{(l)})] \cdots A_{nt}(f^{(n)})\Omega \\ &\qquad + \sum_k A_{1t}(f^{(1)}) \cdots \overset{k}{\vee} \cdots A_{nt}(f^{(n)}) \partial_t A_{kt}(f^{(k)})\Omega \end{aligned} \qquad [6]$$

where $\overset{k}{\vee}$ denotes omission of $A_{kt}(f^{(k)})$. Employing techniques of Araki and Hepp, one can prove that the terms in the first summation on the right-hand side (RHS) of [6], involving commutators, decay rapidly in norm as $t$ approaches infinity because of locality, as indicated above. By applying condition [3] and the fact that the vectors $\partial_t A_{kt}(f^{(k)})\Omega$ do not have a component in the single-particle space $\mathcal{H}_1$, the terms in the second summation on the RHS of [6] can be shown to decay in norm like $|t|^{-\kappa(1+\eta)}$. Thus, the norm of the vector [6] is integrable in $t$, implying the existence of the strong limits

$$\begin{aligned} &\left(P_1 A_1(f^{(1)})\Omega \otimes \cdots \otimes P_1 A_n(f^{(n)})\Omega\right)^{\mathrm{in/out}} \\ &\quad \doteq \lim_{t \to \mp\infty} A_{1t}(f^{(1)}) \cdots A_{nt}(f^{(n)})\Omega \end{aligned} \qquad [7]$$

As indicated by the notation, these limits depend only on the single-particle vectors $P_1 A_k(f^{(k)})\Omega \in \mathcal{H}_1$, $k = 1, \ldots, n$, but not on the specific choice of operators and test functions. In order to establish their Fock structure, one employs results on clustering properties of vacuum correlation functions in theories without strictly positive minimal mass. Using this, one can compute inner products of arbitrary asymptotic states and verify that the maps

$$\left(P_1 A_1(f^{(1)})\Omega \otimes \cdots \otimes P_1 A_n(f^{(n)})\Omega\right) \mapsto \left(P_1 A_1(f^{(1)})\Omega \otimes \cdots \otimes P_1 A_n(f^{(n)})\Omega\right)^{\text{in/out}} \quad [8]$$

extend by linearity to isomorphisms $\Omega^{\text{in/out}}$ from the Fock space $\mathcal{H}_\text{F}$ onto the subspaces $\mathcal{H}^{\text{in/out}} \subset \mathcal{H}$ generated by the collision states. Moreover, the asymptotic states transform under the Poincaré transformations $U(\mathcal{P}_+^\uparrow)$ as

$$U(\lambda)\left(P_1 A_1(f^{(1)})\Omega \otimes \cdots \otimes P_1 A_n(f^{(n)})\Omega\right)^{\text{in/out}} = \left(U_1(\lambda) P_1 A_1(f^{(1)})\Omega \otimes \cdots \otimes \times\, U_1(\lambda) P_1 A_n(f^{(n)})\Omega\right)^{\text{in/out}} \quad [9]$$

Thus, the isomorphisms $\Omega^{\text{in/out}}$ intertwine the action of the Poincaré group on $\mathcal{H}_\text{F}$ and $\mathcal{H}^{\text{in/out}}$. We summarize these results, which are vital for the physical interpretation of the underlying theory, in the following theorem.

**Theorem 1** *Consider a theory of a particle of mass $m > 0$ which satisfies the standing assumptions and the stability condition [3]. Then there exist canonical isometries $\Omega^{\text{in/out}}$, mapping the Fock space $\mathcal{H}_\text{F}$ based on the single-particle space $\mathcal{H}_1$ onto subspaces $\mathcal{H}^{\text{in/out}} \subset \mathcal{H}$ of incoming and outgoing scattering states. Moreover, these isometries intertwine the action of the Poincaré transformations on the respective spaces.*

Since the scattering states have been identified with Fock space, asymptotic creation and annihilation operators act on $\mathcal{H}^{\text{in/out}}$ in a natural manner. This point will be explained in the following section.

## LSZ Formalism

Prior to the results of Haag and Ruelle, an axiomatic approach to scattering theory was developed by Lehmann, Symanzik, and Zimmermann (LSZ), based on time-ordered vacuum expectation values of quantum fields. The relative advantage of their approach with respect to Haag–Ruelle theory is that useful reduction formulas for the $S$-matrix greatly facilitate computations, in particular in perturbation theory. Moreover, these formulas are the starting point of general studies of the momentum space analyticity properties of the $S$-matrix (dispersion relations), as outlined in Dispersion Relations (cf. also Iagolnitzer (1993)). Within the present general setting, the LSZ method was established by Hepp.

For simplicity of discussion, we consider again a single particle type of mass $m > 0$ and integer spin $s$, subject to condition [3]. According to the results of the preceding section, one then can consistently define asymptotic creation operators on the scattering states, setting

$$A(f)^{\text{in/out}}\left(P_1 A_1(f^{(1)})\Omega \otimes \cdots \otimes P_1 A_n(f^{(n)})\Omega\right)^{\text{in/out}} \doteq \lim_{t\to\mp\infty} A_t(f)\left(P_1 A_1(f^{(1)})\Omega \otimes \cdots \otimes P_1 A_n(f^{(n)})\Omega\right)^{\text{in/out}} = \left(P_1 A(f)\Omega \otimes P_1 A_1(f^{(1)})\Omega \otimes \cdots \otimes P_1 A_n(f^{(n)})\Omega\right)^{\text{in/out}} \quad [10]$$

Similarly, one obtains the corresponding asymptotic annihilation operators,

$$A(f)^{\text{in/out}*}\left(P_1 A_1(f^{(1)})\Omega \otimes \cdots \otimes P_1 A_n(f^{(n)})\Omega\right)^{\text{in/out}} = \lim_{t\to\mp\infty} A_t(f)^*\left(P_1 A_1(f^{(1)})\Omega \otimes \cdots \otimes P_1 A_n(f^{(n)})\Omega\right)^{\text{in/out}} = 0 \quad [11]$$

where the latter equality holds if the Fourier transforms of the functions $f, f^{(1)}, \ldots, f^{(n)}$, have disjoint supports. We mention as an aside that, by replacing the time-averaging function $g$ in the definition of $A_t(f)$ by a delta function, the above formulas still hold. But the convergence is then to be understood in the weak Hilbert space topology. In this form, the above relations were anticipated by LSZ (asymptotic condition).

It is straightforward to proceed from these relations to reduction formulas. Let $B$ be any local operator. Then one has, in the sense of matrix elements between outgoing and incoming scattering states,

$$BA(f)^{\text{in}} - A(f)^{\text{out}}B = \lim_{t\to\infty}(BA(f_{-t}) - A(f_t)B) = \lim_{t\to\infty}\left(\int \mathrm{d}^4x f_{-t}(x)BA(x) - \int \mathrm{d}^4x f_t(x)A(x)B\right) \quad [12]$$

$f_t(x) \doteq g_t(x_0) f(x_0)(\text{vec}(x))$. Because of the (essential) support properties of the functions $f_{\pm t}$, the contributions to the latter integrals arise, for asymptotic $t$, from spacetime points $x$ where the localization

regions of $A(x)$ and $B$ have a negative timelike (first term), respectively, positive timelike (second term) distance. One may therefore proceed from the products of these operators to the time-ordered products $T(BA(x))$, where $T(BA(x)) = A(x)B$ if the localization region of $A(x)$ lies in the future of that of $B$, and $T(BA(x)) = BA(x)$ if it lies in the past. It is noteworthy that a precise definition of the time ordering for finite $x$ is irrelevant in the present context – any reasonable interpolation between the above relations will do. Similarly, one can define time-ordered products for an arbitrary number of local operators. The preceding limit can then be recast into

$$\lim_{t\to\infty} \int d^4x (f_{-t}(x) - f_t(x)) T(BA(x)) \qquad [13]$$

The latter expression has a particularly simple form in momentum space. Proceeding to the Fourier transforms of $f_{\pm t}$ and noticing that, in the limit of large $t$,

$$\left(\widetilde{f_{-t}}(p) - \widetilde{f_t}(p)\right)/(p_0 - \omega(\boldsymbol{p})) \longrightarrow -2\pi i \widetilde{f}(\boldsymbol{p})\, \delta(p_0 - \omega(\boldsymbol{p})) \qquad [14]$$

one gets

$$\begin{aligned} BA(f)^{\text{in}} - A(f)^{\text{out}}B &= -2\pi i \int d^3p \widetilde{f}(\boldsymbol{p})(p_0 - \omega(\boldsymbol{p})) \\ &\quad \times T(B\widetilde{A}(-p))\Big|_{p_0 = \omega(\boldsymbol{p})} \end{aligned} \qquad [15]$$

Here $T(B\widetilde{A}(p))$ denotes the Fourier transform of $T(BA(x))$, and it can be shown that the restriction of $(p_0 - \omega(\boldsymbol{p}))T(B\widetilde{A}(-p))$ to the manifold $\{p \in \mathbb{R}^4 : p_0 = \omega(\boldsymbol{p})\}$ (the "mass shell") is meaningful in the sense of distributions on $\mathbb{R}^3$. By the same token, one obtains

$$\begin{aligned} &A(f)^{\text{out}*}B - BA(f)^{\text{in}*} \\ &= -2\pi i \int d^3p \overline{\widetilde{f}(\boldsymbol{p})}\, (p_0 - \omega(\boldsymbol{p})) T(\widetilde{A^*}(p)B)\Big|_{p_0 = \omega(\boldsymbol{p})} \end{aligned} \qquad [16]$$

Similar relations, involving an arbitrary number of asymptotic creation and annihilation operators, can be established by analogous considerations. Taking matrix elements of these relations in the vacuum state and recalling the action of the asymptotic creation and annihilation operators on scattering states, one arrives at the following result, which is central in all applications of scattering theory.

**Theorem 2** *Consider the theory of a particle of mass $m > 0$ subject to the conditions stated in the preceding sections and let $f^{(1)}, \ldots, f^{(n)}$ be any family of test functions whose Fourier transforms have compact and nonoverlapping supports. Then*

$$\begin{aligned} &\Big\langle \left(P_1A_1(f^{(1)})\Omega \otimes \cdots \otimes P_1A_k(f^{(k)})\Omega\right)^{\text{out}}, \\ &\qquad \left(P_1A_{k+1}(f^{(k+1)})\Omega \otimes \cdots \otimes P_1A_n(f^{(n)})\Omega\right)^{\text{in}} \Big\rangle \\ &= (-2\pi i)^n \int \cdots \int d^3p_1 \cdots d^3p_n \overline{\widetilde{f^{(1)}}(\boldsymbol{p}_1)} \cdots \\ &\quad \times \overline{\widetilde{f^{(k)}}(\boldsymbol{p}_k)} \widetilde{f^{(k+1)}}(\boldsymbol{p}_{k+1}) \cdots \widetilde{f^{(n)}}(\boldsymbol{p}_n) \\ &\quad \times \prod_{i=1}^{n} (p_{i_0} - \omega(\boldsymbol{p}_i)) \Big\langle \Omega, T\Big(\widetilde{A_1^*}(p_1) \cdots \\ &\quad \times \widetilde{A_k^*}(p_k) \widetilde{A_{k+1}}(-p_{k+1}) \cdots \\ &\quad \times \widetilde{A_n}(-p_n)\Omega\Big)\Big\rangle\Big|_{p_{j_0} = \omega(\boldsymbol{p}_j)}^{j=1,\ldots,n} \end{aligned} \qquad [17]$$

*in an obvious notation.*

Thus, the kernels of the scattering amplitudes in momentum space are obtained by restricting the (by the factor $\prod_{i=1}^{n}(p_{i_0} - \omega(\boldsymbol{p}_i))$) amputated Fourier transforms of the vacuum expectation values of the time-ordered products to the positive and negative mass shells, respectively. These are the famous LSZ reduction formulas, which provide a convenient link between the time-ordered (Green's) functions of a theory and its asymptotic particle interpretation.

## Asymptotic Particle Counters

The preceding construction of scattering states applies to a significant class of theories; but even if one restricts attention to the case of massive particles, it does not cover all situations of physical interest. For an essential input in the construction is the existence of local operators interpolating between the vacuum and the single-particle states. There may be no such operators at one's disposal, however, either because the particle in question carries a nonlocalizable charge, or because the given family of operators is too small. The latter case appears, for example, in gauge theories, where in general only the observables are fixed by the principle of local gauge invariance, and the physical particle content as well as the corresponding interpolating operators are not known from the outset. As observables create from the vacuum only neutral states, the above construction of scattering states then fails if charged particles are present. Nevertheless, thinking in physical terms, one would expect that the observables contain all relevant information in order to determine the features of scattering states, in particular their collision cross section. That this is indeed the case was first shown by Araki and Haag (Araki 1999).

In scattering experiments, the measured data are provided by detectors (e.g., particle counters) and

coincidence arrangements of detectors. Essential features of detectors are their lack of response in the vacuum state and their macroscopic localization. Hence, within the present mathematical setting, a general detector is represented by a positive operator $C$ on the physical Hilbert space $\mathcal{H}$ such that $C\Omega = 0$. Because of the Reeh–Schlieder theorem, these conditions cannot be satisfied by local operators. However, they can be fulfilled by "almost-local" operators. Examples of such operators are easy to produce, putting $C = L^*L$ with

$$L = \int d^4x\, f(x)\, A(x) \qquad [18]$$

where $A$ is any local operator and $f$ any test function whose Fourier transform has compact support in the complement of the closed forward light cone (and hence in the complement of the energy momentum spectrum of the theory). In view of the properties of $f$ and the invariance of $\Omega$ under translations, it follows that $C = L^*L$ annihilates the vacuum and can be approximated with arbitrary precision by local operators. The algebra generated by these operators $C$ will be denoted by $\mathcal{C}$.

When preparing a scattering experiment, the first thing one must do with a detector is to calibrate it, that is, test its response to sources of single-particle states. Within the mathematical setting, this amounts to computing the matrix elements of $C$ in states $\Phi \in \mathcal{H}_1$:

$$\langle \Phi, C\Phi \rangle = \int\int d^3p\, d^3q\, \overline{\Phi(\boldsymbol{p})}\, \Phi(\boldsymbol{q})\, \langle \boldsymbol{p}|C|\boldsymbol{q}\rangle \qquad [19]$$

Here $\boldsymbol{p} \mapsto \Phi(\boldsymbol{p})$ is the momentum space wave function of $\Phi$, $\langle \cdot|C|\cdot\rangle$ is the kernel of $C$ in the single-particle space $\mathcal{H}_1$, and we have omitted (summations over) indices labeling internal degrees of freedom of the particle, if any. The relevant information about $C$ is encoded in its kernel. As a matter of fact, one only needs to know its restriction to the diagonal, $\boldsymbol{p} \mapsto \langle \boldsymbol{p}|C|\boldsymbol{p}\rangle$. It is called the sensitivity function of $C$ and can be shown to be regular under quite general circumstances (Araki 1999, Buchholz and Fredenhagen 1982).

Given a state $\Psi \in \mathcal{H}$ for which the expectation value $\langle \Psi, C(x))\Psi\rangle$ differs significantly from 0, one concludes that this state deviates from the vacuum in a region about $x$. For finite $x$, this does not mean, however, that $\Psi$ has a particle interpretation at $x$. For that spacetime point may, for example, be just the location of a collision center. Yet, if one proceeds to asymptotic times, one expects, in view of the spreading of wave packets, that the probability of finding two or more particles in the same spacetime region is dominated by the single-particle contributions. It is this physical insight which justifies the expectation that the detectors $C(x)$ become particle counters at asymptotic times. Accordingly, one considers for asymptotic $t$ the operators

$$C_t(h) \doteq \int d^3x\, h(\boldsymbol{x}/t) C(t, \boldsymbol{x}) \qquad [20]$$

where $h$ is any test function on $\mathbb{R}^3$. The role of the integral is to sum up all single-particle contributions with velocities in the support of $h$ in order to compensate for the decreasing probability of finding such particles at asymptotic times $t$ about the localization center of the detector. That these ideas are consistent was demonstrated by Araki and Haag, who established the following result (Araki 1999).

**Theorem 3** *Consider, as before, the theory of a massive particle. Let $C^{(1)}, \ldots, C^{(n)} \in \mathcal{C}$ be any family of detector operators and let $h^{(1)}, \ldots, h^{(n)}$ be any family of test functions on $\mathbb{R}^3$. Then, for any state $\Psi^{\text{out}} \in \mathcal{H}^{\text{out}}$ of finite energy,*

$$\lim_{t\to\infty} \left\langle \Psi^{\text{out}}, C_t^{(1)}(h^{(1)}) \cdots C_t^{(n)}(h^{(n)}) \Psi^{\text{out}} \right\rangle$$
$$= \int \cdots \int d^3p_1 \cdots d^3p_n \langle \Psi^{\text{out}}, \rho^{\text{out}}(\boldsymbol{p}_1) \cdots \rho^{\text{out}}(\boldsymbol{p}_n)\Psi^{\text{out}}\rangle$$
$$\times \prod_{k=1}^{n} h(\boldsymbol{p}_k/\omega(\boldsymbol{p}_k))\langle \boldsymbol{p}_k|C^{(k)}|\boldsymbol{p}_k\rangle \qquad [21]$$

*where $\rho^{\text{out}}(\boldsymbol{p})$ is the momentum space density (the product of creation and annihilation operators) of outgoing particles of momentum $\boldsymbol{p}$, and (summations over) possible indices labeling internal degrees of freedom of the particle are omitted. An analogous relation holds for incoming scattering states at negative asymptotic times.*

This result shows, first of all, that the scattering states have indeed the desired interpretation with regard to the observables, as anticipated in the preceding sections. Since the assertion holds for all scattering states of finite energy, one may replace in the above theorem the outgoing scattering states by any state of finite energy, if the theory is asymptotically complete, that is, $\mathcal{H} = \mathcal{H}^{\text{in}} = \mathcal{H}^{\text{out}}$. Then choosing, in particular, any incoming scattering state and making use of the arbitrariness of the test functions $h^{(k)}$ as well as the knowledge of the sensitivity functions of the detector operators, one can compute the probability distributions of outgoing particle momenta in this state, and thereby the corresponding collision cross sections.

The question of how to construct certain specific incoming scattering states by using only local observables was not settled by Araki and Haag,

however. A general method to that effect was outlined in Buchholz *et al.* (1991). As a matter of fact, for that method only the knowledge of states in the subspace of neutral states is required. Yet in this approach one would need for the computation of, say, elastic collision cross sections of charged particles the vacuum correlation functions involving at least eight local observables. This practical disadvantage of increased computational complexity of the method is offset by the conceptual advantage of making no appeal to quantities which are *a priori* nonobservable.

## Massless Particles and Huygens' Principle

The preceding general methods of scattering theory apply only to massive particles. Yet taking advantage of the salient fact that massless particles always move with the speed of light, Buchholz succeeded in establishing a scattering theory also for such particles (Haag 1992). Moreover, his arguments lead to a quantum version of Huygens' principle.

As in the case of massive particles, one assumes that there is a subspace $\mathcal{H}_1 \subset \mathcal{H}$ corresponding to a representation of $U(\mathcal{P}_+^\uparrow)$ of mass $m=0$ and, for simplicity, integer helicity; moreover, there must exist local operators interpolating between the vacuum and the single-particle states. These assumptions cover, in particular, the important examples of the photon and of Goldstone particles. Picking any suitable local operator $A$ interpolating between $\Omega$ and some vector in $\mathcal{H}_1$, one sets, in analogy to [4],

$$A_t \doteq \int \mathrm{d}^4x\, g_t(x_0) \times (-1/2\pi)\varepsilon(x_0)\,\delta(x_0^2 - \boldsymbol{x}^2)\partial_0 A(x) \qquad [22]$$

Here $g_t(x_0) \doteq (1/|\ln t|)\, g((x_0 - t)/|\ln t|)$ with $g$ as in [4], and the solution of the Klein–Gordon equation in [4] has been replaced by the fundamental solution of the wave equation; furthermore, $\partial_0 A(x)$ denotes the derivative of $A(x)$ with respect to $x_0$. Then, once again, the strong limit of $A_t\Omega$ as $t \to \pm\infty$ is $P_1 A\Omega$, with $P_1$ the projection onto $\mathcal{H}_1$.

In order to establish the convergence of $A_t$ as in the LSZ approach, one now uses the fact that these operators are, at asymptotic times $t$, localized in the complement of some forward, respectively, backward, light cone. Because of locality, they therefore commute with all operators which are localized in the interior of the respective cones. More specifically, let $\mathcal{O} \subset \mathbb{R}^4$ be the localization region of $A$ and let $\mathcal{O}_\pm \subset \mathbb{R}^4$ be the two regions having a positive, respectively, negative, timelike distance from all points in $\mathcal{O}$. Then, for any operator $B$ which is compactly localized in $\mathcal{O}_\pm$, respectively, one obtains $\lim_{t\to\pm\infty} A_t B\Omega = \lim_{t\to\pm\infty} BA_t\Omega = BP_1A\Omega$. This relation establishes the existence of the limits

$$A^{\mathrm{in/out}} = \lim_{t\to\mp\infty} A_t \qquad [23]$$

on the (by the Reeh–Schlieder property) dense sets of vectors $\{B\Omega : B \in \mathcal{A}(\mathcal{O}_\mp)\} \subset \mathcal{H}$. It requires some more detailed analysis to prove that the limits have all of the properties of a (smeared) free massless field, whose translates $x \mapsto A^{\mathrm{in/out}}(x)$ satisfy the wave equation and have c-number commutation relations. From these free fields, one can then proceed to asymptotic creation and annihilation operators and construct asymptotic Fock spaces $\mathcal{H}^{\mathrm{in/out}} \subset \mathcal{H}$ of massless particles and a corresponding scattering matrix as in the massive case. The details of this construction can be found in the original article, cf. Haag (1992).

It also follows from these arguments that the asymptotic fields $A^{\mathrm{in/out}}$ of massless particles emanating from a region $\mathcal{O}$, that is, for which the underlying interpolating operators $A$ are localized in $\mathcal{O}$, commute with all operators localized in $\mathcal{O}_\mp$, respectively. This result may be understood as an expression of Huygens' principle. More precisely, denoting by $\mathcal{A}^{\mathrm{in/out}}(\mathcal{O})$ the algebras of bounded operators generated by the asymptotic fields $A^{\mathrm{in/out}}$, respectively, one arrives at the following quantum version of Huygens' principle.

**Theorem 4** *Consider a theory of massless particles as described above and let $\mathcal{A}^{\mathrm{in/out}}(\mathcal{O})$ be the algebras generated by massless asymptotic fields $A^{\mathrm{in/out}}$ with $A \in \mathcal{A}(\mathcal{O})$. Then*

$$\mathcal{A}^{\mathrm{in}}(\mathcal{O}) \subset \mathcal{A}(\mathcal{O}_-)' \quad \text{and} \quad \mathcal{A}^{\mathrm{out}}(\mathcal{O}) \subset \mathcal{A}(\mathcal{O}_+)' \qquad [24]$$

*Here the prime denotes the set of bounded operators commuting with all elements of the respective algebras (i.e., their commutants).*

## Beyond Wigner's Concept of Particle

There is by now ample evidence that Wigner's concept of particle is too narrow in order to cover all particle-like structures appearing in quantum field theory. Examples are the partons which show up in nonabelian gauge theories at very small spacetime scales as constituents of hadrons, but which do not appear at large scales due to the confining forces. Their mathematical description

requires a quite different treatment, which cannot be discussed here. But even at large scales, Wigner's concept does not cover all stable particle-like systems, the most prominent examples being particles carrying an abelian gauge charge, such as the electron and the proton, which are inevitably accompanied by infinite clouds of ("on-shell") massless particles.

The latter problem was discussed first by Schroer, who coined the term "infraparticle" for such systems. Later, Buchholz showed in full generality that, as a consequence of Gauss' law, pure states with an abelian gauge charge can neither have a sharp mass nor carry a unitary representation of the Lorentz group, thereby uncovering the simple origin of results found by explicit computations, notably in quantum electrodynamics (Steinmann 2000). Thus, one is faced with the question of an appropriate mathematical characterization of infraparticles which generalizes the concept of particle invented by Wigner. Some significant steps in this direction were taken by Fröhlich, Morchio, and Strocchi, who based a definition of infraparticles on a detailed spectral analysis of the energy–momentum operators. For an account of these developments and further references, cf. Haag (1992).

We outline here an approach, originated by Buchholz, which covers all stable particle-like structures appearing in quantum field theory at asymptotic times. It is based on Dirac's idea of improper particle states with sharp energy and momentum. In the standard (rigged Hilbert space) approach to giving mathematical meaning to these quantities, one regards them as vector-valued distributions, whereby one tacitly assumes that the improper states can coherently be superimposed so as to yield normalizable states. This assumption is valid in the case of Wigner particles but fails in the case of infraparticles. A more adequate method of converting the improper states into normalizable ones is based on the idea of acting on them with suitable localizing operators. In the case of quantum mechanics, one could take as a localizing operator any sufficiently rapidly decreasing function of the position operator. It would map the improper "plane-wave states" of sharp momentum into finitely localized states which thereby become normalizable. In quantum mechanics, these two approaches can be shown to be mathematically equivalent. The situation is different, however, in quantum field theory.

In quantum field theory, the appropriate localizing operators $L$ are of the form [18]. They constitute a (nonclosed) left ideal $\mathcal{L}$ in the C*-algebra $\mathcal{A}$ generated by all local operators. Improper particle states of sharp energy–momentum $p$ can then be defined as linear maps $|\cdot\rangle_p : \mathcal{L} \to \mathcal{H}$ satisfying

$$U(x)|L\rangle_p = e^{ipx}|L(x)\rangle_p, \quad L \in \mathcal{L} \qquad [25]$$

It is instructive to (formally) replace $L$ here by the identity operator, making it clear that this relation indeed defines improper states of sharp energy–momentum.

In theories of massive particles, one can always find localizing operators $L \in \mathcal{L}$ such that their images $|L\rangle_p \in \mathcal{H}$ are states with a sharp mass. This is the situation covered in Wigner's approach. In theories with long-range forces there are, in general, no such operators, however, since the process of localization inevitably leads to the production of low-energy massless particles. Yet improper states of sharp momentum still exist in this situation, thereby leading to a meaningful generalization of Wigner's particle concept.

That this characterization of particles covers all situations of physical interest can be justified in the general setting of relativistic quantum field theory as follows. Picking $g_t$ as in [4] and any vector $\Psi \in \mathcal{H}$ with finite energy, one can show that the functionals $\rho_t, t \in \mathbb{R}$, given by

$$\rho_t(L^*L) \doteq \int d^4x \, g_t(x_0) \, \langle \Psi, (L^*L)(x)\Psi \rangle, \quad L \in \mathcal{L} \qquad [26]$$

are well defined and form an equicontinuous family with respect to a certain natural locally convex topology on the algebra $\mathcal{C} = \mathcal{L}^*\mathcal{L}$. This family of functionals therefore has, as $t \to \pm\infty$, weak-$*$ limit points, denoted by $\sigma$. The functionals $\sigma$ are positive on $\mathcal{C}$ but not normalizable. (Technically speaking, they are weights on the underlying algebra $\mathcal{A}$.) Any such $\sigma$ induces a positive-semidefinite scalar product on the left ideal $\mathcal{L}$ given by

$$\langle L_1 | L_2 \rangle \doteq \sigma(L_1^* L_2), \quad L_1, L_2 \in \mathcal{L} \qquad [27]$$

After quotienting out elements of zero norm and taking the completion, one obtains a Hilbert space and a linear map $L \mapsto |L\rangle$ from $\mathcal{L}$ into that space. Moreover, the spacetime translations act on this space by a unitary representation satisfying the relativistic spectrum condition.

It is instructive to compute these functionals and maps in theories of massive particles. Making use of relation [21] one obtains, with a slight change of notation,

$$\langle L_1 | L_2 \rangle = \int d\mu(p) \, \langle p \, | L_1^* L_2 | p \, \rangle \qquad [28]$$

where $\mu$ is a measure giving the probability density of finding at asymptotic times in state $\Psi$ a particle of energy–momentum $p$. Once again, possible summations over different particle types and internal degrees of freedom have been omitted here. Thus,

setting $|L\rangle_p \doteq L\,|p\rangle$, one concludes that the map $L \mapsto |L\rangle$ can be decomposed into a direct integral of improper particle states of sharp energy–momentum, $|\cdot\rangle = \int_\oplus \mathrm{d}\mu(p)^{1/2}|\cdot\rangle_p$. It is crucial that this result can also be established without any *a priori* input about the nature of the particle content of the theory, thereby providing evidence of the universal nature of the concept of improper particle states of sharp momentum, as outlined here.

**Theorem 5** *Consider a relativistic quantum field theory satisfying the standing assumptions. Then the maps $L \mapsto |L\rangle$ defined above can be decomposed into improper particle states of sharp energy–momentum $p$,*

$$|\cdot\rangle = \int_\oplus \mathrm{d}\mu(p)^{1/2}|\cdot\rangle_p \qquad [29]$$

*where $\mu$ is some measure depending on the state $\Psi$ and the respective time limit taken.*

It is noteworthy that whenever the space of improper particle states corresponding to fixed energy–momentum $p$ is finite dimensional (finite particle multiplets), then in the corresponding Hilbert space there exists a continuous unitary representation of the little group of $p$. This implies that improper momentum eigenstates of mass $m = (p^2)^{1/2} > 0$ carry definite (half)integer spin, in accordance with Wigner's classification. However, if $m = 0$, the helicity need not be quantized, in contrast to Wigner's results.

Though a general scattering theory based on improper particle states has not yet been developed, some progress has been made in Buchholz *et al.* (1991). There it is outlined how inclusive collision cross sections of scattering states, where an undetermined number of low-energy massless particles remains unobserved, can be defined in the presence of long-range forces, in spite of the fact that a meaningful scattering matrix may not exist.

## Asymptotic Completeness

Whereas the description of the asymptotic particle features of any relativistic quantum field theory can be based on an arsenal of powerful methods, the question of when such a theory has a complete particle interpretation remains open to date. Even in concrete models there exist only partial results, cf. Iagolnitzer (1993) for a comprehensive review of the current state of the art. This situation is in striking contrast to the case of quantum mechanics, where the problem of asymptotic completeness has been completely settled.

One may trace the difficulties in quantum field theory back to the possible formation of superselection sectors (Haag 1992) and the resulting complex particle structures, which cannot appear in quantum-mechanical systems with a finite number of degrees of freedom. Thus, the first step in establishing a complete particle interpretation in a quantum field theory has to be the determination of its full particle content. Here the methods outlined in the preceding section provide a systematic tool. From the resulting data, one must then reconstruct the full physical Hilbert space of the theory comprising all superselection sectors. For theories in which only massive particles appear, such a construction has been established in Buchholz and Fredenhagen (1982), and it has been shown that the resulting Hilbert space contains all scattering states. The question of completeness can then be recast into the familiar problem of the unitarity of the scattering matrix. It is believed that phase space (nuclearity) properties of the theory are of relevance here (Haag 1992).

However, in theories with long-range forces, where a meaningful scattering matrix may not exist, this strategy is bound to fail. Nonetheless, as in most high-energy scattering experiments, only some very specific aspects of the particle interpretation are really tested – one may think of other meaningful formulations of completeness. The interpretation of most scattering experiments relies on the existence of conservation laws, such as those for energy and momentum. If a state has a complete particle interpretation, it ought to be possible to fully recover its energy, say, from its asymptotic particle content, that is, there should be no contributions to its total energy which do not manifest themselves asymptotically in the form of particles. Now the mean energy–momentum of a state $\Psi \in \mathcal{H}$ is given by $\langle \Psi, P\Psi\rangle, P$ being the energy–momentum operators, and the mean energy–momentum contained in its asymptotic particle content is $\int \mathrm{d}\mu(p)p$, where $\mu$ is the measure appearing in the decomposition [29]. Hence, in case of a complete particle interpretation, the following should hold:

$$\langle \Psi, P\Psi\rangle = \int \mathrm{d}\mu(p)p \qquad [30]$$

Similar relations should also hold for other conserved quantities which can be attributed to particles, such as charge, spin, etc. It seems that such a weak condition of asymptotic completeness suffices for a consistent interpretation of most scattering experiments. One may conjecture that relation [30] and its generalizations hold in all theories admitting a local stress–energy tensor and local currents corresponding to the charges.

# Scattering in Relativistic Quantum Field Theory: The Analytic Program

**J Bros**, CEA/DSM/SPhT, CEA Saclay, Gif-sur-Yvette, France

## Introduction to the Analytic Structures of Quantum Field Theory

The importance of complex variables and of the concept of analyticity in theoretical physics finds one of its best illustrations in the analytic structure of relativistic quantum field theory (QFT). The latter have been investigated from several viewpoints in the last 50 years, according to the successive progress in QFT.

In the two main axiomatic frameworks of QFT, namely the one based on Wightman axioms (for a short presentation, *see* Dispersion Relations and also Axiomatic Quantum Field Theory) and the Haag, Kastler, and Araki theory of "local observables" (*see* Algebraic Approach to Quantum Field Theory), there are general justifications of analyticity properties for relevant "$N$-point structure functions" both in complexified spacetime variables and in complexified energy–momentum variables.

In the Wightman framework, relativistic quantum fields are operator-valued distributions $\Phi_j(x)$ on four-dimensional Minkowski spacetime that transform covariantly under a unitary representation of the Poincaré group in the Hilbert space of states. The basic quantities of QFT are (tempered) distributions on $\boldsymbol{R}^{4N}$ of the form $<\Psi, \Phi(x_1)\cdots\Phi(x_N)\Psi'>$, which depend on pairs of states $\Psi, \Psi'$, belonging to the Hilbert space of the QFT considered: they can be called $N$-point structure functions of the field $\Phi$ "in $x$-space," namely in Minkowski spacetime (here, for brevity, we assume that the system is defined in terms of a single quantum field). In parallel, it is important to consider the Fourier transform $\tilde{\Phi}(p) = \int e^{ip\cdot x}\Phi(x)\,dx$ of the field in the Minkowskian energy–momentum space ($p\cdot x \doteq p_0x_0 - \boldsymbol{p}\cdot\boldsymbol{x}$ denoting the Minkowskian scalar product). The corresponding quantities $<\Psi, \tilde{\Phi}(p_1)\cdots\tilde{\Phi}(p_N)\Psi'>$, can then be called $N$-point structure functions of the field $\Phi$ "in $p$-space," namely in energy–momentum space.

In the algebraic QFT framework, each basic local observable $B$ affiliated to a certain bounded region of spacetime $\mathcal{O}$ generates a Haag–Kastler–Araki quantum field $B(x)$ by the action of the translations of spacetime, namely $B(x) \doteq U(x)BU(x)^{-1}$. Here $U(x)$ denotes the unitary representation of the group of spacetime translations in the Hilbert space of states: $B(x)$ is affiliated to the translated region $\mathcal{O}(x) = \{y; y - x \in \mathcal{O}\}$. Then again one can consider $N$-point structure functions of the theory of the form $<\Psi, B(x_1)\cdots B(x_N)\Psi'>$ and $<\Psi, \tilde{B}(p_1)\cdots\tilde{B}(p_N)\Psi'>$.

To summarize the situation as it occurs in both cases, one can say the following:

1. A certain postulate of relativistic causality implies the analyticity of structure functions of a certain class, often called "Green functions," in the complex energy–momentum variables $k_j = p_j + iq_j$, in particular for purely imaginary energies.
2. "Stability properties" of the states $\Psi, \Psi'$ such as a "bounded energy content" of these states imply

the analyticity of the previous structure functions in the complex spacetime variables, in particular for purely imaginary times.

In both cases, analyticity is obtained as a basic property of the Fourier–Laplace transformation in several variables. Let $V^+$ denote the forward cone of the Minkowskian space ($V^+ \doteq -V^- \doteq \{x;\, x^2 \doteq x \cdot x > 0,\, x_0 > 0\}$) and let

$$\tilde{f}(p + \mathrm{i}q) = \int_{V_a^+} \mathrm{e}^{\mathrm{i}(p+iq)\cdot x}\, f(x)\mathrm{d}x \qquad [1]$$

$$g(x + \mathrm{i}y) = (2\pi)^{-4} \int_{V_P^+} \mathrm{e}^{-\mathrm{i}p(x+iy)}\tilde{g}(p)\mathrm{d}p \qquad [2]$$

be the associated reciprocal Fourier formulas, applied, respectively, to functions $f(x)$ with support contained in the translated forward cone $V_a^+ = -a + V^+$, $a \in V^+$ (or in its closure), and to functions $\tilde{g}(p)$ with support contained in the translated forward cone $V_P^+ = -P + V^+$, $P \in V^+$ of energy–momentum space (or in its closure). Then in view of the convergence properties of the previous integrals, one easily checks that $\tilde{f}(k)$ is holomorphic with possible exponential increase in the imaginary directions controlled by the bound $\mathrm{e}^{q\cdot a}$ in the tube domain $\mathcal{T}^+ = \boldsymbol{R}^4 + \mathrm{i}V^+$; similarly, $g(z)$ is holomorphic with an increase controlled by the exponential bound $\mathrm{e}^{-y\cdot P}$ in the tube domain $\mathcal{T}^- = \boldsymbol{R}^4 + \mathrm{i}V^-$.

On the one hand, for each $N$ the structure functions $<\Psi, \tilde{\Phi}(p_1)\cdots\tilde{\Phi}(p_N)\Psi'>$ (or $<\Psi, \tilde{B}(p_1)\cdots\tilde{B}(p_N)\Psi'>$) have conical support properties of the previous type in the variables $p_j$, as a consequence of the relativistic shape of the energy–momentum spectrum. In both axiomatic frameworks, in fact, one postulates that there is a state of zero energy–momentum $\Omega$, called the vacuum, and that the energy–momentum spectrum $\Sigma$, namely the joint spectrum of the generators $P_\mu$ of the Lie algebra of the group $U(x)$, is contained in the closure of $V^+$: this is the so-called spectral condition. A more refined assumption introduced for the requirements in particle physics is that $\Sigma$ contains discrete parts localized on sheets of (mass-shell) hyperboloids inside $V^+$. These support properties in $p$-space imply that the corresponding inverse Fourier transforms $<\Psi, \Phi(x_1)\cdots\Phi(x_N)\Psi'>$ are boundary values of holomorphic functions in appropriate tube domains of the complex space variables $(z_1, \ldots, z_n)$.

On the other hand, in order to exhibit structure functions with conical support properties in $x$-space, one needs to build appropriate algebraic combinations of functions $<\Psi, \Phi(x_{j_1})\cdots\Phi(x_{j_N})\Psi'>$ with permuted arguments in order to take the benefit of the causality postulate, which is always formulated in terms of the commutator of two field operators. There are two versions of this postulate. In the Wightman framework, causality is expressed by the condition of local commutativity or microcausality,

$$[\Phi(x_1), \Phi(x_2)] = 0 \text{ for } (x_1 - x_2)^2 < 0 \qquad [3]$$

In the algebraic QFT framework, causality is expressed by a similar property in terms of any field $B(x)$ generated by a local observable $B \doteq B(0)$ affiliated to a region of spacetime enclosed in a given "double cone" $\mathcal{O}_b = V_b^+ \cap (-V_b^+)$. The corresponding expression of causality is

$$[B(x_1), B(x_2)] = 0 \quad \text{for } (x_1 - x_2) \notin (V_a^+ \cup (-V_a^+)) \qquad [4]$$

for all $a$ such that $a > 2b$.

So, we see that basically, causality and spectral condition generate analyticity respectively in complexified $p$-space and $x$-space. However, the situation is more intricate, since for each $N$ there are always several holomorphic branches (two in the case $N = 2$) in the variables $(z_1, \ldots, z_n)$ and also in the variables $(k_1, \ldots, k_n)$: each of these two sets is obtained essentially by permutations of the $N$ vector variables. The important point is that these various branches can be seen to "communicate together," thanks to the existence of "coincidence regions" of their boundary values on the reals. Here again the roles played by causality and stability are symmetric (but inverted): while causality produces coincidence regions for the holomorphic functions in complex spacetime, spectral conditions produce coincidence regions for the holomorphic functions in complex energy–momentum space.

In view of a basic theorem of several complex variable analysis, called the edge-of-the-wedge theorem (see below in (4)), the two sets of communicating holomorphic branches actually define by mutual analytic continuation two holomorphic function $H_N^{\Psi,\Psi'}(k_1, \ldots, k_N)$ and $\mathcal{W}_N^{\Psi,\Psi'}(z_1, \ldots, z_N)$ in respective domains $D_N^{\Psi,\Psi'}$ and $\Delta_N^{\Psi,\Psi'}$. However, these two primitive domains are not natural holomorphy domains (a phenomenon which is particular to complex geometry in several variables). The problem of finding their holomorphy envelopes, namely the smallest domains $\hat{D}_N^{\Psi,\Psi'}$ and $\hat{\Delta}_N^{\Psi,\Psi'}$ in which any functions holomorphic in the primitive domains can be analytically continued, is the idealistic purpose of what has been called the analytic program of axiomatic QFT. So, we see that there is an analytic program in $x$-space and there is an analytic program in $p$-space. In practice, except for the case $N = 2$, where the complete answer is known, only a partial knowledge of the holomorphy envelopes has been obtained.

The analytic program in $p$-space, which is the only one to be described in the rest of this article, was often considered as physically more interesting, in view of the fact that it aims to establish analyticity properties of the scattering kernels on the complex mass shell. As a matter of fact, an important part of it concerns the derivation of the analyticity domains of dispersion relations for two-particle scattering amplitudes. This part is important from the historical viewpoint as well as from conceptual, physical, and pedagogical viewpoints (the reader may find it useful to first check the article Dispersion Relations, which illustrates how a structure function of the form $H_2^{\Psi,\Psi'}(k_1, k_2)$ can be used for that purpose with a suitable choice of the states $\Psi$ and $\Psi'$). In the general development of the analytic program (in $x$-space as well as in $p$-space), it is recommended to consider the infinite set of structure functions $H_N \doteq H_N^{\Omega,\Omega}(k_1, \ldots, k_N)$ and $\mathcal{W}_N \doteq \mathcal{W}_N^{\Omega,\Omega}(z_1, \ldots, z_N)$ where $\Omega$ is the privileged vacuum state of the theory, in view of the fact that each of these sets characterizes entirely the field theory considered.

Before shifting to the analytic program in $p$-space, we would like to mention various points of interest of the analytic program in $x$-space:

1. Various results of this program have been extensively used for proving fundamental properties of QFT, such as the PCT-invariance theorem, the spin–statistics connection, etc. A good part of these can be found in the books by Streater and Wightman (1980) and by Jost (1965).
2. The functions $H_N$ and $\mathcal{W}_N$ are holomorphic in their respective $p$-space and $x$-space "Euclidean subspaces." To make this clear, let us assume that a Lorentz frame has been chosen once for all; the linear subspace of complex spacetime (resp. energy–momentum) vectors of the form $z = (\mathrm{i}y_0, \boldsymbol{x})$ (resp. $k = (\mathrm{i}q_0, \boldsymbol{p})$) is called the "Euclidean subspace" of the corresponding complex Minkowskian space, in view of the fact that the quadratic form $z^2 \doteq z \cdot z = -(y_0^2 + \boldsymbol{x}^2)$ (resp. $k^2 \doteq k \cdot k = -(q_0^2 + \boldsymbol{p}^2)$) has a definite (negative) sign on that subspace. Then it has been established that (for each $N$) the restrictions of $H_N$ and $\mathcal{W}_N$ to the corresponding $N$-vector Euclidean subspaces are the Fourier transforms of each other. This fact participates in the foundation of the Euclidean formulation of QFT or "QFT at imaginary times"; the latter has provided many important results in QFT, in particular for the rigorous study of field models (initiated by Glimm and Jaffe in the 1970s).
3. A more recent extension of QFT called thermal QFT (TQFT), which aims to study the behavior of quantum fields in a thermal bath, can be described in terms of a modified analytic program. In the latter, the spectral condition is replaced by the so-called KMS condition, which prescribes $x$-space analyticity properties of a particular type for the structure functions $\mathcal{W}_N$: it requires analyticity together with periodicity conditions with respect to imaginary times, the period being the inverse of the temperature (*see* Thermal Quantum Field Theory). The usual analytic structure for the theories with vacuum and spectral conditions is recovered in the zero-temperature limit.
4. In more recent investigations concerning quantum fields on (holomorphic) curved spacetimes, analyticity properties of the structure functions similar to those of thermal QFT can be established. This is the case in particular with de Sitter spacetime, for which a notion of "temperature of geometrical origin" is most simply exhibited.

In this article, an account of the general analytic program of axiomatic QFT in complex energy–momentum space will be presented; it will describe some of the methods which have been used for establishing analyticity properties of the $N$-point structure functions of QFT and corresponding properties of the $(n \to n')$-particle collision processes, for all $n, n'$ such that $n \geq 2, n' \geq 2, n + n' = N$. (For a more detailed study, in particular concerning the microlocal methods, see the book by Iagolnitzer (1992)).

Concerning the important case $N = 4$, this article gives complements to the results described in the article Dispersion Relations. In fact, the program allows one to justify other important analytic structures of the four-point functions and of two-particle scattering functions. They concern

- the field-theoretical basis of analyticity in the complexified variable of angular momentum, first introduced and developed in potential theory (Regge 1959);
- the Bethe–Salpeter (BS-) type structure (based on the additional postulate of asymptotic completeness), which is a relativistic field-theoretical generalization of the Lippmann–Schwinger structure of nonrelativistic scattering theory (for Schrödinger equations with Yukawa-type potentials).

The latter allows one to introduce the concept of composite particle in the field-theoretical framework (including bound states and unstable particles or "resonances") and also the concept of "Regge particle," thanks to complex angular momentum analysis.

## Various Aspects of the General Analytic Program of QFT in Complex Energy–Momentum Space

### The *N*-Point Structure Functions of QFT

It is proved in the Wightman QFT axiomatic framework that any QFT is completely characterized by the (infinite) sequence of its "*N*-point functions" or "vacuum expectation values" (also called "Wightman functions")

$$W_N(x_1, \ldots, x_N) \doteq < \Omega, \Phi(x_1) \cdots \Phi(x_N)\Omega >$$

which are tempered distributions on $\boldsymbol{R}^{4N}$ satisfying a set of general properties that can be split up into linear and nonlinear conditions. (This is known as the Wightman reconstruction theorem).

**Linear conditions** Each individual *N*-point function satisfies three sets of linear conditions which result, respectively, from:

1. *Poincaré invariance*: typically, for every Poincaré transformation $g$ of Minkowski spacetime
$$W_N(x_1, \ldots, x_N) = W_N(gx_1, \ldots, gx_N)$$
in particular, the $W_N$ are invariant under spacetime translations and therefore defined on the quotient subspace $\boldsymbol{R}^{4(N-1)} \doteq \boldsymbol{R}^{4N}/\boldsymbol{R}^4$ of the differences $x_j - x_k$.
2. *Microcausality*: support conditions on commutator functions of the following form:
$$C^{(j,j+1)}(x_1,\ldots,x_n) \doteq W_N(x_1,\ldots,x_j,x_{j+1},\ldots,x_N) - W_N(x_1,\ldots,x_{j+1}, x_j,\ldots,x_N) = 0$$
in the region of $\boldsymbol{R}^{4N}$ defined by $(x_j - x_{j+1})^2 < 0$.
3. *Spectral condition*: support conditions on the Fourier transform $\tilde{W}_N(p_1, \ldots, p_N) = \delta(p_1 + \cdots + p_N) \times \hat{w}_N(p_1, \ldots, p_{N-1})$ of $W_N$, which assert that $\hat{w}_N(p_1, \ldots, p_{N-1}) = 0$ if either one of the following conditions is fulfilled: $p_1 + \cdots + p_j \notin \Sigma$, for $j = 1, \ldots, N-1$.

For each $N$, one can then construct a set of distributions $R_N^{(\alpha)}(x_1, \ldots, x_N)$, called "generalized retarded functions" (Araki, Ruelle, Steinmann, 1960 (see Iagolnitzer (1992, ref. [EGS])) which are appropriate linear combinations of multiple commutator functions built from $W_N$ and multiplied by products of Heaviside step-functions $\theta(x_{j,0} - x_{k,0})$ of the differences of time coordinates. Each of these distributions $R_N^{(\alpha)}(x_1, \ldots, x_N)$ has its support contained in a convex salient cone $C_\alpha$. This construction can be seen as a generalization of the decomposition [23] of the commutator $C_{\Psi,\Psi'}$ in the article Dispersion Relations. Then in view of the Laplace-transform theorem in several variables, the Fourier transform $\tilde{R}_N^{(\alpha)}(p_1, \ldots, p_N) = \delta(p_1 + \cdots + p_N) \times \tilde{r}_N^{(\alpha)}([p]_N)$ is such that $\tilde{r}_N^{(\alpha)}([p]_N)$ is the boundary value of a holomorphic function $\tilde{r}_N^{(\alpha),(c)}([k]_N)$ defined in a tube $\mathcal{T}_\alpha = \boldsymbol{R}^{4(N-1)} + \mathrm{i}\tilde{C}_\alpha$. Here $[k]_N = [p]_N + \mathrm{i}[q]_N$ belongs to a $4(N-1)$-dimensional complex linear space $M_N^{(c)}$: this is the set of complex vectors $[k]_N \doteq (k_1, \ldots, k_N)$ such that $k_1 + \cdots + k_N = 0$. $\tilde{C}_\alpha$ is the dual cone of $C_\alpha$ in the real $(4(N-1)$-dimensional) $[q]_N$-space. Geometrically, each cone $\tilde{C}_\alpha$ is defined in terms of a certain "cell" of $[q]_N$-space which is defined by prescribing consistent conditions of the form $\varepsilon_J q_J \in V^+$ with $q_J = \sum_{j\in J} q_j$ and $\varepsilon_J = \pm 1$ for all proper subsets $J$ of the set $\{1, 2, \ldots, N\}$. This is the expression of the microcausality postulate (summarized in [3] or [4]) in complex energy–momentum space. Concerning the difference between the two formulations [3] and [4], one can see that there is no geometrical difference concerning the analyticity domains, but differences for the type of increase of the structure functions in their tube domains: in the case of [3], they are bounded by powers of the energy–momenta, while in the case of [4] they may have an exponential increase governed by factors of the type $\mathrm{e}^{q\cdot a}$.

For each $N$, the linear space generated by all the distributions $\tilde{r}_N^{(\alpha)}([p]_N)$ is constrained by a set of linear relations (called Steinmann relations) which result from algebraic expressions of discontinuities of the following type, called (generalized) "absorptive parts,"

$$\tilde{r}_N^{(\alpha)}([p]_N) - \tilde{r}_N^{(\alpha')}([p]_N) = < \Omega, [\tilde{\mathrm{R}}_{J_1}^{(\alpha_1)}([p]_{(J_1)}), \tilde{\mathrm{R}}_{J_2}^{(\alpha_2)}([p]_{(J_2)})]\Omega > \quad [5]$$

for all pairs of adjacent cells $(\alpha, \alpha')_{(J_1,J_2)}$ in the following sense: $\alpha$ and $\alpha'$ only differ by changing the value of $\varepsilon_{J_1} = -\varepsilon_{J_2}, (J_1, J_2)$ denoting any given partition of the set $\{1, 2, \ldots, N\}$. In [5], the symbols $\tilde{\mathrm{R}}_{J_i}^{(\alpha_i)}$ denote generalized retarded operators of lower order and the argument $[p]_{(J)}$ stands for the set of independent 4-momenta $\{p_j; j \in J\}$. Formula [5] may be seen as an $N$-point generalization of formula [26] of Dispersion Relations for the case when the state $\Psi = \Psi'$ is replaced by $\Omega$.

Then by applying to [5] the same argument based on spectral condition as in the exploitation of eqn [26] in Dispersion Relations, one concludes that the two distributions $\tilde{r}_N^{(\alpha)}$ and $\tilde{r}_N^{(\alpha')}$ coincide on an open set $\mathcal{R}_{\alpha,\alpha'}$ of the form $p_{J_1}^2 = p_{J_2}^2 < M_{J_1}^2$, where $p_{J_1} \doteq \sum_{j\in J_1} p_j = -p_{J_2}$. It then follows from the general "oblique edge-of-the-wedge theorem" (Epstein, 1960; see below) that the two corresponding holomorphic functions $\tilde{r}_N^{(\alpha),(c)}([k]_N)$ and $\tilde{r}_N^{(\alpha'),(c)}([k]_N)$

have a common analytic continuation in the union of their tubes together with a certain complex "connecting set," bordered by $\mathcal{R}_{\alpha,\alpha'}$. Since this argument applies to all pairs $(\alpha, \alpha')_{(J_1,J_2)}$, the following important property holds (see Iagolnitzer (1992, refs. [B2], [EGS])):

**Theorem 1**

(i) *All the holomorphic functions* $\tilde{r}_N^{(\alpha),(c)}([k]_N)$ *admit a common analytic continuation* $H_N([k]_N)$, *called the N-point structure function (or Green function) of the given quantum field in complex energy–momentum space. It is holomorphic in a "primitive domain"* $D_N$ *of* $M_N^{(c)}$, *which is the union of all tubes* $\mathcal{T}_\alpha$ *together with complex "connecting sets" bordered by all the coincidence regions* $\mathcal{R}_{\alpha,\alpha'}$ *defined previously.*

(ii) *For each N the complex domain* $D_N$ *contains the whole Euclidean subspace* $\mathcal{E}_N$ *of* $M_N^{(c)}$, *which is the set of all complex vectors* $[k]_N = (k_1, \ldots, k_N)$ *such that* $k_j = (k_{j,0}, \boldsymbol{k}_j); k_{j,0} = iq_{j,0}, \boldsymbol{k}_j = \boldsymbol{p}_J$ *for* $j = 1, 2, \ldots, N$. *(This Euclidean subspace depends on the choice of a given Lorentz frame in Minkowski spacetime.)*

**Positivity Conditions** The Hilbert space framework which underlies the axioms of QFT implies (an infinite set of) positivity inequalities on the $N$-point structure functions of the fields. As a typical example related to the previous formula [5] when $|J_1| = |J_2| = N/2$ (for $N$ even), one can mention the positive-definiteness property of the absorptive parts for appropriate pairs of adjacent cells $(\alpha_1, \alpha_2 = -\alpha_1)_{(J_1,J_2)}$, which simply expresses the positivity of the following Hilbertian squared norm:

$$\left| \int \bar{f}([p]_{(J_2)}) f([p]_{(J_1)}) [\tilde{r}_N^{(\alpha)}([p]_N) - \tilde{r}_N^{(\alpha')}([p]_N)] \mathrm{d}[p]_{(J_1)} \mathrm{d}[p]_{(J_2)} \right| = \left| \int f([p]_{(J_1)}) \tilde{\mathrm{R}}_J^{(\alpha_1)}([p]_{(J_1)}) \Omega > \mathrm{d}[p]_{(J_1)} \right|^2 \geq 0 \quad [6]$$

### Scattering Kernels of General $(n \to n')$-Particle Collisions and General Reduction Formulas

The presentation of $(2 \to 2)$-particle scattering kernels in the article Dispersion Relations can be generalized to arbitrary $(n \to n')$-particle collision processes, involving $n$ incoming massive particles $(n \geq 2)$ and $n'$ outgoing massive particles $(n' \geq 2)$. The big "scattering matrix" or "$S$-matrix" in the Hilbert space of states is the collection of all partial scattering matrices $S_{n,n'}$ or of the equivalent kernels $S_{n,n'}(p_{n,\mathrm{in}}; p_{n',\mathrm{out}})$, defined by a straightforward generalization of formula [20] of the quoted article:

$$\mathrm{S}_{n,n'}(\hat{f}_{n,\mathrm{in}}, \hat{g}_{n',\mathrm{out}}) = \int_{\mathcal{M}_{n,n'}} \hat{f}_{n,\mathrm{in}}(p_{n,\mathrm{in}}) \overline{\hat{g}_{n',\mathrm{out}}}(p_{n',\mathrm{out}}) \times S_{n,n'}(p_{n,\mathrm{in}}; p_{n',\mathrm{out}}) \mu_m^n(p_{n,\mathrm{in}}) \mu_m^{n'}(p_{n',\mathrm{out}}) \quad [7]$$

Here we have considered for simplicity the case of collisions involving a single type of particle with mass $m$. In the arguments of the wave packets, the kernel, and the measures $(\mu_m^n, \mu_m^{n'})$, $p_{n,\mathrm{in}}$ and $p_{n',\mathrm{out}}$, respectively, denote the sets of incoming and outgoing 4-momenta $(p_1, \ldots, p_n)$ and $(p'_1, \ldots, p'_{n'})$ which all belong to the physical mass shell $H_m^+ = \{p; p \in V^+, p^2 = m^2\}$. By supplementing these mass-shell constraints with the relativistic law of conservation of total energy–momentum $p_1 + \cdots + p_n = p'_1 + \cdots + p'_{n'}$, one obtains the definition of the mass-shell manifold $\mathcal{M}_{n,n'}$ of $(n \to n')$-particle collision processes.

We shall reserve the name of scattering kernel (or scattering amplitude), denoted by $T_{n,n'}(p_{n,\mathrm{in}}; p_{n',\mathrm{out}})$, to the so-called "connected component" of the $S$-matrix kernel $S_{n,n'}(p_{n,\mathrm{in}}; p_{n',\mathrm{out}})$. By analogy with the definition of $T$ in terms of $S$ for the two-particle collision processes (*see* Dispersion Relations) $T_{n,n'}$ is defined by a recursive algorithm, which amounts to subtract from $S_{n,n'}$ all the components of the $(n \to n')$-collision processes that are decomposable into independent collision processes involving smaller number of particles, according to all admissible partitions of the numbers $n$ and $n'$.

For any given $N$, let us consider all the "affiliated" scattering kernels $T_{n,n'}$ such that $n + n' = N$ and whose corresponding collision processes, also called "channels," are deduced from one another by the relevant exchange of incoming particles and outgoing antiparticles (e.g., $\Pi_1 + \Pi_2 + \Pi_3 \to \Pi_4 + \Pi_5 + \Pi_6$, $\Pi_1 + \Pi_2 \to \overline{\Pi_3} + \Pi_4 + \Pi_5 + \Pi_6$, and $\Pi_1 + \Pi_3 \to \overline{\Pi_2} + \Pi_4 + \Pi_5 + \Pi_6$). There exist general reduction formulas according to which all these scattering kernels are restrictions to the mass-shell manifold $\mathcal{M}_{(N)}$ of appropriate boundary values of the (so-called) "amputated $N$-point function" $\hat{H}_N(k_1, \ldots, k_N) \doteq (k_1^2 - m^2) \cdots (k_N^2 - m^2) \times H_N(k_1, \ldots, k_N)$. More precisely, these reduction formulas can be written as follows:

$$T_{n,n'}(-p_{n,\mathrm{in}}; p_{n',\mathrm{out}})_{|\mathcal{M}_{(N)}^{(\alpha)}} = \hat{H}_N^{(\alpha)}(p_1, \ldots, p_N)_{|\mathcal{M}_{(N)}^{(\alpha)}} \quad [8]$$

In the latter, $\hat{H}_N^{(\alpha)}$ denotes a certain boundary value of $\hat{H}_N$ on the reals: it is equal to a generalized retarded function $\tilde{r}_N^{(\alpha)}([p]_N)$ which depends in a specific way on a region of the mass shell, called $\mathcal{M}_{(N)}^{(\alpha)}$, in which

the $(n \to n')$-channel is considered. The important thing to be noted in [8] is the sign convention which attributes the notation $-p_j$ to the momentum of any incoming particle and therefore implies that $p_j$ belongs to the negative sheet of hyperboloid $H_m^- \doteq -H_m^+$. This is the price to pay for expressing symmetrically the energy–momentum conservation law as $p_1 + p_2 + \cdots + p_N = 0$ (according to the QFT formalism), but it also displays, as a nice feature, the fact that all the affiliated scattering kernels $T_{n,n'}$ such that $n + n' = N$ are located on the various connected components of the mass shell $\mathcal{M}_{(N)}(p_j \in H_m;\, j = 1, 2, \ldots, N)$: the choice of the sheet $H_m^-$ or $H_m^+$ of $H_m$ is exactly linked to the incoming or outgoing character of the particle considered.

**Remark 1** The reduction formulas are more usually expressed in terms of the Fourier transforms of the (connected parts of the) $N$-point amputated chronological functions $\tau_N([p]_N)$ (*see* Scattering in Relativistic Quantum Field Theory: Fundamental Concepts and Tools). As a matter of fact, the latter coincide with the boundary values $\tilde{r}_N^{(\alpha)}([p]_N)$ of $H_N$ in the corresponding relevant regions $\mathcal{M}_{(N)}^{(\alpha)}$.

**Remark 2** Coming back to the case of two-particle scattering amplitudes (i.e., $n = n' = 2, N = 4$), one can see that the general study presented here implies the consideration of the four-point function $H_4(k_1, k_2, k_3, k_4)$, which is a holomorphic function of three independent complex 4-momenta (since $k_1 + k_2 + k_3 + k_4 = 0$). In that case, the domain $D_4$ contains 32 tubes $\mathcal{T}_\alpha$ which are specified by triplets of conditions such as $q_1 \in V^+$, $q_2 \in V^+$, $q_3 \in V^+$, or $-q_1 \in V^+$, $q_1 + q_2 \in V^+$, $q_1 + q_3 \in V^+$, and those obtained by permutations of the subscripts $(1, 2, 3, 4)$ and also by a global substitution of the cone $V^-$ to $V^+$.

**Remark 3** The logical path from the postulates of QFT to the analyticity properties of two-particle scattering amplitudes that has been followed in the article Dispersion Relations can be seen as a partial exploitation of the general analyticity properties of the four-point function: one was specially interested there in the analyticity properties of $H_4$ in a single 4-momentum $k_1 = -k_3$ (at fixed real values of $p_2 = -p_4$). The "partial reduction formula" [27] of Dispersion Relations corresponds to the restriction of eqn [8] (for $N = 4$) to the linear submanifold $(p_1 = -p_3,\, p_2 = -p_4)$. It may also be worthwhile to stress the fact that, in spite of the exponential bounds on $H_4$ implied by the postulates of algebraic QFT, it has been possible to prove that the scattering function is still bounded by a power of $s$ in its cut-plane (or crossing) domain; the dispersion relations with two subtractions are still justified in that case (Epstein, Glaser, Martin, 1969 (see Martin (1969, preprint))).

### Off-Shell Character of $D_N$: Nontriviality of the Analytic Structure of the Scattering Kernels

One can now see that for each value of $N (N \geq 4)$ the situation created by complex geometry in the space $\mathbf{C}^{4(N-1)}$ of $[k]_N$ is a mere generalization of the one described in a simple situation in the article Dispersion Relations.

1. There exists a fundamental $(3N - 4)$-dimensional complex submanifold, namely the complex mass shell $\mathcal{M}_{(N)}^{(c)}$ defined by the equations $k_j^2 = m^2$; $j = 1, \ldots, N$, which connects together the various real mass-shell components $\mathcal{M}_{(N)}^{(\alpha)}$ interpreted as the various physical regions of a set of affiliated $(n \to n')$-collision processes. The problem of proving the "analyticity of $(n \to n')$-scattering functions" thus amounts to constructing such holomorphic functions on the complex manifold $\mathcal{M}_{(N)}^{(c)}$, whose boundary values on the various real regions $\mathcal{M}_{(N)}^{(\alpha)}$ would reproduce the relevant scattering kernels $T_{n,n'}(-p_{n,\text{in}}; p_{n',\text{out}})$.
2. All the tubes $\mathcal{T}_\alpha$ which generate the primitive domain $D_N$ are off-shell domains, namely their intersections with $\mathcal{M}_{(N)}^{(c)}$ are empty. This simply comes from the fact that the conditions $q_j \in V^\pm$ (included in their definition) and $k_j^2 = m^2 > 0$ are incompatible. One can also check that adding the coincidence regions $\mathcal{R}_{\alpha,\alpha'}$ between adjacent tubes does not improve the situation. However, one can state as a relevant scope the following program.
3. *Linear program* (so-called because it only relies on the linear conditions presented in the section "$N$-point structure functions of QFT"): find parts of the holomorphy envelope of $D_N$ (possibly improved by the exploitation of the Steinmann relations) whose intersections with the complex mass shell $\mathcal{M}_{(N)}^{(c)}$ are nonempty. In the best case, show that such intersections can exist which connect two different regions $\mathcal{M}_{(N)}^{(\alpha)}$ together, which means "proving the crossing property between these two regions."
4. We shall see in the following that, except for the case $N = 4$, the results of this linear program have been rather disappointing as far as reaching the complex mass shell is concerned; however, other interesting analytic structures also coming from positivity conditions and from the additional postulate of asymptotic completeness have been investigated under the general name of

nonlinear program. The "synergy" created by the combination of these two programs remains, to a large extent, to be explored.

### Results of Analytic Completion in the "Linear Program"

We can only outline here some of the geometrical methods which allow one to compute parts of the holomorphy envelopes of the domains $D_N$. One important method, which may be used after applying suitable conformal mappings, reduces to the following basic theorem.

**The tube theorem** *The holomorphy envelope of a "tube domain" of the form* $T_B = \boldsymbol{R}^n + \mathrm{i}B$, *where B is an arbitrary domain in* $\boldsymbol{R}^n$ *called the basis of the tube, is the convex tube* $T_{\hat{B}} = \boldsymbol{R}^n + \mathrm{i}\hat{B}$, *where* $\hat{B}$ *is the convex hull of B.*

The *opposite or oblique edge-of-the-wedge theorem* (Epstein 1960 (see Streater and Wightman (1980, ch. 2, ref. 18))) is a refined local version of the tube theorem, in which the basis $B$ is of the form $B = C_1 \cup C_2$, where $C_1, C_2$ are two disjoint (opposite or nonopposite) cones with apex at the origin and where $T_B$ is replaced by a pair of "local tubes" $(T^{(\mathrm{loc})}_{C_1}, T^{(\mathrm{loc})}_{C_2})$. Here the adjective "local" means that the real parts of the variables are confined in a given open set $\mathcal{U}$ (which can be arbitrarily small). The connectedness of $T_B$ is now replaced by the consideration of any pair of functions $(f_1, f_2)$ holomorphic in these local tubes whose boundary values on their common real set $\mathcal{U}$ coincide. The result is that $f_1$ and $f_2$ admit a common analytic continuation $f$ in a local tube $T^{(\mathrm{loc})}_{C}$, where $C$ is the convex hull of $C_1 \cup C_2$. In the case of opposite cones $(C_1 = -C_2)$, $f$ is then analytic in the real set $\mathcal{U}$, while in the general oblique case $f$ is only analytic in a complex connecting set bordered by $\mathcal{U}$ (namely a set which connects $T^{(\mathrm{loc})}_{C_1}$ and $T^{(\mathrm{loc})}_{C_2}$). There exists an extended version of the edge-of-the-wedge theorem in which the boundary values of $f_1$ and $f_2$ are only defined as distributions.

For simplicity, we shall just give a very rough classification of the type of results obtained. We shall distinguish:

- analyticity domains in the space of several (possibly all) variables: they can be of global type or of microlocal type, namely restricted to complex neighborhoods of real points;
- analyticity domains in special families of one-dimensional complex manifolds; and
- combinations of one-dimensional results which generate domains in several variables by a refined use of the tube theorem, called the *Malgrange–Zerner "flat tube theorem,"* or "flat edge-of-the-wedge theorem." In the latter, the local tubes $T^{(\mathrm{loc})}_{C_1}$ and $T^{(\mathrm{loc})}_{C_2}$ of $f_1$ and $f_2$ reduce to one-variable domains of the upper half-plane in separate variables $z_1 = x_1 + \mathrm{i}y_1, z_2 = x_2 + \mathrm{i}y_2$ but with a common range of real parts $(x_1, x_2) \in \mathcal{U}$. The data $f_1(z_1, x_2)$ and $f_2(x_1, z_2)$ have coinciding boundary values $(f_1(x_1, x_2) = f_2(x_1, x_2))$ in the limit $(y_1 \to 0, y_2 \to 0)$. The result is again the existence of a common analytic continuation to $f_1$ and $f_2$, which is a function of two complex variables $f(z_1, z_2)$ in the intersection of the quadrant $(y_1 > 0,\ y_2 > 0)$ with a complex neighborhood of $\mathcal{U}$. (Note that this result of complex analysis still holds when the real boundary values of the holomorphic functions have singularities, namely are only defined in the sense of distributions).

**Global analyticity properties** The following property (discovered by Streater for three-point functions) looks like an extension of the tube theorem. The holomorphy envelope of the union of two tubes $\mathcal{T}_\alpha, \mathcal{T}_{\alpha'}$ corresponding to adjacent pairs of cells $(\alpha, \alpha')_{(J_1, J_2)}$ together with a complex connecting set bordered by $\mathcal{R}_{\alpha,\alpha'} = \{[p]_N; p^2_{J_1} < m^2_{J_1}\}$ is the convex hull $\mathcal{T}_{\alpha,\alpha'}$ of the union of these tubes minus the following analytic hypersurface $\sigma_{J_1}$ which can be called "a cut": $\sigma_{J_1} = \{[k]_N\colon k^2_{J_1} = m^2_{J_1} + \rho, \rho \geq 0\}$. The interest of this result (although it remains by itself an off-shell result) is that it can generate larger cut-domains by additional analytic completions, which may have intersections with the complex mass shell (see below for the case $N = 4$).

**Microlocal analyticity properties** In the case of the four-point function $\hat{H}_4$, it is possible to consider opposite cut-domains of the previous type, for which $\sigma_{J_1} = \sigma_{\{1,2\}}$ is the energy-cut of the channel $(1, 2 \to 3, 4)$, and for which the spectral conditions prescribe an "edge-of-the-wedge situation" in the neighborhood of the corresponding mass-shell component $\mathcal{M}_{(1,2\to 3,4)}$. The result is that $H_4$ is proved to be holomorphic in a full complex cut-neighborhood of $\mathcal{M}_{(1,2\to 3,4)}$ in the ambient complex energy–momentum space. The intersection of this local domain with the complex mass shell $\mathcal{M}^{(c)}_{(4)}$ is of course a full complex cut-neighborhood of $\mathcal{M}_{(1,2\to 3,4)}$ in $\mathcal{M}^{(c)}_{(4)}$, and this proves that the corresponding scattering amplitude is the boundary value of an analytic scattering function defined as the restriction $\hat{F}(s,t) \doteq \hat{H}_{4|\mathcal{M}^{(c)}_{(4)}}$ of $\hat{H}_4$: it is holomorphic in a domain of complex $(s,t)$ space deprived from the $s$–cut.

In the general case $N > 4$, the results are less spectacular, although a more sophisticated microlocal method involving a "generalized edge-of-the-wedge

theorem" has been applied. This method, which was one of the three methods at the origin of the chapter of mathematics called microlocal analysis (the other two being Hörmander's "analytic wave-front" method and Sato's "microfunctions" method) is based on a local version of the Fourier–Laplace transformation called the FBI transformation (see, e.g., the book on "hypo-analytic structures" by Treves (1992) and in the present context the article "Causality and local analyticity" by Bros and Iagolnitzer (1973) (see Iagolnitzer (1992, ref. [BI1]))).

A first positive result (obtained at first by Hepp in 1965) is the fact that the various real boundary values of $\hat{H}_N$ admit well-defined restrictions as tempered distributions on the corresponding (real) mass shell $\mathcal{M}_{(N)}$; this result is in fact crucial for the rigorous proof of general reduction formulas. However, (according to Bros, Epstein, Glaser, 1972 (see Iagolnitzer (1992, ref. [BEG2])) the local existence of an analytic scattering function in $\mathcal{M}^{(c)}_{(N)}$ is not ensured at all points of the mass shell, but only in certain regions. A rather favourable situation still occurs for $(2 \to 3)$-particle collision amplitudes (i.e., for $N = 5$), but in the general case there are large regions of the mass shell where it is only possible to prove (at least in this linear program) that the amplitude is a sum of a limited number of boundary values of analytic functions, defined in local domains of $\mathcal{M}^{(c)}_{(N)}$ (see in this connection, Iagolnitzer (1992)).

**Analyticity at fixed total energy in momentum transfer variables** A remarkably simple situation had already been exploited before the general analysis of $H_N$ leading to Theorem 1 was carried out. It is the section of the domain of the $N$-point function in the space of the "initial relative 4-momentum" $k = (k_1 - k_2)/2$ of the $s$-channel with initial 4-momenta $(k_1, k_2)$, when the total energy–momentum $P = -(k_1 + k_2)$ with $P^2 = s$ is kept fixed and real. The remaining 4-momenta $p_3, \ldots, p_N$ such that $p_3 + \cdots + p_N = P$ are also kept fixed and real. Consider the case when $P$ is (positive) timelike and such that $s \geq 4m^2$. Then it can be seen that one obtains analyticity of (a certain "1-vector restriction" of) $H_N$ with respect to the vector variable $k$ in the union of the two opposite tubes $\mathcal{T}^+ = \boldsymbol{R}^4 + \mathrm{i}V^+$, $\mathcal{T}^- = \boldsymbol{R}^4 + \mathrm{i}V^-$. Moreover, an edge-of-the-wedge situation holds in view of the spectral coincidence region of the form $k_1^2 = (-P/2 + k)^2 < M_1^2$, $k_2^2 = (-P/2 - k)^2 < M_2^2$. The corresponding holomorphy envelope is given by a Jost–Lehmann–Dyson domain (*see* Dispersion Relations), whose section by the complex mass shell $k_1^2 = k_2^2 = m^2$ turns out to give a "spherical tube domain" of the form $\{k; k = p + iq; k.P = 0, k^2 = -s/4 + m^2; |q^2| < b^2\}$. The $(2 \to N-2)$-particle scattering kernel is therefore the boundary value of a scattering function holomorphic in the previous spherical domain of complex $k$-space. In the special case of the two-particle scattering amplitude $F(s,t)$, one checks that the previous domain yields for each $s, s \geq 4m^2$, an ellipse of analyticity for $\hat{F}(s,t)$ in the $t$-plane with foci at $t = 0$ and $u = 4m^2 - s - t = 0$; this ellipse is called the Lehmann ellipse. (We have considered for simplicity the case of a single type of particle with mass $m$ and two-particle threshold at $2m$.) In fact, the squared momentum transfer $t$ is equal to $(k - k')^2$, if $k' = (k_3 - k_4)/2$ denotes the "final relative momentum" of the $s$-channel, which was here taken to be fixed and real. Moreover, by a similar argument the corresponding absorptive part, namely the discontinuity across the $s$-cut of the scattering amplitude, can be shown to be holomorphic in a larger ellipse with the same foci called the large Lehmann ellipse.

It is interesting to compare the previous result with the one that one obtains when the fixed vector $P$ is chosen to be spacelike, namely when $s$ has a negative, namely "unphysical" value with respect to the distinguished channel $(1, 2 \to 3, 4)$. For that case, the exploitation of the primitive domain $D_4$ shows that for all negative (unphysical) values $\zeta_i = k_i^2 < 0$; $i = 1, 2, 3, 4$, of the squared mass variables, the function $\hat{H}_4$ is holomorphic in a cut-plane of the variable $t$, where the cuts are the $t$-cut ($t = 4m^2 + \rho$, $\rho \geq 0$) and the $u$-cut ($u = 4m^2 - s - t = 4m^2 + \rho'$, $\rho' \geq 0$). This cut-plane has of course to be compared with the off- shell cut-plane domain $\Delta_\zeta$ at the basis of the proof of dispersion relations (*see* Dispersion Relations). Here, however, the choice of the squared momentum transfer $t$ as the variable of analyticity allows one to shift to another interpretation in terms of the concept of angular momentum.

**Analyticity in the complex angular momentum variable** In all the situations previously considered for the case $N = 4$, one can see that at fixed real values of the squared energy $s$ and of the squared masses $\zeta = \{\zeta_i;\ i = 1, 2, 3, 4\}$, the complex initial and final relative 4-momenta $k$ and $k'$ have directions which vary on the complexified sphere $S^{(c)}$. Moreover, the corresponding restriction of $\hat{H}_4$ to that sphere turns out to be always well defined and analytic on the real part of that sphere: it therefore defines a kernel on the sphere, which, in view of Poincaré invariance, is invariant under the rotations and therefore admits a convergent expansion in Legendre polynomials. Let us call $h_\ell(s;\zeta)$ the corresponding sequence of Legendre coefficients.

In the first case considered above, this sequence coincides (all $\zeta_i$ being equal to $m^2$) with what the physicists call the set of partial waves $f_\ell(s)$ of the scattering amplitude. The analyticity of $\hat{H}_4$ on a complex spherical tube of $S^{(c)}$, namely of $\hat{F}(s,t)$ in the Lehmann ellipse, is then equivalent to a certain exponential decrease property with respect to $\ell$ of the sequence of partial waves.

In the second case, where $s$ and the $\zeta_i$ are negative, it can be seen that the sphere $S$ describes 4-momentum configurations which all belong to a certain Euclidean subspace $\mathcal{E}_4$ of $M_4^{(c)}$. But this situation is much more favourable from the viewpoint of analyticity, since $\hat{H}_4$ can be seen to be holomorphic on the full complex submanifold $S^{(c)} \times S^{(c)}$ minus two sets $\sigma_t$ and $\sigma_u$ which correspond to the $t$- and $u$-cuts of the complex $t$-plane. Then this larger analyticity property turns out to be equivalent to the fact that the sequence $h_\ell(s;\zeta)$ admits an interpolation $\tilde{H}(\lambda;s;\zeta)$ holomorphic in a certain half-plane of the form $\mathrm{Re}\,\lambda > \ell_0$ such that for all integers $\ell > \ell_0$ one has: $\tilde{H}(\ell;s;\zeta) = h_\ell(s;\zeta)$. The value of $\ell_0$ is linked to the power bound at large momenta that must be satisfied by $\hat{H}_4$ as a consequence of the temperateness property included in the Wightman axiomatic framework (Bros and Viano 2000).

Of course, this nice analytic structure in a complex angular momentum variable could extend to the set of physical partial waves $f_\ell(s)$ if one could establish the analytic continuation of $\hat{F}(s,t)$ in a cut-plane of $t$ containing the Lehmann ellipses, but this seems out of the possibilities at least of the linear program.

## The "Nonlinear Program" and Its Two Main Aspects

**The extension of the analyticity domains by positivity and the derivation of bounds by unitarity** Positivity conditions of the form [6] have been extensively applied to the case $N = 4$ (namely for subsets $J$ with two elements). The main result (Martin 1969) consists in the possibility of differentiating the forward dispersion relations with respect to $t$ and, as a consequence, to enlarge the analyticity domain in $t$ at fixed $s$: the Lehmann ellipse, whose size shrinks to zero when $s$ tends to infinity, can then be replaced by an ellipse (i.e., the Martin ellipse) whose maximal point $t = t_{\max} > 0$ is fixed when $s$ goes to infinity. This justifies the extension of dispersion relations in $s$ to positive values of $t$; then in a second step the use of unitarity relations for the partial waves allows one to obtain Froissart-type bounds on the scattering amplitudes (see Martin (1969)).

**Asymptotic completeness and BS-type structural analysis** The BS equations have been at first introduced as identities of formal series in the perturbative approach of QFT, and the idea of considering such identities as exact equations having a conceptual content in the general axiomatic framework of QFT has been introduced and developed by Symanzik in 1960. However, it took a long time before its integration in the analytic program of QFT (Bros 1970 (see Iagolnitzer (1992, ref. [B1]))). These developments belong to the nonlinear program since they rely on quadratic integral equations between the various $N$-point functions, which express the postulate of asymptotic completeness via the use of appropriate reduction formulas.

For brevity, the general set of BS-type equations for the $N$-point functions with $N > 4$ will not be presented. The simplest BS-type equation, which concerns the four-point function, can be written as follows:

$$\hat{H}_4(K;k,k') = B(K;k,k') + (\hat{H}_4 \circ_s B)(K;k,k') \quad [9]$$

where

$$(\hat{H}_4 \circ_s B)(K;k,k') = \int_\Gamma \hat{H}_4(K;k,k'')B(K;k'',k')G\left(\frac{K}{2}+k''\right) \times G\left(\frac{K}{2}-k''\right) \mathrm{d}_4k'' \quad [10]$$

In the latter, the $s$-channel is privileged, with $s = K^2, K = -(k_1 + k_2)$; $\hat{H}_4$ is seen as a $K$-dependent kernel ($k$ and $k'$ are the initial and final relative 4-momenta already defined), and the new object $B$ to be studied is also a $K$-dependent kernel. The function $G(k)$ is holomorphic in $k^2$ in a cut-plane except for a pole at $k^2 = m^2$ which plays a crucial role. (It is essentially the "propagator" or two-point function of the field theory considered). Apart from pathologies due to the Fredholm alternative, the correspondence between $\hat{H}_4$ and $B$ is one-to-one, but the peculiarity concerns the integration cycle $\Gamma$ of [10]: it is a complex cycle of real dimension 4, which coincides with the Euclidean space of the vector variable $k''$ when all the 4-momenta are Euclidean, and can always be distorted inside the analyticity domain of $\hat{H}_4$ together with the external variables. The exploitation of the Fredholm equation in complex space with "floating integration cycles" then implies that $B$ is holomorphic at least in the primitive domain of $\hat{H}_4$.

An important geometrical aspect of the integration on the cycle $\Gamma$ in [10] is the fact that this cycle is "pinched" between the pair of poles of the functions $G$ when $K^2$ tends to its threshold value ($s = 4m^2$).

The type of mathematical concept encountered here is closely related to those used in the study of analyticity properties and Landau singularities of the Feynman amplitudes in the perturbative approach of QFT (in this connection, see the books by Hwa and Teplitz (1966) and by F Pham (2005) and references therein).

The first basic result is that it is equivalent for $\hat{H}_4$ to satisfy an asymptotic completeness equation in the pure two-particle region $4m^2 < s < 9m^2$ and for $B$ to satisfy the following property called two-particle irreducibility: $B$ satisfies dispersion relations in $s$ such that the $s$-cut begins at the three-particle threshold: $s = 9m^2$.

The consequence of this extended analyticity property of $B$ is that it generates the following type of analyticity properties for $\hat{H}_4$:

1. *The existence of a two-sheeted analytic structure* for $\hat{H}_4$ over a domain of the $s$-plane containing the interval $4m^2 \leq s < 9m^2$, with a square-root-type branch point at the threshold $s = 4m^2$.
2. *Composite particles*. There exists a Fredholm-type expression

$$\hat{H}_4(K; k, k') = \frac{N(K; k, k')}{D(K^2)} \qquad [11]$$

where $N$ and $D$ are expressed in terms of $B$ via Fredholm determinants, which shows that in its second sheet $\hat{H}_4$ may have poles in $s = K^2$, generated by the zeros of $D$. These poles are interpreted as resonances or unstable particles. The generation of real poles in the first sheet (i.e., bound states) is also possible under special spectral assumptions of QFT.
3. *Complex angular momentum diagonalization of BS-type equations* (Bros and Viano 2000, 2003). The operation $\circ_s$ in the BS-type equation [9] contains not only an integration over squared-mass variables, but also a convolution product on the sphere $S$; the latter is transformed into a product by the Legendre expansion of four-point functions described previously in the subsection "Analyticity in the complex angular momentum variable." As a result, there is a partially diagonalized transform of eqn [9] in terms of the functions $\tilde{H}(\lambda;\, s; \zeta)$ and $\tilde{B}(\lambda;\, s; \zeta)$, which allows one to write a Fredholm formula similar to [11], namely

$$\tilde{H}(\lambda;\; s; \zeta) = \frac{\tilde{N}(\lambda;\; s; \zeta)}{\tilde{D}(\lambda; s)} \qquad [12]$$

Then under suitable increase assumptions on $B$, there may exist a half-plane of the form $\mathrm{Re}\,\lambda > \ell_1$ (with $\ell_1 < \ell_0$) such that $\tilde{H}(\lambda;\, s; \zeta)$ admits poles in the joint variables $\lambda$ and $s$, corresponding to the concept of Regge particle: the composite particles introduced in (2) might then be integrated in the Regge particle, although they manifest themselves physically only for integral values $\ell$ of $\lambda$ with the corresponding spin interpretation. Of course, this scenario is by no means proven to hold in the general analytic program of QFT, but we have seen that the relevant "embryonary structures" are conceptually built-in, so that the phenomenon might hopefully be produced in a definite quantum field model.
4. *Byproducts of BS-type structural analysis for* $N = 5$ *and* $N = 6$. Relativistic exact structural equations for $(3 \to 3)$-particle collision amplitudes, which generalize the Faddeev structural equations of nonrelativistic potential theory, have been shown to be valid in the energy region of "elastic" collisions (i.e., with total energy bounded by $4m$); relevant Landau singularities of tree diagrams and triangular diagrams have been exhibited as a by-product in this low-energy region (Bros, and also Combescure, Dunlop in two-dimensional field models, 1981 (see Iagolnitzer (1992, refs. [B3], [B4], [CD]))). Moreover, crossing domains on the complex mass shell for $(2 \to 3)$-particle collision amplitudes have been obtained (Bros 1986 (see Iagolnitzer (1992, ref. [B1]))) by conjointly using $(N = 5)$ BS-type equations together with analytic completion properties (*see*, e.g., the "Crossing lemma" in Dispersion Relations).

## Introduction

Relativistic quantum field theory (QFT) has been mainly developed since the 1950s in the perturbative framework. Quantities of interest then appear as infinite sums of Feynman integrals, corresponding to infinite series expansions with respect to couplings. This approach has led to basic successes for practical purposes, but suffered due to crucial defects from conceptual and mathematical viewpoints. First, individual terms were *a priori* infinite: this was solved by perturbative renormalization. However, even so, the series remain divergent. Two rigorous approaches have been developed since the 1960s. The axiomatic approach aims to establish a general framework independent of any particular model (Lagrangian interaction) and to analyze general properties that can be derived in that framework from basic principles. The "constructive" approach aims to rigorously establish the existence of nontrivial QFT models (theories) and to directly analyze their properties. Some of the fundamental bases are described in this encyclopedia in the articles by J Bros, D Buchholz and J Summers, and by G Gallavotti, respectively. This article aims to a deeper study of particle analysis and scattering of theories. In contrast to the articles by Buchholz and Summers and G Gallavotti, it is restricted to massive theories, a rather strong restriction, but for the latter goes much beyond in particle analysis.

From a purely physical viewpoint, results remain limited: the models rigorously defined so far are weakly coupled models in spacetime dimensions 2 or 3, results on bound states depend on specific kinematical factors in these dimensions, proofs of asymptotic completeness (AC) are not yet complete, .... On the positive side, we might say that the analysis and results are of interest from both conceptual and physical viewpoints; on the other hand, these works have also largely been related and have contributed to important, purely mathematical developments, for example, in the domain of analytic functions of several complex variables, microlocal analysis, ....

The general framework of QFT based on Wightman axioms is introduced in the next section. Massive theories are characterized in that framework by a condition on the mass spectrum. Haag–Ruelle asymptotic theory then allows one to define, in the Hilbert space $\mathcal{H}$ of states, two subspaces $\mathcal{H}_{\text{in}}$ and $\mathcal{H}_{\text{out}}$ corresponding to states that are asymptotically tangent, before and after interactions, respectively, to free-particle states. The AC condition $\mathcal{H} = \mathcal{H}_{\text{in}} = \mathcal{H}_{\text{out}}$ introduces a further important implicit particle content in the theory. Collision amplitudes or scattering functions are then well defined in the space of on-mass-shell initial and final energy–momenta (satisfying energy–momentum conservation). The LSZ "reduction formulas" give their link with chronological functions of the fields.

Basic properties of scattering amplitudes that follow from the Wightman axioms are then outlined. In particular, these axioms allow one to define the "$N$-point functions," which are analytic in a domain of complex energy–momentum space containing the Euclidean region (imaginary energy components), and from which chronological and scattering functions can be recovered. Other results at that stage include the on-shell physical sheet analyticity properties of four-point functions, as also general asymptotic causality and local analyticity properties for $N \geq 4$.

Next, we describe results derived from AC and regularity conditions on analyticity and asymptotic causality in terms of particles. In particular, the analysis of the links between analyticity properties of irreducible kernels (satisfying Bethe–Salpeter type equations) and AC in low-energy regions are included, following ideas of K Symanzik.

The final three sections are devoted to the analysis of models.

Models of QFT have been rigorously defined in Euclidean spacetime, through cluster and, more generally, phase-space expansions which are shown

to be convergent at small coupling (and replace the nonconvergent expansions, of perturbative QFT). Examples of such models are the super-renormalizable massive $\varphi^4$ models in dimensions 2 or 3 (in the 1970s) and the "just renormalizable" massive (fermionic) Gross–Neveu model – in dimension 2 – in the 1980s. The $N$-point functions of these models can be shown to have exponential fall-off in Euclidean spacetime. By the usual Fourier–Laplace transform theorem, one obtains in turn analyticity properties in corresponding regions away from the Euclidean energy–momentum space.

On the other hand, *à la* Osterwalder–Schrader properties can be established in Euclidean spacetime. By analytic continuation from imaginary to real times, it is in turn shown that a corresponding nontrivial theory satisfying the Wightman axioms is recovered on the Minkowskian side. This analysis is omitted here. However, no information is obtained in that way on the mass spectrum, AC, energy–momentum space analyticity, .... Such results can be obtained through the use of irreducible kernels. This was initiated by T Spencer in the 1970s and then developed along the same line (Spencer and Zirilli, Dimock and Eckmann, Koch, Combescure, and Dunlop). We outline here the more general approach of the present authors. In the latter, irreducible kernels are directly defined through "higher-order" cluster expansions which are again convergent at sufficiently small coupling. They are shown to satisfy exponential fall-off in Euclidean spacetime with rates better than those of the $N$-point functions, and hence corresponding analyticity in larger regions around (and away from) the Euclidean energy–momentum space. Results will then be established by analytic continuation, from the Euclidean up to the Minkowskian energy–momentum space, of structure equations that express the $N$-point functions in terms of irreducible kernels. These structure equations are infinite series expansions, with again convergence properties at small coupling. In the cases $N=2$ and $N=4$ (even theories), the re-summation of these structure equations give, respectively, the Lippmann–Schwinger and Bethe–Salpeter (BS) integral equations (up to some regularization).

The one-particle irreducible (1PI) two-point kernel $G_1$ is analytic up to $s=(2m)^2-\varepsilon$, where $\varepsilon$ is small at small coupling ($s$ is the squared center of mass energy of the channel). A simple argument then allows one to show analyticity of the actual two-point function in the same region up to a pole at $k^2=m_{\text{ph}}^2$: this shows the existence of a first basic physical mass $m_{\text{ph}}$ (close at small coupling to the bare mass $m$). In a free theory (zero coupling) with one mass $m$, there is only one corresponding particle. At small coupling, the existence of other (stable) particles is not *a priori* expected; nevertheless, we will see that such particles (two-particle bound states) will occur in some models in view of kinematical threshold effects.

The 2PI four-point kernel $G_2$ is shown to be analytic up to $s=(4m)^2-\varepsilon$ in an even theory. On the other hand, it satisfies a (regularized) BS equation. In a way analogous to the section "AC and analyticity," starting here from the analyticity of $G_2$, the actual four-point function $F$ is in turn analytic or meromorphic in that region up to the cut at $s\geq 4m^2$, and the discontinuity formula associated with AC in the low-energy region is obtained.

For some models (depending on the signs of some couplings), it will be shown that $F$ has a pole in the physical sheet, below the two-particle threshold (at a distance from it which tends to zero as the coupling itself tends to zero). This pole then corresponds to a further stable particle.

More generally, and up to some technical problems, the structure equations should allow one to derive various discontinuity formulas of $N$-point functions including those associated with AC in increasingly higher-energy regions. Asymptotic causality in terms of particles and related analyticity properties (Landau singularities...) should also follow. However, in this approach, results should be obtained only for very small couplings as the energy region considered increases.

**Note**: Notations used are different in the next two sections on the one hand, and the final three sections on the other. These notations follow the use of, respectively, axiomatic and constructive field theory; for instance, $x$ and $p$ are real on the Minkowskian side in the next two sections whereas they are real on the Euclidean side in the last three sections. The mass $m$ in the next two sections is a physical mass, whereas it is a bare mass in the last three sections (where a physical mass is noted $m_{\text{ph}}$).

## The General Framework of Massive Field Theories

We denote by $x=(x_0,\boldsymbol{x})$ a (real) point in Minkowski spacetime with respective time and space components $x_0$ and $\boldsymbol{x}$ (in a given Lorentz frame); $x^2=x_0^2-\boldsymbol{x}^2$. Besides the usual spacetime dimension $d=4$, possible values 2 or 3 will also be considered. In all that follows, the unit system is such that the velocity $c$ of light is equal to 1. Energy–momentum variables, dual (by Fourier transformation) to time and space

variables, respectively, are denoted by $p=(p_0,\boldsymbol{p})$; $p^2=p_0^2-\boldsymbol{p}^2$.

We describe below the Wightman axiomatic framework, though alternative ones such as "local quantum physics" based on the Araki–Haag–Kastler axioms may be used similarly for present purposes. For simplicity, unless otherwise stated, we consider a theory with only one basic (neutral, scalar) field $A$; A is defined on spacetime as an operator-valued distribution: for each test function $f, A(f)$ (formally $\int A(x)f(x)\mathrm{d}x$) is an operator in a Hilbert space $\mathcal{H}$ of states. A physical state is represented by a (normalized) vector in $\mathcal{H}$ modulo scalar multiples. It has to be physically understood as "sub specie aeternitatis" (i.e., "with all its evolution," the Heisenberg picture of quantum mechanics being always adopted). It is assumed that there exists in $\mathcal{H}$ a representation of the Poincaré group (semidirect product of pure Lorentz transformations and spacetime translations).

The Wightman axioms include:

1. local commutativity: $A(x)$ and $A(y)$ commute if $x-y$ is spacelike: $(x-y)^2<0$.
2. the spectral condition ($=$ positivity of the energy in relativistic form): the spectrum of the energy–momentum operators (infinitesimal generators of spacetime translations) is contained in the cone $V_+(p^2\geq 0, p_0\geq 0)$. In a massive theory, the spectrum is more precisely assumed to be contained in the union of the origin (that will correspond to the vacuum vector introduced next), of one or more discrete mass-shell hyperboloids $H_+(m_i)(p^2=m_i^2, p_0>0)$ with strictly positive masses $m_i$, and of a continuum. For simplicity, and unless otherwise stated, we consider in this section a theory with only one mass $m$ and a continuum starting at $2m$ (but this will not be so in a theory with "two-particle bound states"). This condition introduces a first (partial) particle content of the theory. In models, physical masses will not be introduced at the outset but will have to be determined.
3. existence in $\mathcal{H}$ of a vacuum vector $\Omega$, which is the only invariant vector under Poincaré transformations up to scalar multiples; it is moreover assumed that the vector space generated by the action of field operators on the vacuum is dense in $\mathcal{H}$.
4. Poincaré covariance of the theory.

Subspaces $\mathcal{H}_{\text{in}}$ and $\mathcal{H}_{\text{out}}$ of $\mathcal{H}$ can be defined by limiting procedures. To that purpose, one considers test functions $f_{j,t}(x)$ with Fourier transforms of the form $\tilde{f}_j(p)\mathrm{e}^{\mathrm{i}(p_0-[\boldsymbol{p}^2+m^2]^{1/2})t}$, where the functions $\tilde{f}_j$ have their supports in a neighborhood of the mass-shell $H_+(m)$. It can then be shown that vectors of the form $\Psi_t=A(f_{1,t})A(f_{2,t})\cdots A(f_{n,t})\Omega$ converge to limits in $\mathcal{H}$ when $t\to\pm\infty$, respectively, and that these limits depend only on the mass-shell restrictions of the test functions $\tilde{f}_{j|H_+(m)}$.

$\mathcal{H}_{\text{in}}$ and $\mathcal{H}_{\text{out}}$ are interpreted physically as subspaces of states that are "asymptotically tangent" before, respectively, after the interactions, to free-particle states with particles of mass $m$. They are in fact both isomorphic to the free-particle Fock space $\mathcal{F}$, namely the direct sum of $n$-particle spaces of "wave functions" depending on $n$ on mass-shell energy–momenta $p_1,p_2,\ldots,p_n$.

AC is the assertion that $\mathcal{H}=\mathcal{H}_{\text{in}}=\mathcal{H}_{\text{out}}$, that is, that each state in $\mathcal{H}$ is asymptotically tangent to a free-particle state, with particles of mass $m$, both before and after interactions (the two free-particle states are different if there are interactions). This condition cannot be expected to always hold in the general framework introduced above, even if we restrict our attention to "physically reasonable" theories in which states of $\mathcal{H}$ are asymptotically tangent to free-particle states before and after interactions: the absence of other stable particles with different masses is not guaranteed. For instance, even if $A$ is "neutral," the action of field operators on the vacuum might generate pairs of "charged" particles with opposite charges, whatever "charge" one might imagine. Individual charged particles cannot occur in the neutral space $\mathcal{H}$ and their mass thus does not appear in the spectral condition. Hence, such states of pairs of charged particles will not belong to $\mathcal{H}_{\text{in}}$ or $\mathcal{H}_{\text{out}}$ although they belong to $\mathcal{H}$. However, if the set of charged particles is known, it can be shown that the above framework might be enlarged by defining charged fields, in such a way that AC might still be valid in the enlarged framework (see the article of Buchholz and Summers). For simplicity, we restrict below our attention to the simplest theories in which AC holds in the way stated above.

If AC holds, it is shown that there exists a linear operator $S$ from $\mathcal{H}$ to $\mathcal{H}$, called "collision operator" or "$S$-matrix," that relates the "initial" and "final" free-particle states to which a state in $\mathcal{H}$ is tangent before and after interactions, respectively; if AC does not hold, $S$ can also be defined as in operator in $\mathcal{F}$. Collision amplitudes or scattering functions are the energy–momentum kernels of $S$ for given numbers $m$ and $n$ of initial and final particles. As easily seen, they are well-defined distributions on the space of all initial and final on-shell energy–momenta. For convenience, we will denote by $p_k$ the physical energy–momentum of a final particle with index $k(p_k\in H_+(m))$, and by $-p_k$ the physical energy–momentum of an initial particle $(-p_k\in H_+(m))$.

### Wightman Functions, Chronological Functions, and LSZ Reduction Formulas

The $N$-point Wightman "functions" $W_N$ are defined as the vacuum expectation values (VEVs) of the products of $N$ field operators, namely:

$$W_N(x_1, x_2, \ldots, x_N) \\ = < \Omega, A(x_1)A(x_2)\cdots A(x_N)\Omega >$$

The chronological functions $T_N$ are the VEVs of the chronological products of the fields $A(x_1), \ldots, A(x_N)$: in the latter, fields are ordered according to decreasing values of the time components of the points $x_k$. $T_N$ is essentially well defined due to local commutativity with, however, problems not treated here at coinciding points.

$\tilde{T}_N(p_1, \ldots, p_N)$ will denote the Fourier transform of $T_N$. In view of the invariance of the theory under spacetime translations, functions above are invariant under global spacetime translation of all points $x_k$ together. Hence, their Fourier transforms contain an energy–momentum conservation (e.m.c.) delta function $\delta(p_1 + p_2 + \cdots + p_N)$. Connected $N$-point functions are defined by induction (over $N$) via a formula expressing each (nonconnected) function as the sum of the corresponding connected function and of products of connected functions depending on subsets of points. In contrast to nonconnected functions, the analysis shows that connected functions in energy–momentum space do not contain in general e.m.c. delta functions involving subsets of energy–momenta.

It can be shown that the two-point function $\tilde{T}_2(p_1, p_2) = \delta(p_1 + p_2)\tilde{T}_2(p_1)$ has a pole of the form $1/(p_1^2 - m^2)$ and that $\tilde{T}_N$ has similar poles for each energy–momentum variable $p_k$ on the mass-shell. The connected, amputated chronological function $\tilde{T}_N^{\mathrm{amp,c}}$ is defined by multiplying $(\tilde{T}_N)_{\mathrm{connected}} = \tilde{T}_N^{\mathrm{c}}$ (for $N \geq 2$) by the product of all factors $p_k^2 - m^2$ that cancel these poles. It is then shown that it can be restricted as a distribution to the mass-shell of any physical process with $m$ initial and $n$ final particles, with $m + n = N$, and that this restriction coincides with the collision amplitude of the process. A process is here characterized by fixing the initial and final indices.

The analyticity properties of interest (described below) will apply to the connected functions after factoring out their global e.m.c. delta functions.

### The Analytic *N*-point Functions

The Wightman axioms (without so far AC) yield general analyticity, as also asymptotic causality, properties that we now describe. The analysis is essentially based on the interplay of support properties in $x$-space arising from local commutativity and the definition of chronological operators, and support properties in $p$-space due to the spectral condition. Support properties in $x$-space apply to cell and more general "paracell" functions which are VEVs of adequate combinations of products of "partial" chronological operators. It is shown that each such function has support in $x$-space in a closed cone $C_S$ (with apex at the origin). Moreover, for cell functions, the cone $C_S$ is convex and salient. Hence, in view of the usual Laplace transform theorem, the cell function in $p$-space (after Fourier transformation) is the boundary value of a function analytic in complex space in the tube $\mathrm{Re}\, p$ arbitrary, $\mathrm{Im}\, p$ in the open dual cone $\tilde{C}_S$ of $C_S$. It is also shown that, near any real point $P = (P_1, \ldots, P_N)$, the chronological function in $p$-space coincides with one or more cell functions.

Together with support properties in $p$-space arising from the spectral condition and the use of coincidence relations between some cell functions (in adequate real regions in $p$-space), one then shows the existence, for each $N$, of a well-defined, unique analytic function $F_N$, called the "analytic $N$-point function," whose domain of analyticity, the "primitive domain of analyticity," in complex $p$-space contains all the tubes $\mathcal{T}_S$ associated with the cell functions. It also contains in particular a complex neighborhood of the Euclidean energy–momentum space which consists of energy momenta $P_k$ with real $\boldsymbol{P}_k$ and imaginary energies $(P_k)_0$. Moreover, the chronological function $\tilde{T}_N^{\mathrm{amp,c}}$ is the boundary value of $F_N$ at all real points $P$, from imaginary directions which include those of the convex envelope of the cones $\tilde{C}_S$ associated with cell functions that coincide locally with $\tilde{T}_N^{\mathrm{amp,c}}$.

However, the primitive domain has an empty intersection with the complex mass-shell, and thus gives no result on analyticity properties of collision amplitudes on the (real or complex) mass-shell. For $N = 4$, it has been possible to largely extend the primitive domain (which is not a "natural domain of holomorphy") by computing (parts of) its holomorphy envelope, which now has a nonempty intersection with the complex mass shell. It is shown in turn that the four-point function $F_4$ can be restricted to the complex mass-shell in a one-sheeted domain, called the "physical sheet," that admits each (real) physical region on its boundary (there is here one physical region for each choice of the two initial and the two final indices, the corresponding physical regions being disconnected from each other). In each physical region, the collision amplitude is the boundary value of the mass-shell restriction of $F_4$, from the corresponding half-space of "$+\mathrm{i}\varepsilon$" directions $\mathrm{Im}\ s > 0$, where $s$ is the (squared) energy of the process.

The analyticity domain on the complex mass-shell contains paths of analytic continuation between the various physical regions (“crossing property”) and admits cuts $s_{ij}$ real $\geq (2m)^2$ covering the various physical regions. From these analyticity properties in the physical sheet, one can also derive “dispersion relations” (*see* Dispersion Relations).

#### Asymptotic causality and analyticity properties for $N \geq 4$

No similar result has been achieved at $N > 4$, and as a matter of fact, no similar result is expected if the AC condition is not assumed. The best results achieved so far are decompositions of the collision amplitude, in various parts of its physical region, as a sum of boundary values of functions analytic in domains of the complex mass-shell. In contrast to the case $N = 4$, the sum reduces to one term only in a certain subset of the physical region. Near other points, the $N$-point analytic function cannot be restricted locally to the complex mass-shell, though it can be decomposed as a sum of terms which, individually, are locally analytic in a larger domain that intersects the complex mass-shell.

These analyticity properties for $N \geq 4$ are a direct consequence of (and equivalent to) an asymptotic causality property that we now outline. Let $f_{k,\tau}(p)$ be, for each index $k$, a test function of the form

$$f_{k,\tau}(p) = \mathrm{e}^{\mathrm{i}p.\tau u_k}\, \mathrm{e}^{-\gamma\tau|p_k - P_k|^2}$$

where each $u_k$ is a point in spacetime, $P_k$ is a given on-shell energy–momentum, and $\tau$ will be a spacetime dilatation parameter ($\gamma > 0$). It is well localized in $p$-space around the point $P_k$ and its Fourier transform is well localized in $x$-space around the point $\tau u_k$ up to an exponential fall-off of width $\sqrt{\gamma\tau}$ which is small compared to $\tau$ as $\tau \to \infty$.

We now consider the action of the (connected, amputated) chronological function on such test functions. A configuration $u = (u_1, \ldots, u_N)$ will be called “noncausal” at $P = (P_1, \ldots, P_N)$ if this action decays exponentially as $\tau \to \infty$. In mathematical terms, $u$ is then outside the “essential support” or “microsupport” at $P$. The asymptotic causality property established, has roughly the following content: the only possible causal configurations $u$ at $P$ are those for which energy–momentum can be transferred from the initial to the final points in future cones. Moreover, at least two initial “extremal” points must coincide, as also two extremal final points. The simplest example is the case $N = 4$; if, for example, indices 1,2 are initial and $3, 4$ final, then the only *a priori* possible causal situations are such that $u_3 = u_4$ is in the future cone of $u_1 = u_2$ (in this particular case Lorentz invariance implies that $u_3 - u_1$ must be proportional to $P_3 + P_4$). In more general cases, the possible causal configurations $u$ depend on $P$.

## AC and Analyticity

### Asymptotic Causality in Terms of Particles and Landau Singularities

As a matter of fact, a better causality property “in terms of particles” – which is the best possible one – is expected for “physically reasonable” theories if the (stable) particles of the theory are known. (By physically reasonable, we mean the absence of “à la Martin” pathologies such as the occurrence of an infinite number of unstable particles with arbitrary long lifetime). That property expresses the idea that the only causal configurations $u$ at $P$ are those for which the energy–momentum can be transferred from the initial to the final points via intermediate stable particles in accordance with classical laws: there should exist a classical connected multiple scattering diagram in spacetime joining the initial and final points $u_k$, with physical on-shell energy–momenta for each intermediate particle and energy–momentum conservation at each (pointwise) interaction vertex.

This property, if it holds, yields in turn (and is equivalent to) improved analyticity of the analytic $N$-point function near real physical regions: the (on-shell) collision amplitude is the boundary value of a unique analytic function in its physical region, at least away from some “exceptional points.” The boundary value (namely the collision amplitude) is moreover analytic outside Landau surfaces $L_+(\Gamma)$ of connected multiple scattering graphs $\Gamma$; and along these surfaces (which are in general smooth codimension-1 surfaces), it is in general obtained from well-specified “$+\mathrm{i}\varepsilon$” directions (that depend in general on the real point $P$ of $L_+$).

Exceptional points are those that lie at the intersection of two (or several) surfaces $L_+(\Gamma_1)$, $L_+(\Gamma_2) \ldots$, with opposite causal directions, and hence having no $+\mathrm{i}\varepsilon$ directions in common (in the on-shell framework). Such points do not occur at $N = 4$ for two-body processes, in which case the surfaces $L_+$ are the $n$-particle thresholds $s = (nm)^2$, with $n \geq 2, s = (p_1 + p_2)^2$. They do occur more generally: in a $3 \to 3$ process, 1,2,3 initial, 4,5,6 final, this is the case of all points $P$ such that $-P_1 = P_4$, $-P_2 = P_5$, $-P_3 = P_6$ which all belong to the Landau surfaces of the two graphs $\Gamma_1, \Gamma_2$, with only one internal line joining two interaction

vertices: in the case of $\Gamma_1$, (resp., $\Gamma_2$), the first vertex involves the external particles 1, 2, 4 (resp., 1, 3, 5), while the second one involves 3, 5, 6 (resp., 2, 4, 6). If moreover $P_1, P_2, P_3$ lie in a common plane, previous points $P$ also lie on surfaces $L_+$ of "triangle" graphs with again opposite causal directions at $P$. The fact that $+i\epsilon$ directions are opposite can equally be checked for the corresponding Feynman integrals of perturbative field theory.

**Remark** The above points are no longer exceptional in spacetime dimension 2. In fact, all surfaces $L_+$ mentioned then coincide with the (on-shell) codimension-1 surface $-p_1 = p_4, -p_2 = p_5, -p_3 = p_6$, with two opposite causal directions. The previous asymptotic causality property, together with a further "causal factorization" property for causal configurations, then yields along that surface an actual factorization of the three-body (nonconnected) $S$-matrix into a product of two-body scattering functions modulo an analytic background. The latter vanishes outside the surface, hence is identically zero, for some special two-dimensional models.

In the absence of the AC condition, one clearly sees why the above causality in terms of particles cannot be established: as we have seen, there is *a priori* no control on the stable particles of the theory and on their masses, and pathologies such as those mentioned above cannot be excluded. Hopefully, the first problem should be solved if AC is assumed, and the second one should be removed by adequate regularity assumptions. This is the purpose of the so-called axiomatic nonlinear program, in which one also wishes to examine further problems, for example, analytic continuation into unphysical sheets, with the occurrence of possible unstable particle poles and other singularities, nature of singularities, possible multiparticle dispersion relations, . . . , to cite only a few. Results so far remain limited but provide a first insight into such problems.

### The Nonlinear Axiomatic Program

Results described below are based on discontinuity formulas arising from – and essentially equivalent in adequate energy regions to – AC, together with some regularity conditions. They can be established either with or without the introduction of adequate "irreducible" kernels. The methods rely on some general preliminary results on Fredholm theory in complex space (and with complex parameters). Irreducible kernels are defined through integral (Fredholm type) equations, first in the Euclidean region (imaginary energies) and then by local distortions of integration contours allowing one to reach the Minkowskian region. From discontinuity formulas and algebraic arguments, these irreducible kernels are shown to have analyticity (or meromorphy) properties associated with the physical idea of irreducibility (see examples below).

Results obtained so far with or without irreducible kernels are comparable in the simplest cases. However, the method based on irreducible kernels gives more refined results and seems best adapted to "extricate" the analytic structure of $N$-point functions for $N > 4$.

### $N = 4$, Two-Body Processes in the Low-Energy Region

By even theory, we mean theories in which $N$-point function vanishes identically for $N$ odd.

Standard results on two-body processes with initial (resp., final) energy–momenta $p_1, p_2$ (resp., $p'_1, p'_2$) in the low-energy region $(2m)^2 \leq s < (3m)^2$ ($s = (p_1 + p_2)^2 = (p'_1 + p'_2)^2$) are based on the "off-shell unitarity equation"

$$F_+ - F_- = F_+ \star F_- \qquad [1]$$

where $F_+(p_1, p_2; p'_1, p'_2)$ and $F_-(p_1, p_2; p'_1, p'_2)$ denote, respectively, the $+i\varepsilon$ and $-i\varepsilon$ boundary values of the four-point function $F_4$ from above or below the cut $s \geq (2m)^2$ in the physical sheet, and $\star$ denotes on-shell convolution over two intermediate energy–momenta. This relation is a direct consequence of AC for $s$ less than $(3m)^2$, or less than $(4m)^2$ in an even theory. When the four external energy–momentum vectors $p_1$, $p_2$, $p'_1$, $p'_2$ are put on the mass shell (on both sides of that relation), one recovers the usual elastic unitarity relation for the collision amplitude $T_+$ and its complex conjugate $T_-$:

$$T_+ - T_- = T_+ \star T_-$$

In the exploitation of these relations outlined below, a regularity condition is moreover needed, for example, the continuity of $F_+$ in the low-energy region.

By considering the unitarity equation as a Fredholm equation for $T_+$ at fixed $s$ (in the complex mass shell), one obtains the following result: $T_+$ can be analytically continued as a meromorphic function of $s$ through the cut (in the low-energy region) in a two-sheeted ($d$ even) or multisheeted ($d$ odd) domain around the two-particle threshold. Possible poles in the second sheet (generated by Fredholm theory) will correspond physically to unstable particles. The singularity at the two-particle threshold is of the square-root type in $s$ for $d$ even, or in

$1/\log s$ for $d$ odd. The difference between the two cases is due to the power $(d-1)/2$ of $s$, integer or half-integer, in the kinematical factor arising from on-shell convolution. This result can also be extended to the off-shell function $F_4$ by applying a further argument of analytic continuation making use of the off-shell unitarity equation.

Restricting now our attention to an even theory (for simplicity), a similar result also follows from the introduction of a two 2PI BS type kernel $G$ satisfying (and here defined from $F$ through) a regularized BS equation of the form

$$F = G + F \circ_M G \qquad [2]$$

where $\circ_M$ denotes convolution over two intermediate energy–momenta with two-point functions on the internal lines and a regularization factor in order to avoid convergence problems at infinity ($G$ then depends on the choice of this factor but its properties and the subsequent analysis do not). Alternatively, one may also introduce a kernel satisfying a renormalized BS equation, but this is not useful for present purposes.

Starting from the above discontinuity formula [1], one shows in turn that $G$ is indeed "2PI" in the analytic sense:

$$G_+ = G_- \qquad [3]$$

in the low-energy region. More precisely, $G$ is analytic or meromorphic (with poles that may arise from Fredholm theory) in a domain that includes the two-particle threshold $s=(2m)^2$, in contrast to $F$ itself.

The proof of [3] is based on the relation independent of $M$ (and thus leaving the $M$ dependence implicit).

$$\circ_+ - \circ_- = \star \qquad [4]$$

(which is a nontrivial adaptation of the decomposition of a mass-shell delta function as a sum of plus and minus i$\varepsilon$ poles). A simple algebraic argument then shows essentially the equivalence between the discontinuity formulas [1] and [3].

In turn, assuming that $G$ has no poles, this analyticity allows one to recover the two-sheetedness ($d$ even) or multisheetedness ($d$ odd, singularity in $1/\log$) of $F$, in view of the BS type equation.

### $N=6$, 3–3 Process in the Low-Energy Region (Even Theory)

The result, in the neighborhood of the 3–3 physical region, is here a "structure equation" expressing the 3–3 function $F$ in the low-energy region as a sum of "à la Feynman contributions" associated with graphs with one internal line and with triangle graphs, with two-point functions on internal lines and four-point functions at each vertex, plus a remainder $R$. The latter is shown to be a boundary value from $+\mathrm{i}\varepsilon$ directions Im $s$ positive, where $s=(p_1+p_2+p_3)^2, p_1, p_2, p_3$ denoting the energy–momentum vectors of the initial particles. Further regularity conditions are needed to recover its local physical region analyticity. The various explicit contributions that we have just mentioned yield the actual physical region Landau singularities expected in the low-energy 3–3 physical region.

A more refined result, in the approach based on irreducible kernels outlined below, applies in a larger region and then includes further à la Feynman contributions associated with 2-loop and 3-loop diagrams (the latter do not contribute to "effective" singularities in the neighborhood of the physical region).

The first result can be established from discontinuity formulas for the three-point function around two-particle thresholds, arising from AC, and "microsupport" analysis of all terms involved. In the approach based on irreducible kernels, it is useful to introduce in particular a 3PI kernel $G_3$ that, in contrast to the 3–3 function, will be analytic or meromorphic in a domain including the three-particle threshold. To that purpose, an adequate set of integral equations is introduced and the three-particle irreducibility of $G_3$ in "the analytic sense" is then established. In turn it provides the complete structure equation mentioned above.

### More General Analysis

There are so far only preliminary steps in more general situations, in view of (difficult) technical problems involved and the need of *ad hoc* regularity assumption at each stage. As already mentioned, the approach based on irreducible kernels seems best adapted. The analysis should clearly involve more general irreducible kernels with various irreducibility properties with respect to various channels (and not only with respect to the basic channel considered such as the 3–3 channel in the case above). From a heuristic viewpoint, one may first consider to that purpose adequate formal expansions into (infinite) sums of "à la Feynman contributions" adapted to the energy regions under investigation. These à la Feynman contributions will involve adequate irreducible kernels in the graphical sense at each vertex, and the above expansions correspond formally to the best possible regroupings of Feynman integrals with respect to the energy region considered. From such expansions, one might

determine adequate sets of integral equations allowing one, together with regularity assumptions, to carry out an analysis similar to above.

## The Models

A Euclidean field-theoretical model can be defined by a probability measure $d\mu(\varphi)$ on the space of tempered distributions $\varphi$ in Euclidean spacetime, whose moments verify the Osterwalder–Schrader (or similar) axioms. The moments of $d\mu$ are, for each $N$, the Euclidean (Schwinger) $N$-point functions:

$$S(x_1, \ldots, x_N) = \int \varphi(x_1) \cdots \varphi(x_N)\, d\mu(\varphi) \qquad [5]$$

In what follows, the measure $d\mu$ will be a perturbed Gaussian measure which, for the massive $\varphi^4$ model with a volume cutoff $\Lambda$ and an ultraviolet cutoff $\rho$, is given in $d$ dimensions by

$$d\mu_{\Lambda,\rho} = e^{-\lambda(\rho)\int_\Lambda \varphi^4(z)\,dz + a(\rho)\int_\Lambda \varphi^2(z)dz}\, d\nu_\rho(\varphi)/Z_{\Lambda,\rho} \qquad [6]$$

where $Z_{\Lambda,\rho}$ is the normalization factor and where $d\nu_\rho(\varphi)$ is the Gaussian measure of mean zero ($\int \varphi\, d\nu = 0$) and covariance

$$C(x-y;\rho) = \int d^d p\, e^{ip(x-y)}\, e^{-p^2/\rho^2}/(\zeta(\rho)p^2 + m^2)$$

where by convention $m$ is called the bare mass.

For $d = 2$ or 3 one can show that, for $\lambda(\rho) = \lambda$ small enough (depending on $m$) and $\zeta(\rho) = 1$, there exists a function $a(\rho)$ ($a(\rho) = O(\lambda)$ as $\lambda \to 0$) such that, for any set of $N$ distinct points, the function $S(x_1, \ldots, x_N) = \lim_{\Lambda,\rho\to\infty} S_{\Lambda,\rho}(x_1, \ldots, x_N)$ exists, is not Gaussian (hence does not correspond to a trivial, free theory), and satisfies the Osterwalder–Schrader axioms. The connected part $S(x_1, \ldots, x_N)_{\text{connected}}$ has the following perturbative series:

$$\lim_{\Lambda,\rho\to\infty} \sum_n \frac{(-1)^n}{n!} \int \varphi(x_1) \ldots \varphi(x_N) \times \left[\int_\Lambda [\lambda\varphi^4 - a(\rho)\varphi^2](z)\, dz\right]^n d\nu_{\Lambda,\rho}(\varphi)\big|_{\text{connected}} \qquad [7]$$

which is the (divergent) sum of the connected renormalized (Euclidean) Feynman graphs.

The study of the perturbative series leads to the distinction of:

1. the super-renormalizable theories, where it is possible to take $\lambda(\rho), \zeta(\rho)$ not depending on $\rho$. In dimension 2, all the models where $\lambda\varphi^4$ is replaced by

$$c_{2p}\varphi^{2p} + c_{2p-1}\varphi^{2p-1} + \cdots + c_5\varphi^5 + \lambda\varphi^4 + c_3\varphi^3 \qquad [8]$$

   also exist provided that $c_{2p} > 0$ is small enough depending on $m$ and on the other coefficient $c$'s and $\lambda$, and
2. the just renormalizable theories where $\lambda(\rho)$ (and possibly $\zeta(\rho)$) depend in general on $\rho$. In models mentioned below $\lambda(\rho) \to 0$ as $\rho \to \infty$; this characterizes "asymptotic freedom."

The proof of the existence of the $N$-point functions makes use of Taylor type expansions with remainder. The first orders are used to compute $\lambda(\rho), \zeta(\rho), a(\rho)$. The idea is to consider the functional integral [5] – at $\Lambda, \rho$ finite – as an integral over roughly $\Lambda\rho^d$ "degrees of freedom" which are weakly coupled. This corresponds to a decomposition of the phase space (with cutoff both in $x$-space (the box $\Lambda$) and in $p$-space (roughly $|p| < \rho$)). The coupling between different regions in $x$-space comes from the propagators $C_\rho$; the coupling between different frequencies in $p$-space comes from the $\varphi^4$ term (the interaction vertex). The expansion is then, for each degree of freedom, a finite expansion in the coupling between this degree and the others so that, even if the expansion is perturbative up to the order $\Lambda\rho^d$, the bound on each term is qualitatively the one on a product of $\Lambda\rho^d$ finite order-independent expansions, the order of which can be fixed uniformly in $\rho$ (and depending only on $\lambda$). To achieve this program, the propagator linking two points of distance of order $L$ must have a decrease of order $e^{-L^{-1}|x-y|}$, that is, have momentum larger than $L^{-1}$, so that one must localize both in $x$-space and $p$-space ; for example, the smallest cells of phase space correspond to fields $\varphi$ localized in $x$, $p$-spaces, the $x$-boxes being of side $\rho^{-1}$ and the $p$-localization consisting of values such that roughly $(\rho/2) \le |p| \le \rho$. More generally, a generic cell (of index i) corresponds to fields $\varphi$ at point $x$ and momentum $p$, with $x$ in a box of side $2^i\rho^{-1}$ and $2^{-i-1}\rho < |p| < 2^{-i}\rho$.

These expansions are mimicking the à la Wilson renormalization group. For just renormalizable theories (where $\lambda(\rho)$ depends on $\rho$), one is led to introduce the effective coupling constant $\lambda(2^{-i}\rho)$ whose perturbative expansion is the value at momentum zero of the sum of all the (connected, amputated) four-point functions containing only propagators of momentum (roughly) bigger than $2^{-i}\rho$ (plus $\lambda(\rho)$ which in fact tends to zero as $\rho \to \infty$).

Then by small coupling we mean a theory where $\lambda(2^{-i}\rho)/\zeta(2^{-i}\rho)^2$ is small for all $i$.

By convention we write $\lambda_{\text{ren}}, \zeta_{\text{ren}}, a_{\text{ren}}$ for the effective parameters of the theory at zero momentum.

The expansion obtained expresses $S_{\text{connected}}$ as a sum of terms each of them being associated to a

given set of phase-space cells which are "connected" together by "links" that are either propagators or vertices. Each term decreases exponentially with the difference $i_{\max} - i_{\min}$ of the upper and lower indices of the phase-space cells involved. Moreover, each set must contain the cells associated to the fields $\varphi(x_1)\cdots\varphi(x_N)$ whose indices are fixed by the order of magnitude of the distances between the points. On the other hand, the difference between the theory of cutoff $\rho$ and the one of cutoff $2\rho$ are terms containing at least one cell of momentum of order $\rho$; these terms are thus small like $\mathrm{cst}(x_1,\ldots,x_N)\mathrm{e}^{-(\mathrm{cst})\rho}$, so that the limit as $\rho\to\infty$ exists.

So far, the "construction" of models is possible only at small coupling, apart from special cases. The $\varphi^4$ theory in dimension 4 is just renormalizable (from the perturbative viewpoint) but the above condition of small coupling cannot be achieved (and it is generally believed that this model cannot be defined as a nontrivial theory). A just renormalizable model has been shown to exist, namely the Gross–Neveu model which is a fermionic theory in dimension 2. The elementary particle physics models are just renormalizable but their construction has not been completed so far (in particular in view of the confinement problem). *See* Constructive Quantum Field Theory for details.

To state the result in a form convenient for our purposes here, we introduce a splitting of the covariance in two parts:

$$C(x-y;\rho) = C_M(x-y;\rho) + C_{>M}(x-y;\rho), \quad M > m$$
$$\tilde{C}_M(p;\rho) = (\mathrm{e}^{-p^2/\rho^2}/p^2 + m^2) - (\mathrm{e}^{-p^2/\rho^2}/p^2 + M^2)$$

so that $C_M(x-y)$ behaves like $C$ at large distances but has an ultraviolet cutoff of size $M$, and $|C_{>M}(x-y)| \le \mathrm{e}^{-M|x-y|}$ decreases exponentially depending on the (technical) choice of $M$. Let $\mathrm{d}\nu_M(\varphi)$ be the Gaussian measure of covariance $C_M$.

One divides also $\Lambda$ in unit cubes and obtains for the connected $N$-point function an expansion as a sum over connected trees; a tree $T$ is composed of lines $\ell$ and vertices $v$; each line joins two vertices or one of the external points $x_1,\ldots,x_N$ and a vertex; moreover, there are no loops.

To each line $\ell$ is associated a propagator $C_M(z_\ell, z'_\ell) = C_M(\ell)$.

To each vertex $v$ are associated:

1. two subsets $I_v, I'_v$ of $\{\ell\}$,
2. a connected set $X_v$ of unit cubes such that all the $z_\ell, \ell\in I_v$ and all the $z'_\ell, \ell \in I'_v$ are contained in $X_v$; $|X_v|$ is the volume of $X_v$, and
3. a kernel $K_{X_v}(\{z,z'\}_v;\varphi)$

Finally, the external points are by convention $z_\ell$ points; then:

$$\begin{aligned}&S_{\Lambda,\rho}(x_1,\ldots,x_N)_{\text{connected}}\\&\quad= \int \mathrm{d}\nu_M(\varphi)\sum_T \frac{1}{|T|!}\sum_{\substack{\{X_v\}\\ \text{nonoverlapping}}}\\&\qquad\times\int\Bigg[\prod_{\substack{\ell\\ z_\ell \text{ not external}}}\mathrm{d}z_\ell\Bigg]\Bigg[\prod_{\ell\in T}\mathrm{d}z'_\ell C_M(\ell)\Bigg]\\&\qquad\times\prod_{v\in T}K_{X_v}(\{z,z'\}_v;\varphi)\end{aligned} \qquad [9]$$

where for coupling small enough:

$$\int \mathrm{d}\nu_M(\varphi)\prod_{v\in T}|K_{X_v}(\{z,z'\}_v;\varphi)| \le \prod_{v\in T}\mathrm{e}^{-M(1-\epsilon)|X_v|} \qquad [10]$$

The $X$'s are $2\times 2$ nonoverlapping; however, it will suffice to sum over all $X$'s (without restriction) to get a bound showing the convergence of the expansion as $\Lambda\to\infty$. In this formula the $K(.,\varphi)$'s are still coupled by the measure $\mathrm{d}\nu_M(\varphi)$; all the nonperturbativity is hidden in the $K$'s (in particular the contribution of momentum bigger than $M$).

As a consequence of [9] and if $a(\rho,\lambda)$ has been chosen such that $a_{\text{ren}} = 0$, for $M$ large enough and at small coupling (depending on $M$, $m$):

$$\begin{aligned}&|S(x,y)_{\text{connected}}|\\&\quad\le |C_M(x-y)| + \int \mathrm{d}z'_1\mathrm{d}z'_2|C_M(x-z'_1)\\&\qquad\times \mathrm{e}^{-M(1-\epsilon)|z'_1-z'_2|}C_M(z'_2-y)| + \cdots\\&\quad\le (\mathrm{cst})\mathrm{e}^{-m(1-\epsilon)|x-y|}\end{aligned} \qquad [11]$$

More generally, the connected $N$-point function satisfies

$$|S(x_1,\ldots,x_N)_{\text{connected}}| \le \mathrm{cst}\ \mathrm{e}^{-m(1-\epsilon)d(x_1,\ldots,x_N)} \qquad [12]$$

where $d(x_1,\ldots,x_N)$ is the length of the smallest tree joining $x_1,\ldots,x_N$, with possibly intermediate points.

## The Irreducible Kernels

### The 1PI Kernel and a Lippmann–Schwinger Equation

To then show that a theory – if the perturbation series heuristically shows it – contains only one particle of mass smaller than $2m(1-\epsilon)$, it is necessary to expand further the coupling between the $K$'s in [9]. Each perturbative step relatively to this coupling will generate a sum of terms such that in each one there is a "new" propagator $C_M$ between two $K$'s.

The fact that in [9] the $X$'s are nonoverlapping has the consequence that an expansion where for each pair of $K_X$ the number of propagators $C_M$

remains bounded (say by $n+1$) is convergent (for small enough couplings depending on $m$, $n$); this is because, for a given $X$, the others must be farther and farther as their number increases, and in view of the exponential decrease (in $x$-space) of $C_M$.

We then consider the expansion where we have further expanded the two-point function $S(x,y)$ such that each term can be decomposed in the channel $x \to y$ in $C_M$ propagators and 1PI contributions (in the sense that any line cutting such a 1PI contribution (and outside the $X's$) cuts at least two propagators); that means that these 1PI contributions are no longer coupled by the $d\nu_M(\varphi)$ measure. They are made of propagators and of $K_X$ which still have nonoverlapping restrictions; the latter are straightforwardly expanded using a kind of (convergent) Mayer expansion; the result is finally a Lippmann–Schwinger type equation:

$$S(x,y)_{\text{connected}} = C_M(x-y) + \int dz_1\, dz_2\, C_M(x-z_1) \times G_1(z_1,z_2)\, C_M(z_2-y) + \cdots \qquad [13]$$

or

$$S(x,y)_{\text{connected}} = \left[ C_M \sum_{p\geq 0} [G_1 C_M]^p \right](x,y)$$

which is equivalent to

$$S_{\text{connected}} = C_M + C_M G_1 C_M + C_M G_1 S_{\text{connected}} \qquad [14]$$

where $G_1$ is a 1PI kernel that satisfies the bound

$$|G_1(t,u)| \leq \lambda_{\text{ren}} e^{-2m(1-\epsilon)|t-u|} \qquad [15]$$

In Fourier transform, eqn [14] becomes

$$F(p) = \tilde{C}_M(p) + \tilde{C}_M(p)\tilde{G}_1(p)\tilde{C}_M(p) + \tilde{C}_M(p) G_1(p) F(p) \qquad [16]$$

Denoting by $\delta(p+q)\, F(p,q)$ the Fourier transform of $S(x,y)_{\text{connected}}$, we can then compute $F(p)$:

$$F(p) = \frac{(p^2+m^2)[\tilde{C}_M + \tilde{C}_M \tilde{G}_1](p)}{(p^2+m^2) - (p^2+m^2)\tilde{C}_M \tilde{G}_1(p)} \qquad [17]$$

where $(p^2+m^2)\tilde{C}_M(p) \to (1-m^2/M^2)$ as $p\to 0$ and $|\tilde{G}_1(p)| \leq \lambda_{\text{ren}}\, \text{cst}(m)$ so that (as expected) $F$ has no pole in the Euclidean region at small coupling; but, as will be seen in the next section, it has a pole outside the Euclidean region.

### The 2PI Kernel and a BS Equation

From the previous discussion, it is clear that one can extract from [9] as many propagators as we want between kernels $K_X$. If one considers a splitting of the external points in incoming $x_1,\ldots,x_p$ and outgoing $x_{p+1},\ldots,x_N$ points, this defines a channel. One then obtains $n$PI kernels (in the given channel). In the same way as above, one obtains a relevant structure equation; this equation makes sense only if the kernels $K_X$ have a decrease corresponding to $n$-particle irreducibility; to that purpose we take $M > nm$. The expansion converges for couplings small enough depending on $m$ and $n$.

In the case $n=2$ this gives a kind of BS equation (the Lippmann–Schwinger equation corresponding to the case $n=1$); if we restrict, for simplicity, the analysis to even theories one is led to jump directly to the case $n=3$:

$$S(x_1,x_2;x_3,x_4)_{\text{connected}} = \int dz_1\, dt_1\, dz_2\, dt_2 (\circ_M)(x_1,x_2;z_1,t_1) \times G_2(z_1,t_1;z_2,t_2)(\circ_M)(z_2,t_2;x_3,x_4) + \cdots \qquad [18]$$

$$S = \circ_M \sum_{p\geq 1} [G_2 \circ_M]^p$$

or

$$S = \circ_M G_2 \circ_M + \circ_M G_2 S \qquad [19]$$

where

$$(\circ_M)(x_1,x_2;x_3,x_4) = S(x_1,x_3)S(x_2,x_4) + S(x_1,x_4)S(x_2,x_3)$$

and where

$$|G_2(t_1,t_2;u_1,u_2)| \leq \lambda_{\text{ren}} \exp\{-4m(1-\epsilon)\max_{i,j}(|t_i-u_j|)\} \qquad [20]$$

Equation [19] once amputated, and after Fourier transformation, is eqn [2].

### More General Irreducible Kernels and Structure Equations

Irreducible kernels with various degrees of irreducibility in various channels can be defined in a similar way. Corresponding expansions of $N$-point functions follow, in terms of integrals involving these kernels and two-point functions. These kernels are again convergent at small coupling ($\to 0$ as their irreducibility $\to \infty$) as well as the corresponding structure equations (which generalize eqn [18]).

## Analyticity, AC, and Bound States

As explained in the introduction, we now proceed by analytic continuation away from the Euclidean region in complex energy–momentum space.

First, it is easily seen that the two-point function is analytic in the region $s < (2m)^2 - \epsilon$ apart from a pole at $s = m_{\text{ph}}^2$ which defines the physical mass $m_{\text{ph}}$ ($m_{\text{ph}}^2$ is the zero in $p^2$ of the denominator in formula [17]). In view of the bounds of the previous two sections, $m_{\text{ph}}$ is close to the "bare" mass $m$.

The 2PI kernel, for even theories, is shown, again by Laplace transform theorem, to be analytic and bounded in domains around and away from the Euclidean region up to $s = (4m)^2 - \epsilon$, and is of the order of $\lambda_{\text{ren}}$.

As we have seen in the section "AC and analyticity," the analyticity of $G_2$ entails the analytic structure of $F$ (two-sheeted or multisheeted at the threshold). On the other hand, further poles of $F$ can be generated by the BS integral equation [2] in the physical or unphysical sheets. If a pole in the physical sheet occurs at $s < (2m_{\text{ph}})^2$ real, it will correspond to a new particle in the theory, namely a two-particle bound state.

### AC in the Low-Energy Region

The analysis of possible bound states, which will be presented in the following, will show that there might be at most one two-particle bound state of mass $m_{\text{B}} < 2m_{\text{ph}}$ which tends to $2m_{\text{ph}}$ as the couplings tends to zero.

On the other hand, for even theories, in view of the analyticity properties of the two-point function and of the 2PI kernel $G_2$, equation [1] holds in the region $(2m_{\text{ph}}^2) < s < (4m_{\text{ph}})^2 - \epsilon$, where $*$ is on-shell convolution with particles of mass $m_{\text{ph}}$.

If there is no two-particle bound state, this characterizes the AC of the theory for $s < (4m_{\text{ph}})^2 - \epsilon$.

If there is a bound state of mass $m_{\text{B}}$, AC is established only in the region $s < (3m_{\text{ph}})^2 - \epsilon$.

For non-even theories, the analysis is similar but requires the introduction of new irreducible kernels in view of the fact that the non-evenness opens new channels. AC in all cases can be established, for small couplings, up to $s < (3m_{\text{ph}})^2 - \epsilon$.

### Analysis of Possible Two-Particle Bound States for Even Theories at Small Coupling

It can be checked that such poles of $F$, if there are, either lie far away in the unphysical sheet(s) or are close to the two-particle threshold ($s = (2m_{\text{ph}})^2$). This is due to the convergence, at small coupling, of the Neumann series $F = G_2 + G_2 \circ_M G_2 + \cdots$. Individual terms $G_2 \circ_M \cdots \circ_M G_2$ are, in fact, defined away from the Euclidean region by analytic continuation in a two-sheeted ($d$ even) or multisheeted ($d$ odd) domain around the threshold: to that purpose locally distorted integration contours (initially the Euclidean region) are introduced as in the section "AC and analyticity," so as to avoid the pole singularities of the two-point functions involved in $\circ_M$, the threshold singularities being due to the pinching of this contour between the two poles as $s \to (2m_{\text{ph}})^2$. If a fixed neighborhood of the threshold is excluded, one does obtain uniform bounds of the form (cst $\lambda_{\text{ren}})^q$ (for a term with $q$ factors $G_2$) in any bounded domain, which ensures the convergence of the Neumann series.

It remains to study the neighborhood of the threshold. To that purpose, the following method is convenient. One shows that the convolution operator $\circ_M$ can be written in the form

$$\circ_M = g(s) * + \nabla \qquad [21]$$

where $*$ is, as in the section "AC and analyticity," on-shell convolution for $s > (2m_{\text{ph}})^2$ or is obtained by analytic continuation for complex value of $s$ around the threshold; $g(s) = 1/2$ for $d$ even and, if $d$ is odd, $g(s) = (\text{i}/2\pi)\log\sigma$, where $\sigma = 4m_{\text{ph}}^2 - s$. In view of this definition of $g(s)$, the operator $\nabla$ is regular: it is an analytic one-sheeted operation around the threshold (this is equivalent to [4]), and it has no pole singularities. This property of $\nabla$ can be established by geometric methods or by an explicit evaluation.

It is then useful to introduce a new kernel $U$ linked to $G_2$ by the integral equation

$$U = G_2 + U \nabla G_2 \qquad [22]$$

In view of the regularity and bounds of $\nabla$ and $G_2$, one sees (e.g., by a series expansion) that $U$, like $G_2$, is analytic in a neighborhood of the threshold and behaves in the same way at small $\lambda_{\text{ren}}$.

By a simple algebraic argument $F$ and $U$ are related by the integral equations

$$F = U + g(s)U * F = U + g(s)F * U \qquad [23]$$

**Two-dimensional models** We start the analysis with the case $d = 2$. The mass shell is trivial in this case; let $f$ be the restriction of $F$ to the mass shell; it depends only on $s = (p_3 + p_4)^2$ due to the mass shell and e.m.c. constraints (as also Lorentz invariance). On the mass shell, the operation $*$ becomes a mere multiplication and the integral equation [23] becomes

$$f(s) = u(s) + \frac{1}{a(s)} f(s)u(s) \qquad [24]$$

where $u$ is the mass shell restriction of $U$ and the factor $a(s)$ arising from $*$ is of the form $a(s) = \text{cst}\ s^{1/2}\sigma^{1/2}, \sigma = (2m_{\text{ph}})^2 - s$, which gives

$$f(s) = \frac{a(s)u(s)}{a(s) - u(s)} \qquad [25]$$

In turn one obtains

$$F = U + \frac{U_| \, {}_|U}{a(s) - u(s)} \qquad [26]$$

where $U_|$ (resp., ${}_|U$) is $U$ with $p_3, p_4$ (resp., $p_1, p_2$) restricted to the mass shell. Equation [26] completely characterizes the local structure of $F$ in view of the local analyticity of $U$.

The analysis of the possible poles follows from the fact that $U$ is equal to $G_2$ up to higher order in $\lambda_{\rm ren}$; on the other hand, $G_2$ is equal to a first known term plus higher-order corrections in $\lambda_{\rm ren}$ (if we expand in $\lambda_{\rm ren}$ the expression for $G_2$ obtained in the previous section), so that the leading contribution of $u(s)$ is known and the results follow.

For a theory (see [8]) containing a $\lambda_{\rm ren}\varphi^4$ term there is exactly one pole, which corresponds to the zero of $a(s) - u(s)$, lying in the region $(2m_{\rm ph})^2 - \epsilon < s < (2m_{\rm ph})^2$. This pole is either in the physical sheet for $\lambda_{\rm ren} < 0$ or in the second sheet if $\lambda_{\rm ren} > 0$. In the case $\lambda_{\rm ren} < 0$, this pole corresponds to a two-particle bound state of physical mass $m_{\rm B}$ which tends to $2m_{\rm ph}$ as $\lambda_{\rm ren} \to 0$.

In a model without $\varphi^4$ term ($\lambda_{\rm ren} = 0$) the lowest-order contribution to $G_2$, hence to $U$, is in general of the order of the square of the leading coupling, in which case there is always one bound state.

The treatment of the fermionic Gross–Neveu model, which involves spin and color indices, is analogous, with minor modifications. Equations now involve, in the two-particle region, $4 \times 4$ matrices; poles of $F$ are now the zeros of $\det(a(s)I - m(s)u(s))$, where $m(s)$ is the $4 \times 4$ matrix obtained from $2 \times 2$ residue matrices (whose leading matrix elements are explicitly computable). The detailed analysis, which requires the consideration of different channels (various color and spin indices) is omitted.

**Three-dimensional models** The results are similar: $F$ is decomposed as $F' + F''$, where $F'$ is the $\ell = 0$ "partial wave component" of $F$, namely $F' = (1/2\pi) \int F \, d\theta$, where $\theta$ is the "scattering angle" of the channel; its complement $F''$ is shown to be locally bounded in view of a further factor $\sigma$. The analysis is then analogous to the case $d = 2$ with $a(s)$ now behaving like $\mathrm{cst}/\log\sigma$ as $\sigma \to 0$. There is, *a priori*, either no pole, or one pole in the physical sheet at $s = m_{\rm B}^2 < (2m_{\rm ph})^2$ with $m_{\rm B} = 2m_{\rm ph} + O(e^{-\mathrm{cst}/\lambda_{\rm ren}})$, depending again on the signs of the couplings. For the existing even models such as the $\varphi^4$ model, there is no pole, hence no two-particle bound state.

**Four-dimensional models** The existence of the $\varphi^4$ model in dimension 4 is doubtful. If a four-dimensional model were defined, and if the 2PI kernel $G_2$ of a massive channel could be defined and shown to satisfy analyticity properties analogous to above, there would be no two-particle bound state at small coupling. In fact, the kinematical factor $\sigma^{(d-3)/2}$ (for $d$ even) generated by the mass shell convolution is no longer equal to $\sigma^{-1/2}$ as in the $d = 2$ case but now to $\sigma^{1/2}$. As a consequence, the Neumann series giving $F$ in terms of $G_2$ is convergent also in the neighborhood of the two-particle threshold.

**Non-even theories** The analysis for the non-even theories follows similar lines. As already mentioned, the analysis requires the introduction of new irreducible kernels. For the models $\lambda\varphi^4 + c_3\varphi^3$, which do exist at small couplings in dimensions 2 and 3, there will be either exactly one or no two-particle bound state, depending on the respective values of $\lambda, c_3$.

### Structure Equations and AC in Higher-Energy Regions

The structure equations of the previous section provide, after analytical continuation away from the Euclidean region, a rigorous version of the analysis presented at the end of the section "AC and analyticity." The irreducible kernels can here be defined in a direct way following the previous section, together with their analyticity properties. One has then to derive the discontinuity formulas that in turn characterize AC. This program has been carried out in the $3 \to 3$ particle region, and partly in the general case. It seems possible to complete general proofs up to some technical (difficult) problems. As already mentioned, in this approach, the coupling should be taken smaller and smaller as the energy region considered increases.

# Schrödinger Operators

**V Bach**, Johannes Gutenberg-Universität, Mainz, Germany

Schrödinger operators are linear partial differential operators of the form

$$H_V = -\Delta + V(x) \qquad [1]$$

acting on a suitable dense domain $\mathrm{dom}(H_V) \subseteq L^2(\Omega)$ in the Hilbert space of square-integrable functions on a spatial domain $\Omega \subseteq \mathbb{R}^d$, where $d \in \mathbb{N}$. Here, $H_0 = -\Delta = -\sum_{\nu=1}^{d} \partial^2/\partial x_\nu^2$ is (minus) the Laplacian on $\Omega$, and the potential $V : \Omega \to \mathbb{R}$ acts as a multiplication operator, $[V\psi](x) := V(x)\psi(x)$.

## Historical Origin and Relation to Theoretical Physics

In 1926, Schrödinger formulated quantum theory as wave mechanics and proved later that it is equivalent to Heisenberg's matrix mechanics. He proposed that the state of a physical system at time $t \in \mathbb{R}$ is given by a normalized wave function $\psi_t \in L^2(\Omega)$ whose dynamics is determined by a linear Cauchy problem: $\psi_0$ is the state at time $t = 0$, and for $t > 0$, it evolves according to

$$\mathrm{i}\frac{\partial \psi_t}{\partial t} = H\,\psi_t \qquad [2]$$

the Schrödinger equation. More generally, $\psi_0$ is a normalized element of a Hilbert space $\mathcal{H}$, and the Hamiltonian $H_V$ is a self-adjoint operator, that is, $\mathrm{dom}(H_V) = \mathrm{dom}(H_V^*) \subseteq \mathcal{H}$ and $H_V = H_V^*$ on $\mathrm{dom}(H_V)$. Formally, eqn [2] is solved by the evolution operator or propagator $\exp(-\mathrm{i}tH_V)$ in the form $\psi_t = \exp(-\mathrm{i}tH_V)\psi_0$. The self-adjointness of $H_V$ insures the existence and unitarity of the propagator $\exp(-\mathrm{i}tH_V)$, for all $t \in \mathbb{R}$, so $\|\psi_t\| = \|\psi_0\| = 1$. For physics, this unitarity is crucial, because $\|\psi_t\|^2$ is interpreted as the total probability of the system to be at time $t$ in some state in $\mathcal{H}$. The general validity of eqn [2] as the fundamental dynamical law of all physical theories, including, for example, nonrelativistic and (special) relativistic quantum mechanics, quantum field theory, and string theory, deserves appreciation.

If the physical system under consideration is a nonrelativistic point particle of mass $m > 0$ in a potential $\widetilde{V} : \mathbb{R}^d \to \mathbb{R}$, then, according to the principles of classical (Newtonian) mechanics, its state is determined by its momentum $p \in \mathbb{R}^d$ and its position $x \in \mathbb{R}^d$, its kinetic energy is $(1/2m)p^2$, its potential energy is $\widetilde{V}(x)$, and the dynamics is given by the Hamiltonian flow generated by the Hamiltonian function $H_{\mathrm{class}}(p, x) = (1/2m)p^2 + \widetilde{V}(x)$. Schrödinger derived the Hamiltonian (operator) $H = -(\hbar^2/2m)\Delta + \widetilde{V}(x)$ in [2] from the replacement of the momentum $p \in \mathbb{R}^d$ by the momentum operator $-\mathrm{i}\hbar\nabla_x$. This prescription is called quantization and is further discussed in the section "Quantization and semiclassical limit." The Schrödinger operator $H_V$ in [1] is then obtained after an additional unitary rescaling, $\psi(x) \mapsto \mu^{d/2}\psi(\mu x)$, by $\mu := \hbar(2m)^{-1/2}$, and a redefinition $V(x) := \widetilde{V}(x/\mu)$ of the potential.

For more details, we refer the reader to Schrödinger (1926) and Messiah (1962).

## Self-Adjointness

Led by the requirement of unitarity of the propagator, the domain $\mathrm{dom}(H_V)$ in [1] is usually chosen such that $H_V$ is self-adjoint, which, in turn, is most often established by means of the Kato–Rellich perturbation theory, briefly described below. If $V \equiv 0$, then $H_0$ equals the Laplacian $-\Delta$, which is a positive self-adjoint operator, provided $\mathrm{dom}(H_0) = W^2_{\mathrm{b.c.}}(\Omega)$ is the second Sobolev space with suitable conditions on the boundary $\partial\Omega$ of $\Omega$. Typical examples are $\mathrm{dom}(H_0) = W^2(\mathbb{R}^d)$, for $\Omega = \mathbb{R}^d$, and $W^2_{\mathrm{Dir}}(\Omega)$ and $W^2_{\mathrm{Neu}}(\Omega)$ with Dirichlet or Neumann boundary conditions on $\partial\Omega$, respectively, in case that $\Omega$ is a bounded, open domain in

$\mathbb{R}^d$ with smooth boundary $\partial\Omega$. Starting from this situation, $V$ is required to be relatively $H_0$-bounded, that is, that $M(V,r) := V(-\Delta + r\mathbb{1})^{-1}$ defines (extends to) a bounded operator on $L^2(\Omega)$, for any $r > 0$. If $\lim_{r\to\infty} \|M(V,r)\| < 1$, then $H_V$ is self-adjoint on $\mathrm{dom}(H_0)$ and semibounded, that is, the infimum $\inf \sigma(H_V)$ of its spectrum $\sigma(H_V)$ is finite; in other words, $H_V \geq c\mathbb{1}$, for some $c \in \mathbb{R}$, as a quadratic form. (The semiboundedness corresponds to quasidissipativity, as a generator of the semigroup $\exp(-\beta H_V)$.)

A fairly large class of potentials fulfilling these requirements is defined by

$$\lim_{\alpha\searrow 0}\left\{\sup_{x\in\Omega}\int_{|x-y|\leq\alpha}|x-y|^{4-d}V(y)^2\,\mathrm{d}^d y\right\} = 0 \qquad [3]$$

for $d \neq 4$, and with $|x-y|^{4-d}$ replaced by $(\ln|x-y|)^{-1}$, for $d = 4$. For $d \leq 3$, [3] is equivalent to the uniform local square integrability of $V$, that is, $\sup_{x\in\Omega}\int_{|x-y|\leq 1} V(y)^2\,\mathrm{d}^d y < \infty$. Note that [3] allows for local singularities of $V$, provided they are not too severe; in this respect, quantum mechanics is more general than classical mechanics. Equation [3] is a sufficient condition for $H_V = -\Delta + V$ to be self-adjoint on $\mathrm{dom}(-\Delta)$ because $\lim_{r\to\infty}\|M(V,r)\| = 0$. Moreover, as eqn [3] only misses some borderline cases, it is also almost necessary for the self-adjointness of $H_V$. By means of Kato's inequality, the conditions on $V$, especially on its positive part $V_+ := \max\{V, 0\}$, can be further relaxed. Also, if one realizes $H_V$ as the Friedrichs extension of a semi-bounded quadratic form, the conditions to impose on $V$ are milder. One possibly loses, however, control over the operator domain $\mathrm{dom}(H_V)$, and typically $\mathrm{dom}(-\Delta)$ is only a core for $H_V$.

For further details on self-adjointness, we refer the reader to Reed and Simon (1980a, b), Kato (1976), and Cycon *et al.* (1987).

## Spectral Analysis

The self-adjointness of $H_V$ establishes a functional calculus, generalizing the notion of diagonalizability of finite-dimensional self-adjoint matrices: there exists a unitary transformation $W : L^2(\Omega) \to L^2(\sigma(H_V), \mathrm{d}\mu)$ such that $H_V$ acts on elements $\varphi$ of $L^2(\sigma(H_V), \mathrm{d}\mu_{H_V})$ as a multiplication operator, $[H_V\varphi](\omega) = \omega\varphi(\omega)$. The spectral measure $\mu_{H_V}$ decomposes into an absolutely continuous (ac) part $\mu_{H_V,\mathrm{ac}}$, a pure point (pp) part $\mu_{H_V,\mathrm{pp}}$, and a singular continuous (sc) part $\mu_{H_V,\mathrm{sc}}$, mutual disjointly supported on the ac spectrum $\sigma_{\mathrm{ac}}(H_V)$, the pp spectrum $\sigma_{\mathrm{pp}}(H_V)$, and the sc spectrum $\sigma_{\mathrm{sc}}(H_V) \subseteq \mathbb{R}$, respectively, whose union is the spectrum $\sigma(H_V)$ of $H_V$. There is an additional decomposition of the spectrum of $H_V$ into the discrete spectrum $\sigma_{\mathrm{disc}}(H_V)$, which consists of all isolated eigenvalues of $H_V$ of finite multiplicity, and its complement $\sigma_{\mathrm{ess}}(H_V) = \mathbb{R}\setminus\sigma_{\mathrm{disc}}(H_V)$, the essential spectrum of $H_V$, as its residual spectrum is void. One of the main goals of the spectral analysis is to determine the spectral measure for a given potential $V$ as precisely as possible.

In many applications, $\Omega = \mathbb{R}^d$ and the potential $V$ in $H_V$ is not only relatively $H_0$-bounded, but even relatively $H_0$-compact, that is, $M(V,1)$ is compact. In this case, $\lim_{r\to\infty}\|M(V,r)\| = 0$, insuring self-adjointness on $\mathrm{dom}(H_0)$ and semiboundedness of $H_V$. Moreover, a theorem of Weyl implies that its essential spectrum agrees with the one of $H_0$, that is, with the positive half-axis $\mathbb{R}_0^+$, and the discrete spectrum is contained in the negative half-axis $\mathbb{R}^-$. If, furthermore, $(H_0+1)^{-1}\,[x\cdot\nabla V(x)](H_0+1)^{-1}$ is compact, then the essential spectrum on the positive half-axis is purely absolutely continuous, $\sigma_{\mathrm{ess}}(H_V)\cap\mathbb{R}^+ = \sigma_{\mathrm{ac}}(H_V)\cap\mathbb{R}^+$, and hence $\sigma_{\mathrm{disc}}(H_V) \subseteq \sigma_{\mathrm{pp}}(H_V) \subseteq \sigma_{\mathrm{disc}}(H_V)\cup\{0\}$; the singular continuous spectrum is void.

We remark that the absence of singular continuous spectrum is not understood. Indeed, it is possible to explicitly construct potentials $V$ such that $H(V)$ has singular continuous spectrum. In terms of the Baire category, singular continuous spectrum is even typical. The appearance of singular continuous spectrum can, perhaps, be easier understood in terms of the dynamical properties of $\exp[-itH_V]$, rather than the spectral analysis of its generator $H_V$: Singular continuous spectrum occurs when initially localized states are not bound states, but move out to infinity very slowly.

The reader is referred to Simon (2000), Reed and Simon (1980a, b) and Cycon *et al.* (1987) for further detail.

## Properties of Eigenfunctions

Let us assume $\Omega = \mathbb{R}^d$, that $V \leq 0$ is nonpositive, fulfills [3], and that $\lim_{|x|\to\infty} V(x) = 0$. From the statements in the last section we conclude that $H_V = -\Delta + V(x)$ is semibounded, that the essential spectrum is the positive half-axis and that all eigenvalues are negative and of finite multiplicity, possibly accumulating only at 0. We collect some properties of the eigenfunctions $\psi_j \in L^2(\mathbb{R}^d)$ with corresponding eigenvalue $e_j < 0$, that is, $H_V\psi_j = e_j\psi_j$. The smallest eigenvalue $e_0 := \inf\sigma(H_V)$ (coinciding with the bottom of the spectrum) is simple, and the corresponding eigenfunction $\psi_0(x) > 0$ is strictly positive a.e. Elliptic regularity implies that at a given point $x \in \mathbb{R}^d$, the eigenfunction $\psi_j$ is almost $2 - d/2$ degrees more regular than $V$. For example,

if $V \in C^k[B_{2\epsilon}(x)]$, for some $\epsilon > 0$, then $\psi_j \in C^{k+\ell}[B_\varepsilon(x)]$, for all $\ell < 2 - d/2$. Agmon estimates (originally obtained by S'nol and also known in mathematical physics as Combes–Thomas argument) furthermore show that, for unbounded $\Omega$, the eigenfunction $\psi_j$ decays exponentially: $|\psi_j(x)| \leq C_\alpha e^{-\alpha|x|}$, for any $0 < \alpha < e_j$.

For more details, see Reed and Simon (1978, 1980a, b) and Cycon *et al.* (1987).

## One Dimension and Sturm–Liouville Theory

For $d = 1$, the stationary Schrödinger equation reduces to a second-order ordinary differential equation known as a Sturm–Liouville problem,

$$-\psi''(x) + V(x)\psi(x) = E\psi(x) \qquad [4]$$

on $L^2([a,b])$, with $V \in L^1([a,b])$ and independent boundary conditions at $-\infty \leq a < b \leq \infty$, say. Equation [4] admits an almost explicit solution by means of the Prüfer transformation defined by $\varphi(x) := \arctan[\psi(x)/\psi'(x)]$ and $R(x) := \ln\left(\sqrt{\psi(x)^2 + \psi'(x)^2}\right)$. The key point about the Prüfer transformation is that it effectively reduces the second-order differential equation [4] into a (nonlinear) first-order equation for $\varphi$,

$$\varphi'(x) = (E - V(x))\sin^2[\varphi(x)] + \cos^2[\varphi(x)] \qquad [5]$$

Note that [5] does not involve $R$ and that the boundary conditions on $\psi$ and $\psi'$ at $a$ and $b$ can be easily expressed in terms of $\varphi(a)$ and $\varphi(b)$. Moreover, having determined $\varphi$ on $[a,b]$ from [5], the function $R$ is immediately obtained by integrating $R'(x) = [1 + V(x) - E]\sin[\varphi(x)]\cos[\varphi(x)]$. In case of a bounded interval, $-\infty < a < b < \infty$, or a confining potential, $\lim_{x\to\pm\infty} V(x) = \infty$, it is not difficult to derive from [5] the following basic facts: the spectrum of $H(V)$ consists only of simple eigenvalues $E_0 < E_1 < E_2 < \cdots$ with $\lim_{n\to\infty} E_n = \infty$. Moreover, the corresponding eigenfunction $\psi_n \neq 0$, $n \in \mathbb{N}_0$, with $H(V)\psi_n = E_n\psi_n$, has precisely $n$ zeros, and Sturm's oscillation theorem holds.

See Amrein *et al.* (2005) for more details.

## Quantization and Semiclassical Limit

The quantization procedure postulated by Schrödinger is the replacement of the classical momentum $p \in \mathbb{R}^d$ by the quantum-mechanical momentum operator $-i\hbar\nabla_x$. It is known (and, in fact, easy to see, cf. Messiah (1962)) that the classical Hamiltonian equation of motions is invariant under symplectic transformations, but Schrödinger's quantization procedure does not commute with symplectic changes of the classical variables. The question of the geometrically sound definition of quantization, with a general $d$-dimensional manifold replacing the spatial domain $\Omega$, has attracted many mathematicians and has led to the mathematical fields of geometric quantization and deformation quantization.

It is remarkable, however, that Schrödinger himself discovered already in his early paper the fact that classical dynamics derives as the scaling limit $\hbar \to 0$ from quantum mechanics. The systematic study of the convergence of wave functions and of operators and their spectral properties is known as semiclassical analysis, which is nowadays considered to be part of microlocal analysis. We illustrate the type of results one obtains by the following example on $\Omega = \mathbb{R}^d$.

Let $F \in C_0^\infty(\mathbb{R};\mathbb{R})$ be a smooth characteristic function, compactly supported in an interval $I \subset \mathbb{R}^-$ away from the essential spectrum of the semiclassical Schrödinger operator $H_\hbar = -\hbar^2\Delta + V$ with a smooth potential $V \in C_0^\infty(\mathbb{R}^d)$ of compact support. We define the operator $F[H_\hbar]$ by functional calculus (note that $I \subset \sigma_d(H_V)$ and $F[H_\hbar]$ is of trace class).

Let, furthermore, $A_\hbar = \sum_{|\alpha|\leq M} a_\alpha(x)\partial_x^\alpha$ be a differential operator representing an observable. Then $\mathrm{tr}\{A_\hbar F[H_\hbar]\}$, which exists because the eigenfunctions of $H_\hbar$ are smooth and decay exponentially, is, up to normalization, interpreted to be the expectation of the observable $A_\hbar$ in the state represented by the spectral projection of $H_\hbar$ in $I$, approximated by $F[H_\hbar]$.

Semiclassical analysis then yields an asymptotic expansion of the form

$$\mathrm{tr}\{A_\hbar F[H_\hbar]\} = \hbar^{-d}(c_0 + c_1\hbar + \cdots + c_n\hbar^n + o(\hbar^n))$$

for arbitrarily large integers $n \in \mathbb{N}$. The leading-order coefficient $c_0$ is determined by Bohr's correspondence principle,

$$\begin{aligned}\mathrm{tr}\{A_\hbar\, F[H_\hbar]\} &= \int_{\mathbb{R}^{2d}} a[x,p]F[p^2 + V(x)]\frac{\mathrm{d}p\,\mathrm{d}y}{(2\pi\hbar)^d} \\ &\quad + o\left((2\pi\hbar)^{-d}\right)\end{aligned} \qquad [6]$$

Semiclassical analysis thus provides the mathematical link between quantum and classical mechanics. The proof of [6] usually involves pseudodifferential and/or Fourier integral operators, depending on the method. Advanced topics in semiclassical analysis studied more recently are the construction of quasimodes, that is, wave functions $\psi_{E,\hbar,n}$ which solve the eigenvalue problem $(H_\hbar - E)\psi_{E,\hbar,n} = O(\hbar^n)$ up to errors of order $\hbar^n$, for arbitrarily large $n \in \mathbb{N}$, and the relation between semiclassical asymptotics

and the KAM (Kolmogorov–Arnold–Moser) theory from classical mechanics.

For more details, see Dimassi and Sjöstrand (1999), and Robert (1987). *See also* Stability Theory and KAM, KAM Theory and Celestial Mechanics in this encyclopedia.

## Lieb–Thirring Inequalities

Lieb–Thirring inequalities are estimates on eigenvalue sums of $H_{-V} = -\Delta - V(x)$, where $V \geq 0$ is assumed to be non-negative (note that we changed the sign of $V$) and vanishing at $\infty$; the most important examples for these sums are the number of eigenvalues below a given $-E \leq 0$ and the sum of its negative eigenvalues, counting multiplicities. More generally, denoting by $[\lambda]_+ := \max\{\lambda, 0\}$ the positive part of $\lambda \in \mathbb{R}$, Lieb–Thirring inequalities are estimates on $\mathrm{tr}\{[-E - H_{-V}]_+^\gamma\}$, for $\gamma \geq 0$. The number of eigenvalues below $-E$ is then obtained in the limit $\gamma \to 0$, and the sum of the negative eigenvalues corresponds to $E = 0$ and $\gamma = 1$. We henceforth assume $E = 0$, for simplicity. A guess inspired by [6] with $F[\lambda] := [-\lambda]_+^\gamma$, $A = 1$, and $\hbar = 1$ then is that $\mathrm{tr}\{[-H_{-V}]_+^\gamma\}$ is approximately given by

$$\int_{\mathbb{R}^{2d}} [V(x) - p^2]_+^\gamma \frac{\mathrm{d}^d x\, \mathrm{d}^d p}{(2\pi)^d} = C_{\mathrm{SC}}(\gamma, d) \int_{\mathbb{R}^d} V(x)^{(d/2)+\gamma}\, \mathrm{d}^d x \qquad [7]$$

for a suitable constant $C_{\mathrm{SC}}(\gamma, d) > 0$ depending only on $\gamma$ and $d$ (but not on $V$). While this guess is wrong, it is nevertheless a useful guiding principle. Namely, in a rather large range of $\gamma$ and $d$, there exist constants $C_{\mathrm{LT}}(\gamma, d) > 0$ such that

$$\mathrm{tr}\{[-H_{-V}]_+^\gamma\} \leq C_{\mathrm{LT}}(\gamma, d) \int_{\mathbb{R}^d} V(x)^{(d/2)+\gamma}\, \mathrm{d}^d x \qquad [8]$$

for all $V \geq 0$, for which the right-hand side is finite (with the understanding that this finiteness also insure that $[-H_{-V}]_+^\gamma$ is trace class, in the first place).

Of course, $C_{\mathrm{LT}}(\gamma, d) \geq C_{\mathrm{SC}}(\gamma, d)$, by [6]. The Lieb–Thirring conjecture, which is still open today, says that the best possible choice of $C_{\mathrm{LT}}(1, 3)$ equals $C_{\mathrm{SC}}(1, 3)$ in the physically most relevant case $\gamma = 1$ and $d = 3$. It is known that $C_{\mathrm{LT}}(\gamma, d) > C_{\mathrm{SC}}(\gamma, d)$, for $\gamma < 1$ or $d < 3$.

Lieb–Thirring estimates have been derived for various modifications of the original model, depending on the application. One of these are pseudorelativistic Hamiltonians of the form $H = T(p) - V$, where $T(p) = \sqrt{p^2 + m^2}$, with $m \geq 0$, another one includes an external magnetic field, for example, $H = (p - A)^2 - V$ (see the next and the last section).

The reader is referred to Thirring (1997), Reed and Simon (1978), and Simon (1979) for further details.

## Magnetic Schrödinger Operators

Magnetic Schrödinger operators are Hamiltonians of the form

$$H_{\mathrm{mc}}(\boldsymbol{A}, V) = (\boldsymbol{p} - \boldsymbol{A}(\boldsymbol{x}))^2 - V(x) \quad \text{on } L^2(\mathbb{R}^3) \qquad [9]$$

or

$$H_{\mathrm{Pauli}}(\boldsymbol{A}, V) = [\boldsymbol{\sigma} \cdot (\boldsymbol{p} - \boldsymbol{A}(\boldsymbol{x}))]^2 - V(\boldsymbol{x}) \quad \text{on } L^2(\mathbb{R}^3) \otimes \mathbb{C}^2 \qquad [10]$$

where $V$ is the (electrostatic) potential; as before, $\boldsymbol{A} : \mathbb{R}^3 \to \mathbb{R}^3$ is the vector potential of the magnetic field $B = \boldsymbol{\nabla} \wedge \boldsymbol{A}$, and $\boldsymbol{\sigma} = (\sigma_1, \sigma_2, \sigma_3)$ are the Pauli matrices. $H_{\mathrm{mc}}(\boldsymbol{A}, V)$ and $H_{\mathrm{pauli}}(\boldsymbol{A}, V)$ generate the dynamics of a particle moving in an external electromagnetic field of spin $s = 0$ and spin $s = 1/2$, respectively. The operator $H_{\mathrm{Pauli}}(\boldsymbol{A}, V)$ is usually called Pauli Hamiltonian, and we refer to $H_{\mathrm{mc}}(\boldsymbol{A}, V)$ as the magnetic Hamiltonian. To keep the exposition simple, we assume henceforth that $A_\nu$ and $\partial_\mu A_\nu$ are uniformly bounded, which suffices to prove the self-adjointness of both Hamiltonians.

At a first glance, the magnetic and the Pauli Hamiltonians may seem to differ only marginally, but in fact, some of their spectral properties are fundamentally different.

1. The magnetic Hamiltonian fulfills the diamagnetic inequality, $|\mathrm{e}^{-\beta H_{\mathrm{mc}}(\boldsymbol{A}, V)}(x, y)| \leq \mathrm{e}^{-\beta H_{\mathrm{mc}}(0, V)}(x, y)$, for almost all $x, y \in \mathbb{R}^3$, where $m(x, y)$ denotes the integral kernel of an operator $m$. As a consequence, $\inf \sigma[H_{\mathrm{mc}}(\boldsymbol{A}, V)] \leq \inf \sigma[H_{\mathrm{mc}}(0, V)] = \inf \sigma[H(V)]$, and the quadratic form of the magnetic Hamiltonian is semibounded, for all choices of $\boldsymbol{A}$, provided $H(V)$ is.
2. If $\inf \sigma[H_{\mathrm{mc}}(\boldsymbol{A}, V)]$ is an eigenvalue, the diamagnetic inequality reflects the fact that the corresponding eigenvector is not positive or of constant phase. The determination of the nodal set of eigenfunctions is a difficult task on its own.
3. For $V = 0$, the diamagnetic inequality and the minimax principle imply that $\boldsymbol{p} - \boldsymbol{A}$ has no zero eigenvalue.
4. The diamagnetic inequality fails to hold for the Pauli Hamiltonian. On the contrary, if $\boldsymbol{A}$ is carefully adjusted in $H_{\mathrm{mc}}(\boldsymbol{A}, -Z|x|^{-1})$, and $Z$ is sufficiently large, then the corresponding

quadratic form may assume arbitrarily small values (even if the corresponding field energy is added).

5. For many choices of $\boldsymbol{A}$, the (Dirac) operator $\boldsymbol{\sigma}\cdot(\boldsymbol{p}-\boldsymbol{A})$ has a nontrivial kernel.

From (1)–(4) it is clear that the proof of stability of matter (see the next section) in presence of a magnetic field is more difficult than in absence of it. This can be illustrated by the fact that magnetic Lieb–Thirring inequalities, being the natural analog of eqn [8], are more involved to derive than the original estimate [8]. The currently best bound is of the form

$$\begin{aligned}\mathrm{tr}\{[-H_{-V}]_+^{\gamma}\} &\\ \leq C_{\mathrm{mLT}}\int_{\mathbb{R}^d}\Big\{&[V(x)]_+^{5/2}+|B(x)|\,[V(x)]_+^{3/2}\\ &+\Big(|B(x)|+L_c(x)^{-2}\Big)L_c(x)^{-1}[V(x)]_+\Big\}\,\mathrm{d}^dx\end{aligned}\qquad [11]$$

for some universal $C_{\mathrm{mLT}}<\infty$, where $L_c(x)$ is a local length scale associated with $B$. It is nonlocal in $x$ and somewhat reminiscent of a maximal function.

We further remark that if restricted to two dimensions, $d=2$, both the magnetic and the Pauli Hamiltonians play an important role in the theory of the (integer) quantum Hall effect.

For more details, see Simon (1979), Cycon *et al.* (1987), Rauch and Simon (1997), and Erdös and Solovej (2004). See also the article Quantum Hall Effect in this encyclopedia.

## *N*-Body Schrödinger Operators

The origin of quantum mechanics is atomic ($K=1$ below) or molecular ($K\geq 2$) physics. If we regard the nuclei of the molecule as fixed point charges $\underline{Z}:=(Z_1,\ldots,Z_K)>0$ at respective positions $\underline{R}:=(R_1,\ldots,R_K)\in\mathbb{R}^3$, then the Hamiltonian (in convenient units) of this molecule with $N\in\mathbb{N}$ electrons is the following Schrödinger operator:

$$\begin{aligned}H_N(\underline{Z},\underline{R}) &=\sum_{n=1}^{N}\left\{-\Delta_n-\sum_{k=1}^{K}\frac{Z_k}{|x_n-R_k|}\right\}\\ &\quad+\sum_{1\leq m<n\leq N}\frac{1}{|x_m-x_n|}\end{aligned}\qquad [12]$$

defined on $\mathcal{H}^{(N)}:=\bigwedge_{n=1}^{N}L^2[\mathbb{R}^3\times\mathbb{Z}_2]\subseteq L^2[(\mathbb{R}^3\times\mathbb{Z}_2)^N]$, the space of totally antisymmetric, square-integrable wave functions in $N$ space–spin variables $(x_1,\sigma_1),\ldots,(x_N,\sigma_N)\in\mathbb{R}^3\times\mathbb{Z}_2$. The antisymmetry of the wave function accounts for the fact that electrons are fermions and is of crucial importance. Note that the number $N$ of electrons is possibly very large. It is clear that we cannot expect to carry out the spectral analysis of this Schrödinger operator directly, but rather only suitable approximations.

In spite of the fact that $H_N(\underline{Z},\underline{R})$ was one of the basic operators of quantum mechanics from its very beginning in the late 1920s, $H_N(\underline{Z},\underline{R})$ was, strictly speaking, not known to be self-adjoint before Kato developed the perturbation theory (described in the section "Self-adjointness") some 20 years later, which then also yielded the semiboundedness of $H_N(\underline{Z},\underline{R})$. So, the ground-state energy $E_N(\underline{Z},\underline{R}):=\inf\sigma[H_N(\underline{Z},\underline{R})]>-\infty$ is finite. From the HVZ (Hunziker–van Winter–Zishlin) theorem follows that $\inf\sigma_{\mathrm{ess}}[H_N(\underline{Z},\underline{R})]=E_{N-1}(\underline{Z},\underline{R})$, which particularly implies that $E_N(\underline{Z},\underline{R})$ is monotonically decreasing in $N$ and negative (because $E_1(\underline{Z},\underline{R})<0$).

It is known that $E_N(\underline{Z},\underline{R})=E_{N+1}(\underline{Z},\underline{R})$ and that $H_N(\underline{Z},\underline{R})$ has no eigenvalue, for $N\geq 2Z_{\mathrm{tot}}+1$, where $Z_{\mathrm{tot}}:=\sum_{k=1}^{K}Z_k$ is the total nuclear charge of the atom. On the other hand, it is known that $E_N(\underline{Z},\underline{R})$ is an eigenvalue, provided $N<Z_{\mathrm{tot}}$. Thus, defining $N_{\mathrm{crit}}$ to be the smallest number such that $E_N(\underline{Z},\underline{R})$ is not an eigenvalue, for all $N\geq N_{\mathrm{crit}}$, that is, $N_{\mathrm{crit}}$ is the maximal number of electrons the molecule can bind, we have that $Z_{\mathrm{tot}}\leq N_{\mathrm{crit}}\leq 2Z_{\mathrm{tot}}+1$. In increasing precision, asymptotic neutrality, $N_{\mathrm{crit}}=Z_{\mathrm{tot}}+R(Z_{\mathrm{tot}})$, with $R(Z_{\mathrm{tot}})=o(Z_{\mathrm{tot}})$ and $R(Z)=o(Z^{5/7})$, was shown for atoms and for molecules, respectively. The ionization conjecture states that $N_{\mathrm{crit}}\leq Z_{\mathrm{tot}}+\mathrm{C}$, for some universal constant $C$. It is still open for the full model represented by $H_N(\underline{Z},\underline{R})$, but has been proved in the Hartree–Fock approximation. It has been proved in the Hartree–Fock approximation by Solovej.

The semiboundedness of $H_N(\underline{Z},\underline{R})$, for fixed $\underline{Z},\underline{R}$, and $N$, alone does not rule out a physical collapse of the matter described by $H_N(\underline{Z},\underline{R})$, but the stronger property of stability of matter does. It holds if there exists a constant $C$, possibly depending on $\underline{Z}$, such that

$$E_N(\underline{Z},\underline{R})+\sum_{1\leq k<\ell\leq K}\frac{Z_k\,Z_\ell}{|R_k-R_\ell|}\geq -\mathrm{C}(N+K)\qquad [13]$$

that is, if the ground-state energy plus the repulsive electrostatic energy of the nuclei is bounded below by a constant times the total number $N+K$ of particles in the system. Equation [13] was shown to hold for $H_N(\underline{Z},\underline{R})$.

In connection with stability of matter, Thomas–Fermi theory and the question of the limit of large nuclear charge came into the focus of research. For simplicity, we restrict ourselves to atoms, $K=1$, that is, there is one nucleus of charge $Z:=Z_1$ at the origin, $R_1=0$, and we consider $E(Z):=\min_{N\in\mathbb{N}}E_N(Z,0)$ (which amounts to fixing $N:=N_{\mathrm{crit}}$). An asymptotic expansion for $E(Z)$ of increasing

precision in $Z$ was obtained by ever-finer estimates; presently, one knows that

$$E(Z) = E_{\mathrm{TF}} Z^{7/3} + \tfrac{1}{4} Z^2 + C_{\mathrm{DS}} Z^{5/3} + o(Z^{5/3}) \qquad [14]$$

where the leading contribution $E_{\mathrm{TF}} Z^{7/3}$ is the Thomas–Fermi energy, $(1/4)Z^2$ is the Scott correction, and $C_{\mathrm{DS}} Z^{5/3}$ is the Dirac–Schwinger term. The computation of this last term requires semiclassical analysis sketched in the section "Quantization and semiclassical limit."

For more details, see Cycon *et al.* (1987), Rauch and Simon (1997), Thirring (1997), and Solovej (2003). See also the article Stability of Matter in this encyclopedia.

## Scattering Theory

The study of the properties of the propagator $\exp(-\mathrm{i}tH)$ of a self-adjoint operator $H = H^*$, as $t \to \infty$, is the concern of scattering theory. To obtain a well-defined mathematical object in this limit, it is necessary to compose $\exp(-\mathrm{i}tH)$ with the inverse of some explicitly accessible comparison dynamics before passing to the limit $t \to \infty$. If $V$ is a short-range potential, that is, $V$ is relatively $H_0$-compact and $|V(x)| \le C|x|^{-\nu}$, for some $\nu > 1$ and $C < \infty$, then the comparison dynamics appropriate for $H_V$ is generated by $H_0$: the wave operators $\Omega^{\pm}$ are defined as the strong limits

$$\Omega^{\pm} := \lim_{t \to \pm\infty} \mathrm{e}^{\mp \mathrm{i}tH_V} \mathrm{e}^{\pm \mathrm{i}tH_0} \qquad [15]$$

A general technique in scattering theory to prove the existence of such limits is Cook's argument, which formally amounts to an application of the fundamental theorem of calculus. For example, for the existence of $\Omega^+$, one writes

$$\begin{aligned} \Omega^+ - \mathbb{1} &= \int_0^\infty \mathrm{d}t \left\{ \frac{\mathrm{d}}{\mathrm{d}t} \left( \mathrm{e}^{-\mathrm{i}tH_V} \mathrm{e}^{\mathrm{i}tH_0} \right) \right\} \\ &= -\mathrm{i} \int_0^\infty \mathrm{d}t \, \{ \mathrm{e}^{-\mathrm{i}tH_V} \, V \, \mathrm{e}^{\mathrm{i}tH_0} \} \end{aligned} \qquad [16]$$

and additionally proves the absolute integrability of $t \mapsto \mathrm{e}^{-\mathrm{i}tH_V} V \mathrm{e}^{\mathrm{i}tH_0} \varphi$, for $\varphi$ in a dense subset of $\mathcal{H}$, like $\mathrm{dom}(H_0) = \mathrm{dom}(H_V)$.

Research in scattering theory in the past two decades or so was focused around the question of asymptotic completeness, which is a mathematically precise formulation

$$\mathrm{Ran}\Omega^+ = \mathrm{Ran}\Omega^- = \mathcal{H}_{\mathrm{pp}}^{\perp}(H_V) \qquad [17]$$

of the physical expectation that the states in $\mathcal{H}$ are either bound states (eigenvectors) of $H_V$ or scattering states (states in the range of $\Omega^{\pm}$) of $H_V$. The intertwining property $H_V \Omega^{\pm} = \Omega^{\pm} H_0$ (which easily follows from [15]) implies that the restriction of $H_V$ to $\mathrm{Ran}\Omega^{\pm}$ is unitarily equivalent to $H_0$, hence $\mathrm{Ran}\Omega^{\pm} \subseteq \mathcal{H}_{\mathrm{ac}}(H_V) \subseteq \mathcal{H}_{\mathrm{pp}}^{\perp}(H_V)$. The difficult part of the proof of asymptotic completeness is to show that $\mathcal{H}_{\mathrm{pp}}^{\perp}(H_V) \subseteq \mathrm{Ran}\Omega^{\pm}$.

Much effort has been spent to prove asymptotic completeness for $N$-body Schrödinger operators on $\mathcal{H}^{(N)} := \bigotimes_{n=1}^N L^2(\mathbb{R}^3)$ of the form

$$\begin{aligned} H_N(V) &= \sum_{n=1}^N \frac{-\Delta_n}{2\, m_n} + V(x) \\ &\text{with } V(x) := \sum_{1 \le m < n \le N} V_{mn}(x_m - x_n) \end{aligned} \qquad [18]$$

where each pair potential $V_{mn}$ obeys $|\partial_y^{\alpha} V_{mn}(y)| \le C(1 + |y|)^{-\mu - |\alpha|}$, with $\alpha \in \mathbb{N}_0^d$ being a multi-index. If $\mu > 1$ for all $m \ne n$ then $V$ is called a short-range potential. Conversely, if $0 < \mu \le 1$ then $V$ is a long-range potential. Note that even though each $V_{mn}$ decays at infinity, $|x|^2 = x_1^2 + x_2^2 + \cdots + x_n^2 \to \infty$ alone does not imply that $V(x) \to \infty$. In fact, physical intuition tells us that for a cluster $\mathcal{C}$ of $N$ particles, whose dynamics is generated by $H_N(V)$, several scenarios for the long-time asymptotic behavior of the evolution are possible:

1. The $N$ particles stay together in their cluster $\mathcal{C}$ whose center of mass moves in space at constant velocity.
2. The cluster breaks up into two (or even more) subclusters, $\mathcal{C}_1$ and $\mathcal{C}_2$, of $N_1$ and $N_2 = N - N_1$ particles, respectively, whose centers of mass drift apart from each other at constant velocities (in the short-range case). For each subcluster $\mathcal{C}_1$ and $\mathcal{C}_2$, both scenarios may appear again, after waiting sufficiently longer.
3. In the limit $t \to \infty$, possibly after going through (1) and (2) several times, the initial cluster $\mathcal{C}$ is broken up into $1 \le K \le N$ subclusters $\mathcal{C}_1, \ldots, \mathcal{C}_K$, whose centers of mass drift apart from each other at constant velocities according to a free and independent dynamics of their centers of mass.

In some sense, asymptotic completeness says that nothing else than (1)–(3) can possibly happen. (Strictly speaking, asymptotic completeness is a statement about the limit $t \to \infty$ and only involves (3) – the actual behavior of $\exp[-itH_V]$ at intermediate times in terms of (1)–(3) is beyond the reach of current mathematics.) It is a key insight of scattering theory that the asymptotics of the time evolution in the sense of (3) is completely

characterized by the asymptotic velocity defined by the strong limit

$$P^+ := \lim_{t\to\infty}\left(\mathrm{e}^{-\mathrm{i}tH_N(V)}\frac{x}{t}\mathrm{e}^{\mathrm{i}tH_N(V)}\right) \qquad [19]$$

It is a nontrivial fact that $P^+$ exists, commutes with $H_N(V)$, and that bound states are precisely the states with zero asymptotic velocity, while states with nonzero asymptotic velocity are scattering states in $\mathrm{Ran}\Omega^{\pm}$. This then implies asymptotic completeness for short-range potentials. The proof of this dichotomy builds essentially upon positive commutator or Mourre estimates. Given an interval $J$ localized (in energy) away from any eigenvalue of any possible subcluster configuration $\mathcal{C}_1, \ldots, \mathcal{C}_K$ (called thresholds), the Mourre estimate asserts the existence of a positive constant $M > 0$ and a compact operator $R \in \mathcal{B}(\mathcal{H}^{(N)})$ such that

$$\mathbb{1}_{\mathcal{J}}\,\mathrm{i}[H_N(V), A]\,\mathbb{1}_{\mathcal{J}} \geq M\mathbb{1}_{\mathcal{J}} - R \qquad [20]$$

as a quadratic form, for some suitable operator $A$. This operator $A$ is often chosen to be the dilation generator $A = (1/2)\{p\cdot x + x\cdot p\}$ or a variant thereof.

Again, the proof of asymptotic completeness for long-range potentials is still more difficult and has been carried out only for $\mu > \sqrt{3} - 1$. The additional problem is the comparison dynamics of the relative motion of the clusters $\mathcal{C}_1$ and $\mathcal{C}_2$ in (2), which is not the free one; the clusters rather influence each other even at large distances.

For more details, see Reed and Simon (1980c) and Derezinski and Gérard (1997). See also the articles Scattering in Relativistic Quantum Field Theory: Fundamental Concepts and Tools, Scattering, Asymptotic Completeness and Bound States in this encyclopedia.

## Random Schrödinger Operators

Schrödinger operators $H(V_\omega)$ on $L^2(\mathbb{R}^d)$ or $\ell^2(\mathbb{Z}^d)$ with a random potential $V_\omega$ are called random Schrödinger operators. (If $H(V_\omega)$ acts on $\ell^2(\mathbb{Z}^d)$, then the (continuum) Laplacian $-\Delta$ is replaced by the discrete Laplacian on $\mathbb{Z}^d$ defined by $[-\Delta_{\mathrm{disc}} f](x) = \sum_{\nu=1}^{d}\{2f(x) - f(x - e_\nu) - f(x + e_\nu)\}$.) More precisely, given a probability space $(\Omega, P, \mu)$ and a random variable $\Omega \ni \omega \mapsto V_\omega$, the family $\{H(V_\omega)\}_{\omega\in\Omega}$ defines an operator-valued random variable that we refer to as a random Schrödinger operator. Random quantum systems are physically relevant as models for amorphous materials, and for solids in very heterogenous external fields or coupled to quantized fields. Suitable ergodicity assumptions on $\omega \to V_\omega$ ensure that the domain of $H_\omega$ and even many spectral properties (in particular, the spectrum $\sigma(H(V_\omega)) \subseteq \mathbb{R}$ itself) are independent of $\omega$ $P$-almost surely. For example, assuming an independent, identical distribution (i.i.d.) of $V_\omega$ in the discrete case on $\mathbb{Z}^d$, one arrives at the Anderson model, which has been most thoroughly studied. Its counterpart for continuum models is a Poisson-distributed $V_\omega$. A model which also has ergodic properties, although deterministic, is the Hofstadter or the Mathieu problem. Most research has been focused on localization, that is, spatial decay properties of the resolvent $\{H(\lambda V_\omega) - E\}^{-1}(x, y)$ of $H(\lambda V_\omega)$, as $|x - y| \to \infty$, and particularly the question of presence or absence of exponential decay (localization), as this is an important indicator for the transport properties of the material under consideration. Exponential localization of eigenstates has been established for $d = 1$ or strong disorder or sufficiently high energies $E \gg 1$. Localization is also intimately related to bounds on moments of the form $\|x^{\mu/2}\psi_t\| \leq C_\mu t^\beta$. The study of the asymptotic distribution of eigenvalues close to the lowest threshold leads to the so-called Lifshitz tails.

The reader is referred to Figotin and Pastur (1992), Cycon *et al.* (1987), and Stollmann (2001).

## (Pseudo)relativistic Schrödinger Operators

Schrödinger operators of the form $H(V) = p^2 + V(x)$ do not observe the invariance principles of (special) relativity, as their derivation is based in classical (Newtonian) mechanics. The free Dirac operator $D := \boldsymbol{\alpha}\cdot\boldsymbol{p} + m\beta$ (here, $\alpha_\nu$ and $\beta$ are self-adjoint $4\times 4$ matrices) possesses the desired relativistic invariance, but it is not semibounded, and the definition of an interacting Dirac operator is notoriously difficult (and unsolved). The replacement of the kinetic energy $(1/2m)p^2$ by the Klein–Gordon operator $\sqrt{p^2 + m^2}$ is a step towards relativistic invariance, which, at the same time, yields a positive operator. This replacement may also be viewed as the restriction of the free Dirac operator to its positive-energy subspace. The virtue of this replacement is that it immediately allows for the study of interacting $N$-particle operators,

$$H_N^{\mathrm{rel}}(\underline{Z}, \underline{R}) = \sum_{n=1}^{N}\left\{\sqrt{-\Delta_n + m^2} - \sum_{k=1}^{K}\frac{Z_k}{|x_n - R_k|}\right\} + \sum_{1\leq \ell < n \leq N}\frac{1}{|x_\ell - x_n|} \qquad [21]$$

much like in [12]. Since $\sqrt{p^2 + m^2} \sim |p|$, as $p \to \infty$, the pseudorelativistic kinetic energy $\sqrt{p^2 + m^2}$ can

balance only less severe local singularities of the potential $V$ than the nonrelativistic kinetic energy $(1/2m)p^2$. Indeed, already the quadratic form $\sqrt{p^2+m^2} - g|x|^{-1}$ on $C_0^\infty(\mathbb{R}^3)$ associated to a hydrogen-like atom is unbounded from below if $g > 2/\pi$. Hence, the stability of matter becomes a more subtle property of pseudorelativistic matter. The relaxation of the restriction onto the positive subspace of the free Dirac operator also got into the focus of research.

For more details, we refer the reader to Thirring (1997).

# Schwarz-Type Topological Quantum Field Theory

**R K Kaul and T R Govindarajan**, The Institute of Mathematical Sciences, Chennai, India

**P Ramadevi**, Indian Institute of Technology Bombay, Mumbai, India

## Introduction

Topological quantum field theories (TQFTs) provide powerful tools to probe topology of manifolds, specifically in low dimensions. This is achieved by incorporating very large gauge symmetries in the theory which lead to gauge-invariant sectors with only topological degrees of freedom. These theories are of two kinds: (1) Schwarz type and (2) Witten type.

In a Witten-type topological field theory, action is a BRST exact form, so is the stress energy tensor $T_{\mu\nu}$ so that their functional averages are zero (Witten 1988). The BRST charge is associated with a certain shift symmetry. The topological observables form cohomological classes and semiclassical approximation turns out to be exact. In four dimensions, such theories involving Yang–Mills gauge fields provide a field-theoretic representation for Donaldson invariants.

On the other hand, Schwarz-type TQFTs are described by local action functionals which are not total derivatives but are explicitly independent of metric (Schwarz 1978, 1979, 1987, Witten 1989).

The examples of such theories are topological Chern–Simons (CS) theories and BF theories.

Metric independence of the action $S$ of a Schwarz-type gauge theory implies that stress–energy tensor is zero:

$$\frac{\delta S}{\delta g_{\mu\nu}} \equiv T_{\mu\nu} = 0$$

More generally, in the gauge-fixed version of such theories, stress–energy can be BRST exact, where BRST charge corresponds to gauge fixing in contrast to Witten-type theories where corresponding BRST charge corresponds to a combination of shift symmetry and gauge symmetry. There are no local propagating degrees of freedom; the only degrees of freedom are topological. Expectation values of metric-independent operators $W$ are also independent of the metric:

$$\frac{\delta\langle W\rangle}{\delta g_{\mu\nu}} = 0$$

Three-dimensional CS theories are of particular interest, for these provide a framework for the study of knots and links in any 3-manifold. Pioneering indications of the fact that topological invariants can be found in such a setting came in very early when A S Schwarz demonstrated that a particular topological invariant, Ray–Singer analytic torsion (which is equivalent to combinatorial Reidemeister–Franz torsion) can be interpreted in terms of the partition function of a quantum gauge field theory (Schwarz 1978, 1979). In particular, in the weak-coupling limit of CS theory of gauge group $\mathcal{G}$ on a manifold $\mathcal{M}$, contribution from each topologically distinct flat connection (characterized by the equivalence classes of homomorphisms: $\pi_1(\mathcal{M}) \rightarrow \mathcal{G}$) to the partition function is given by metric-independent Ray–Singer torsion of the flat connection up to a phase. This phase factor is also a topological invariant of framed 3-manifold $\mathcal{M}$ (Witten 1989). It was Schwarz who first discussed CS theory as a topological field theory and also conjectured that the well-known Jones polynomial may be related to it (Schwarz 1987). In his famous paper Witten (1989) not only demonstrated this connection, but also set up a general field-theoretic framework to study the topological properties of knots and links in any arbitrary 3-manifold. In addition, this framework provides a method of obtaining some new manifold invariants. As discussed by A Achúcaro and P K Townsend, CS theory also describes gravity in three-dimensional spacetime (Carlip 2003).

BF theories in three dimensions provide another framework for field-theoretic description of topological properties of knots and links. These theories with bilinear action in fields can also be defined in higher dimensions. In particular in $D=4$, BF theory, besides describing two-dimensional generalizations of knots and links, also provides a field-theoretic interpretation of Donaldson invariants. This provides a connection of these theories with Witten-type TQFTs of Yang–Mills gauge fields. We shall not discuss BF theories in the following and refer to the article BF Theories in this Encyclopedia.

Witten (1995) has also formulated CS theories in three complex dimensions described in terms of holomorphic 1-forms. Such a theory on Calabi–Yau spaces can be interpreted as a string theory in terms of a Witten-type topological field theory of a sigma model coupled to gravity. General topological sigma models in Batalin–Vilkovisky formalism have been constructed by Alexandrov *et al.* (1997). This is a Schwarz-type theory. However, in its gauge-fixed version, it can also be interpreted as a Witten-type theory. This construction provides a general formulation from which numerous topological field theories emerge. In particular, the Witten $A$ and $B$ models and also multidimensional CS theories are special cases of this construction.

In the following, we shall survey three-dimensional CS theory as a description of knots/links, indicate how manifold invariants can be constructed from invariants for framed links, and also discuss its application to three-dimensional gravity.

## Three-Dimensional CS Theory with Gauge Group U(1)

The simplest Schwarz-type topological field theory is the U(1) CS theory described by the action:

$$S = -\frac{1}{8\pi}\int_{\mathcal{M}} A\,\mathrm{d}A \qquad [1]$$

where $A$ is a connection 1-form $A = A_\mu \mathrm{d}x^\mu$ and $\mathcal{M}$ is the 3-manifold, which we shall take to be $S^3$ for the discussion below. The action has no dependence on the metric. Besides being the U(1) gauge invariant, it is also general coordinate invariant.

In quantum CS field theory, we are interested in the functional averages of gauge-invariant and metric-independent functionals $W[A]$:

$$\langle W[A]\rangle = \frac{1}{\mathcal{Z}}\int [\mathcal{D}A]\, W[A] \exp\{\mathrm{i}kS\}$$
$$\mathcal{Z} = \int [\mathcal{D}A] \exp\{\mathrm{i}kS\} \qquad [2]$$

This theory captures some of the simple, but interesting, topological properties of knots and links in three dimensions. For a knot $K$, we associate a knot

operator $\oint_K A$ which is gauge invariant and also does not depend on the metric of the 3-manifold. Then for a link made of two knots $K_1$ and $K_2$, we have the loop correlation function $\langle \oint_{K_1} A \oint_{K_2} A \rangle$, which can be evaluated in terms of two-point correlator $\langle A_\mu(x) A_\nu(y) \rangle$ in $R^3$ (with flat metric). This correlator in Lorentz gauge ($\partial_\mu A^\mu = 0$) is:

$$\langle A_\mu(x) A_\nu(y) \rangle = \frac{\mathrm{i}}{k} \epsilon_{\mu\nu\rho} \frac{(x-y)^\rho}{|x-y|^3}$$

so that for two distinct knots $K_1$ and $K_2$

$$\left\langle \oint_{K_1} A \oint_{K_2} A \right\rangle = \frac{4\pi \mathrm{i}}{k} \mathcal{L}(K_1, K_2) \qquad [3]$$

where

$$\mathcal{L}(K_1, K_2) = \frac{1}{4\pi} \oint_{K_1} \oint_{K_2} \mathrm{d}x^\mu \mathrm{d}y^\nu \epsilon_{\mu\nu\rho} \frac{(x-y)^\rho}{|x-y|^3}$$

This integral is the well-known topological invariant called "Gauss linking number" of two distinct closed curves. It is an integer measuring the number of times one knot $K_1$ goes through the other knot $K_2$. Linking number does not depend on the location, size, or shape of the knots. In electrodynamics, it has the physical interpretation of work done to move a monopole around a knot while electric current runs through the other knot.

Abelian CS theory also provides a field-theoretic representation for another topological quantity called "self-linking number," also known as "framing number," of the knot. It is related to the functional average of $\langle \oint_K A \oint_K A \rangle$ where two loop integrals are over the same knot. Coincidence singularity is avoided by a topological loop-splitting regularization. For a knot $K$ given by $x^\mu(s)$ parametrized along the length of the knot by $s$, we associate another closed curve $K_\mathrm{f}$ given by $y^\mu(s) = x^\mu(s) + \epsilon\, n^\mu(s)$, where $\epsilon$ is a small parameter and $n^\mu(s)$ is a principal normal to the curve at $s$. The coincidence limit is then obtained at the end by taking the limit $\epsilon \to 0$. Such a limiting procedure is called framing and knot $K_\mathrm{f}$ is the "frame" of knot $K$. Linking number of the knot $K$ and its frame $K_\mathrm{f}$ is the self-linking number of the knot:

$$S\mathcal{L}(K, n^\mu) = \frac{1}{4\pi} \oint \oint \mathrm{d}x^\mu\, \mathrm{d}y^\nu \frac{\epsilon_{\mu\nu\rho}(x-y)^\rho}{|x-y|^3}$$

Hence coincidence two loop correlator is

$$\left\langle \oint_K A \oint_K A \right\rangle = \frac{4\pi \mathrm{i}}{k} S\mathcal{L}(K, n^\mu) \qquad [4]$$

Notice that the self-linking number of a knot is independent of the regularization parameter $\epsilon$, but does depend on the topological character of the normal vector field $n^\mu(s)$. It is also related to two geometric quantities called "twist" $T(K)$ and "writhe" $w(K)$ through a theorem due to Calugareanu:

$$S\mathcal{L}(K) = T(K) + \omega(K) \qquad [5]$$

where

$$T(K) = \frac{1}{2\pi} \oint_K \mathrm{d}s\, \epsilon_{\mu\nu\rho} \frac{\mathrm{d}x^\mu}{\mathrm{d}s} n^\nu \frac{\mathrm{d}x^\rho}{\mathrm{d}s}$$
$$\omega(K) = \frac{1}{4\pi} \oint_K \mathrm{d}s \oint_K \mathrm{d}t\, \epsilon_{\mu\nu\rho} \frac{\mathrm{d}e^\mu}{\mathrm{d}s} \frac{\mathrm{d}e^\nu}{\mathrm{d}t} e^\rho$$

Here

$$e^\mu(s,t) = \frac{y^\mu(t) - y^\mu(s)}{|y(t) - y(s)|}$$

is a unit map from $K \otimes K \longrightarrow S^2$ and $n^\mu(s)$ is a normal unit vector field. $T(K)$ and $\omega(K)$ are not in general integers and represent the amount of twist and coiling of the knot. These are not topological invariants but their sum, self-linking number, is indeed always an integer and a topological invariant. This result has found interesting applications in the studies of the action of enzymes on circular DNA.

## Nonabelian CS Theories

Nonabelian CS theories provide far more information about the topological properties of the manifolds as well as knots and links.

Nonabelian CS theory in a 3-manifold $\mathcal{M}$ (which as in last section is taken to be $S^3$) is described by the action functional

$$S = \frac{1}{4\pi} \int_{\mathcal{M}} \mathrm{tr}\left(A \wedge \mathrm{d}A + \tfrac{2}{3} A \wedge A \wedge A\right) \qquad [6]$$

where $A$ is a gauge field 1-form which takes its value in the Lie algebra $\mathcal{LG}$ of a compact semisimple Lie group $\mathcal{G}$. For example, we may take this group to be SU($N$) and $A = A^a T^a$, where $T^a$ is the fundamental $N$-dimensional representation with $\mathrm{tr}\, T^a T^b = -1/2\delta^{ab}$. Under homotopically nontrivial gauge transformations this action is not invariant, but changes by an amount $2\pi n$ where integers $n$ are the winding numbers characterizing the gauge transformations which fall in homotopic classes given by $\Pi_3(\mathcal{G}) = \mathcal{Z}$ for a compact semisimple group $\mathcal{G}$. However, for quantum theory what is relevant is $\exp[\mathrm{i}kS]$ which is invariant even under homotopically nontrivial gauge transformations provided the coupling $k$ takes integer values. This quantized nature of the coupling was pointed out by Deser *et al.* (1982a, b) (and also they were first to introduce the nonabelian CS term as a gauge-invariant topological

mass term in gauge theories). So for integer $k$, the quantum field theory we discuss here is gauge invariant.

The topological operators are Wilson loop operators for an oriented knot $K$:

$$W_R[K] = \mathrm{tr}\, P \exp \oint_K A_R \quad [7]$$

where $A_R = A^a T^a_R$ with $T^a_R$ as the representation matrices of a finite-dimensional representation $R$ of the $\mathcal{LG}$. $P$ stands for the path ordering of the exponential. The observable Wilson link operator for a link $L = \bigcup_1^n K_i$, carrying representations $R_i$ on the respective component knots, is

$$W_{R_1 R_2 \cdots R_n}[L] = \prod_1^n W_{R_i}[K_i] \quad [8]$$

Expectation values of these operators are:

$$V_{R_1, R_2 \cdots R_n}[L] = \frac{\int [\mathcal{D}A]\, W_{R_1 \cdots R_n}[L] e^{ikS}}{\int [\mathcal{D}A] e^{ikS}} \quad [9]$$

The measure $[\mathcal{D}A]$ has to be metric independent. These expectation values depend not only on the isotopy of the link $L$ but also on the set of the representations $\{R_i\}$. These can be evaluated in principle nonperturbatively. For example, when $\mathcal{LG} = \mathrm{su}(N)$ and each of the component knot of the links carries the fundamental $N$-dimensional representation, the Wilson link expectation values satisfy a recursion relation involving three link diagrams which are identical except for one crossing where they differ as over crossing ($L_+$), under crossing ($L_-$), and no crossing ($L_0$) as shown in the Figure 1.

The expectation values of these links are related as (Witten 1989):

$$q^{N/2} V_N[L_+] - q^{-N/2} V_N[L_-] = \left(q^{1/2} - q^{-1/2}\right) V_N[L_0] \quad [10]$$

where

$$q = \exp\left(\frac{2\pi i}{k+N}\right)$$

This is precisely the well-known skein relation for the HOMFLY polynomial. The famous Jones one-variable polynomial (whose two-variable generalization is the HOMFLY polynomial) corresponds to the case of spin-1/2 representation of SU(2) CS theory: $V_2[L] =$ Jones polynomial $[L]$, up to an overall normalization. These skein relations are sufficient to recursively find all the expectation values of links with only fundamental representation on the components. To obtain invariants for any other representation, more general methods have to be developed. A complete and explicit solution of the CS field theory is thus obtained. One such method has been reviewed in Kaul (1999). The method makes use of the following important statement:

**Proposition:** *CS theory on a 3-manifold $\mathcal{M}$ with boundary $\Sigma$ is described by a WZNW (Wess–Zumino–Novikov–Witten) conformal field theory (CFT) on the boundary* (Figure 2).

Using the same identification, functional average for Wilson lines ending at $n$ points on the boundary $\Sigma$ is obtained from WZNW field theory on the boundary with $n$ punctures carrying representations $R_i$ (Figure 3):

We can represent CS functional integral as a vector (Witten 1989) in the Hilbert space $\mathcal{H}$ associated with the $n$-point vacuum expectation values of primary fields in WZNW conformal field theory on the boundary $\Sigma$. Next, to obtain a complete and explicit nonperturbative solution of the CS theory, the theory of knots and links and their connection to braids is invoked.

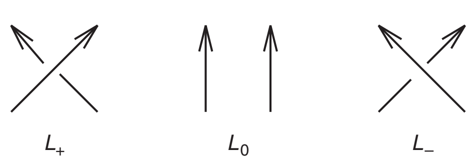

**Figure 1** Skein related links.

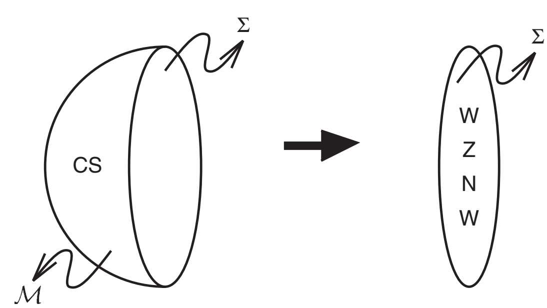

**Figure 2** Relation of CS to CFT.

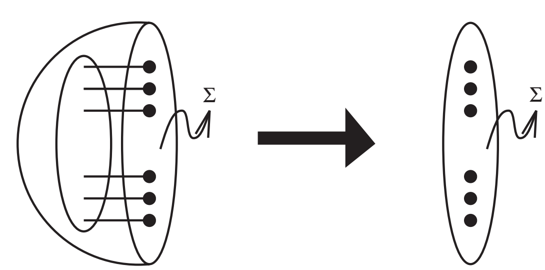

**Figure 3** CS functional integrals with Wilson lines and CFT on punctured boundary.

### Knots/Links and Braids

Braids have an intimate connection with knots and links which can be summarized as follows:

1. An $n$-braid is a collection of nonintersecting strands connecting $n$ points on a horizontal rod to $n$ points on another horizontal rod below strictly excluding any backward traversing of the strands. A general braid can be written as a word in terms of elementary braid generators.
2. We associate representations $R_i$ of the group with the strands as their colors. We also put an orientation on each strand. When all the representations are identical and also all strands are unoriented, we get ordinary braids, otherwise we get colored oriented braids.
3. The colored oriented braids form a groupoid where product of the different braids is obtained by joining them with both colors and orientations matching on the joined strands. Unoriented monochromatic braids form a group.
4. A knot/link can be formed from a given braid by a process called platting. We connect adjacent strands namely the $(2i+1)$th strand to $2i$th strand carrying the same color and opposite orientations in both the rods of an even-strand braid (Figure 4a).

   There is a theorem due to Birman which states that all colored oriented knots/links can be obtained through platting. This construction is not unique.
5. There is another construction associated with braids which relates them to knots and links. We obtain a closure of a braid by connecting the ends of the first, second, third, ... strands from above to those of the respective first, second, third, ... strands from below as shown in the Figure 4b. There is theorem due to Alexander which states that any knot or link can be obtained as a closure of a braid, though again not uniquely.

### Link Invariants

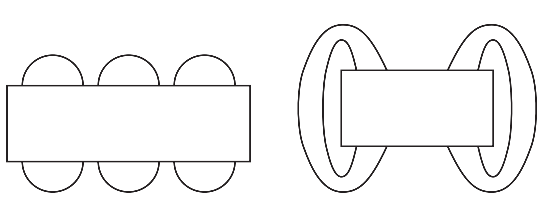
This connection of braids to knots and links can be used to construct link invariants, say in $S^3$. To do so, two nonintersecting 3-balls are removed from the 3-manifold $S^3$ to obtain a manifold with two $S^2$ boundaries. Then we arrange $2n$ Wilson lines of, say SU($N$) CS theory, as a $2n$-strand oriented braid carrying representations $R_i$ in this manifold. The CS functional integral over this manifold is a state in the tensor product of the Hilbert spaces $\mathcal{H}_1 \otimes \mathcal{H}_2$ associated with conformal field theory on the two boundaries. These boundaries have $2n$ punctures carrying the set of representations $\{R_i\}$ and $\{R'_i\}$, respectively, the two sets being permutations of each other. This state can be expanded in terms of some convenient basis given by the conformal blocks for the $2n$-point correlation functions of $\mathrm{SU}(N)_k$ WZNW conformal field theory. The duality of these correlation functions represents the transformation between different bases for the Hilbert space. Their monodromy properties allow us to write down representations of the braid generators. Since an arbitrary braid is just a word in terms of these generators, this construction provides us a matrix representation $\mathcal{B}(\{R_i\},\{R'_j\})$ for the colored oriented braid in the manifold with two $S^2$ boundaries. Then we plat this braid by gluing two balls $B_1$ and $B_2$ with Wilson lines as shown in Figure 5.

Each of the two caps again represents a state $|\psi(\{R_j\})\rangle$ in the Hilbert space associated with the conformal field theory on punctured boundary ($S^2$). Platting of the braid then simply is the matrix element of braid representation $\mathcal{B}(\{R_i\},\{R'_j\})$ with respect to these states $|\psi(\{R_i\})\rangle$ and $|\psi(\{R'_j\})\rangle$ corresponding to two caps $B_1, B_2$. Thus, for a link in $S^3$ the invariant is given by the following theorem:

**Theorem** *The vacuum expectation value of Wilson loop operator of a link L constructed from platting of a colored oriented 2n braid with representation* $\mathcal{B}(\{R_i\},\{R'_j\})$ *is given by* (Kaul 1999):

$$V[L] = \langle \psi(\{R_i\}) | \mathcal{B}(\{R_i\},\{R'_j\}) | \psi(\{R'_j\}) \rangle \qquad [11]$$

This theorem can be used to calculate the invariant for any arbitrary link. For an unknot $U$



(a) (b)

**Figure 4** (a) Platting and (b) closure of braids.

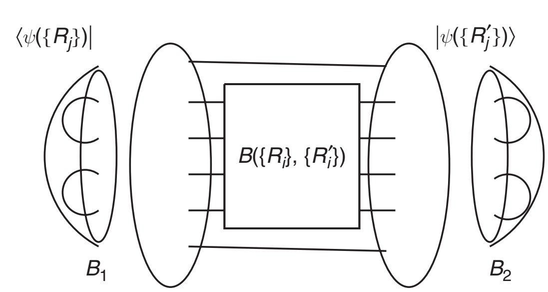


**Figure 5** Construction of the link invariant.

carrying an $N$-dimensional representation in an SU($N$) CS theory, the knot invariant is:

$$V_N[U] = [N], \quad \text{where } [N] = \frac{q^{N/2} - q^{-N/2}}{q^{1/2} - q^{-1/2}}$$

Wilson link expectation values calculated this way depend on the regularization, that is, the definition of framing used in defining coincident loop correlators. One such regularization usually used is the standard framing, where the frame for every knot is so chosen that its self-linking number is zero.

The procedure outlined here has been used for explicit computations of knot/link invariants. This has led to answers to several questions of knot theory. One such question relates to distinguishing chirality of knots (Kaul 1999). In this context, newer invariants constructed with arbitrary representations living on the knots are more powerful than the older polynomial invariants. For example, invariants with spin-3/2 representation in an SU(2) CS theory are sensitive to chirality of many knots which otherwise is not detected by Jones, HOMFLY, and Kauffman polynomials. However, invariants obtained from CS theories do not distinguish all chiral knots. There is a class of links known as "mutants" which are not distinguished by CS link invariants (Kaul 1999). A mutant link is obtained by removing a portion of weaving pattern in a link and then gluing it back after rotating it about any one of three orthogonal axes by an amount $\pi$.

The CS invariants of knots and links can also be used to construct special 3-manifold invariants. Hence, CS theory provides an important tool to study these.

## Manifold Invariants from CS Theory

Different 3-manifolds can be constructed through a procedure called "surgery of framed knots and links" in $S^3$ (Lickorish–Wallace theorem). This construction is not unique. That is, there are many framed knots and links which give the same manifold. However, rules of this equivalence are known: these are called "Kirby moves."

Classification of 3-manifolds would involve finding a method of associating a quantity with the manifold obtained by surgery on the corresponding framed knot/link on $S^3$. If the Kirby moves on the framed knot/link leave this quantity unchanged, then it is a 3-manifold invariant. Knot/link invariants of nonabelian CS theories provide a method of finding such 3-manifold invariants. Equivalently, this procedure gives an algebraic meaning to the surgery construction of 3-manifolds. Details of this method for generating manifold invariants are given in Kaul (1999) and Kaul and Ramadevi (2001).

### Surgery of Framed Knots/Links and Kirby Moves

As discussed earlier, frame of a knot $K$ is an associated closed curve $K_f$ going along the length of the knot wrapping around it certain number of times. Self-linking number (also called framing number) is equal to the linking number of the knot with its frame. There are several ways of fixing this framing. The "standard" framing is one in which the frame number of the knot, that is, the linking number of the knot and its frame is zero. On the other hand, "vertical" framing is obtained by choosing the frame vertically above the knot projected on to a plane. In such a frame, the framing number of a knot is the same as its crossing number. In constructing the 3-manifold invariants from CS theories, we need vertical framing. The framing number may be denoted by writing the integer by the side of knot. We denote a framed $r$-component link by $[L, f]$ where framing $f = (n(1), n(2), \ldots, n(r))$ is a set of integers denoting the framing number of component knots $K_1, K_2, \ldots, K_r$ in the link $L$.

According to the Lickorish–Wallace theorem, surgery over links with vertical framing in $S^3$ yields all the 3-manifolds. This surgery is performed in the following way.

Take a framed $r$-component link $[L, f]$ in $S^3$. Thicken the component knots $K_1, K_2, \ldots, K_r$ such that the solid tubes $N_1, N_2, \ldots, N_r$ so obtained are nonintersecting. Then the compliment $S^3 - (N_1 + N_2 + \cdots + N_r)$ will have $r$ toral boundaries. On the $i$th toral boundary, we imagine an appropriate curve winding $n(i)$ times around the meridian and once along the longitude. Perform a modular transformation so that this curve bounds a disk. This construction is done with each of the toral boundaries. The tubes $N_1, N_2, \ldots, N_r$ are then glued back in to the respective gaps. This surgery thus yields a new 3-manifold. This construction is not unique. The rules of equivalence for surgery on framed knots/links in $S^3$ are two independent Kirby moves.

**Kirby move I** Take an arbitrary $r$-component framed link $[L, f]$ in $S^3$ and consider a curve $C$ with framing number +1 going around the unlinked strands of $L$ as in Figure 6a. We refer to this $(r + 1)$-component link as $H[X]$, where $X$ represents a weaving pattern of the strands. Kirby move I consists of twisting the disk enclosed by $C$ in the clockwise direction from below by an amount $2\pi$. This twisting thereby introduces new crossings

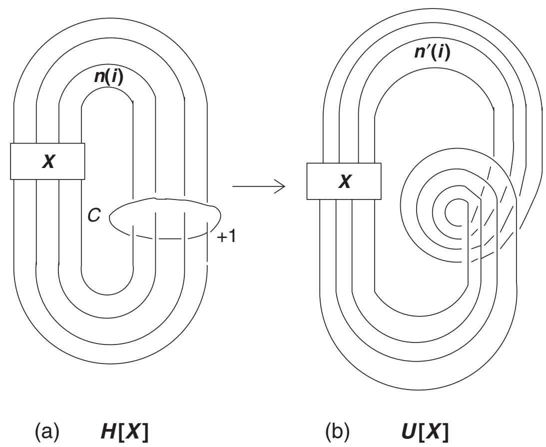

**Figure 6** Kirby move I.

between the curve $C$ and the strands enclosed by it. Then the curve $C$ is removed giving us a new $r$-component link $U[X]$ of Figure 6b. Framing numbers $n'(i)$ of the component knots in link $U[X]$ are related to the framing number $n(i)$ of framed link $[L, f]$ as $n'(i) = n(i) - (\mathcal{L}(K_i, C))^2$, where $\mathcal{L}(K_i, C)$ is the linking number of knot $K_i$ and closed curve $C$. The surgery of the framed links in Figures 6a and 6b will give the same 3-manifold.

Inverse Kirby move I involves removal of a curve $C$ with framing number –1 (instead of +1) after making one complete anticlockwise twist from below on the disk enclosed by $C$. In the process the unlinked strands get twisted in the anticlockwise direction leading to changed framing numbers $n'(i) = n(i) + (\mathcal{L}(K_i, C))^2$ of the component knots $K_i$.

**Kirby move II** This move consists of removing a disjoint unknot $C$ with framing –1 from framed link $[L, f]$ without changing the rest of the link as in Figure 7. Surgery of the two links in Figure 7 will give the same manifold.

Inverse Kirby move II involves removal of a disjoint unknot with framing +1 (instead of –1) from a framed link.

### 3-Manifold Invariants

Now a 3-manifold invariant can be constructed by an appropriate combination of the invariants of framed links in such a way that this algebraic expression is unchanged under the Kirby moves. We

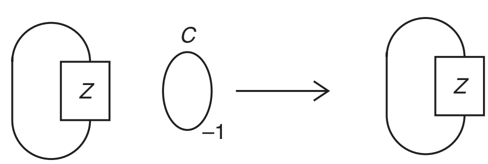

**Figure 7** Kirby move II.

need for this purpose invariants for links in $S^3$ with vertical framing.

Let $\mathcal{M}$ be the manifold obtained from surgery of an $r$-component framed link $[L, f]$ in $S^3$. Then a manifold invariant $\hat{F}^{(\mathcal{G})}[\mathcal{M}]$ is given as a linear combination of the framed link invariants $V^{(\mathcal{G})}_{R_1,\ldots,R_r}[L, f]$, with representations $R_1, R_2, \ldots, R_r$ living on component knots, obtained from CS theory based on a compact semisimple group $\mathcal{G}$:

$$\hat{F}^{(\mathcal{G})}[\mathcal{M}] = \alpha^{-\sigma[L,f]} \sum_{R_1,\ldots R_r} \left( \prod_{i=1}^{r} \mu_{R_i} \right) \times V^{(\mathcal{G})}_{R_1,R_2,\ldots,R_r}[L, f] \qquad [12]$$

Here $\sigma[L, f]$ is the signature of the linking matrix and $\mu_{R_i} = S_{0R_i}$, $\alpha = \mathrm{e}^{\mathrm{i}\pi c/4}$, where $c$ is the central charge of the associated WZNW conformal field theory and $S_{0R_i}$ denotes the matrix element of the modular matrix $S$. General $S$-matrix elements for any compact group are given by

$$S_{R_1R_2} = (-\mathrm{i})^{(d-r)/2} |L_\omega/L|^{-1/2} (k + C_v)^{-1/2} \times \sum_{\omega \in W} \epsilon(\omega) \exp\left( \frac{-2\pi\mathrm{i}}{k + C_v} (\omega(\Lambda_{R_1} + \rho), \Lambda_{R_2} + \rho) \right)$$

where $W$ denotes the Weyl group and its elements $\omega$ are words constructed using the generator $s_{\alpha_i}$ – that is, $\omega = \prod_i s_{\alpha_i}$ and $\epsilon(\omega) = (-1)^{\ell(\omega)}$ with $\ell(\omega)$ as length of the word. Here $\Lambda_{R_i}$'s denotes the highest weights of the representations $R_i$'s and $\rho$ is the Weyl vector. The action of the Weyl generator $s_\alpha$ on a weight $\Lambda_R$ is

$$s_\alpha(\Lambda_R) = \Lambda_R - 2\alpha \frac{(\Lambda_R, \alpha)}{(\alpha, \alpha)}$$

and $|L_\omega/L|$ is the ratio of weight and coroot lattices (equal to the determinant of the Cartan matrix for simply laced algebras). Also $C_v$ is quadratic Casimir invariant for the adjoint representation.

It is important to stress that the expression $\hat{F}^{(\mathcal{G})}[\mathcal{M}]$ is unchanged under both Kirby moves I and II (for detailed proof, see Kaul (1999) and Kaul and Ramadevi (2001)). Notice that for every compact gauge group, we have a new 3-manifold invariant.

**Few examples of 3-manifolds** Table 1 lists the algebraic expressions of this invariant calculated explicitly from the formula in eqn [12] for a few 3-manifolds. All these examples can be constructed by surgery on an unknot $U(f)$ with different frame numbers $f$.

In Table 1 $\mathcal{L}[p, q]$ stands for Lens spaces of the type $(p, q)$ and $C_R$ is the quadratic Casimir invariant

**Table 1** Invariants for some simple manifolds

| $U(f)$ | $\mathcal{M}$ | $\hat{F}^{(\mathcal{G})}[\mathcal{M}]$ |
|---|---|---|
| $U(0)$ | $S^2 \times S^1$ | $1/S_{00}$ |
| $U(\pm 1)$ | $S^3$ | $1$ |
| $U(+2)$ | $RP^3$ | $\alpha^{-1} \sum_R \frac{S_{0R}\, q^{2C_R}\, S_{0R}}{S_{00}}$ |
| $U(+p)$ | $\mathcal{L}[p,1]$ | $\alpha^{-1} \sum_R \frac{S_{0R}\, q^{pC_R}\, S_{0R}}{S_{00}}$ |

for representation $R$ of the Lie algebra of the gauge group $\mathcal{G}$.

Partition function of a CS theory on $\mathcal{M}$ is also an invariant characterizing the 3-manifold. This has been calculated for several manifolds by different methods. Invariant $\hat{F}^{(\mathcal{G})}[\mathcal{M}]$ listed above for various manifolds is related to the CS partition function $Z^{(\mathcal{G})}[\mathcal{M}]$: $\hat{F}^{(\mathcal{G})}[\mathcal{M}] = S_{00}^{-1} Z^{(\mathcal{G})}[\mathcal{M}]$. So the method of constructing 3-manifold invariants above can also be used to calculate the partition function of CS theories.

## 3D Gravity and CS Theory

Three-dimensional CS theory also provides a description of gravity. The 3D gravity including cosmological constant has been first discussed by Deser and Jackiw (1984). The action with cosmological constant $\Lambda = \pm 1/\ell^2$ is:

$$S = \frac{1}{16\pi G} \int_{\mathcal{M}} \mathrm{d}^3x \sqrt{-g}(R - 2\Lambda) \qquad [13]$$

G is the Newton's constant, $g_{\mu\nu}$ is the metric on the 3-manifold $\mathcal{M}$, and R is scalar curvature. Solutions of Einstein equations of motion have a constant positive (negative) curvature if $\Lambda$ is positive (negative). It is also well known that there are no dynamical degrees of freedom for gravity in dimensions $D \leq 3$; it is indeed described by topological field theories. The gravity action above can be rewritten as a CS gauge theory in first-order formulation (Carlip 2003). For triads $e^a_\mu$ and spin connection $\omega^a_\mu$ of Euclidean gravity, we define 1-forms $e = e^a_\mu T^a\, \mathrm{d}x^\mu, \omega = \omega^a_\mu T^a \mathrm{d}x^\mu$, which have values in the Lie algebra of SU(2) whose generators are $T^a = \mathrm{i}\sigma^a/2$ with $\sigma^a$ as three Pauli matrices. In terms of these we define two gauge field 1-forms $A$ and $\bar{A}$ as:

$$A = \left(\frac{\mathrm{i}e}{\ell} + \omega\right), \qquad \bar{A} = \left(\frac{\mathrm{i}e}{\ell} - \omega\right)$$

Then the Euclidean gravity action can be written in terms of two CS actions, $S_{\mathrm{CS}}[A]$ and $S_{\mathrm{CS}}[\bar{A}]$, as

$$S = kS_{\mathrm{CS}}[A] - kS_{\mathrm{CS}}[\bar{A}] \qquad [14]$$

where the coupling constant $k = \ell/(4G)$ for negative cosmological constant $\Lambda = -1/\ell^2$. The gauge group for this theory is $\mathrm{SL}(2, C)$. Infinitesimal diffeomorphisms are described by field-dependent gauge transformations. The corresponding gauge group for Minkowski gravity with negative cosmological constant $\Lambda$ is $\mathrm{SO}(2,R) \otimes \mathrm{SO}(2,R)$. For positive $\Lambda$, one gets $\mathrm{SO}(3,1)$ and $\mathrm{SO}(4)$ for Minkowski and Euclidean metrics, respectively. For $\Lambda = 0$, we have $\mathrm{ISO}(2,1)$ ($\mathrm{ISO}(3)$) as the gauge group for Minkowski (Euclidean) gravity. Hence, the sign of cosmological constant determines the gauge group of the CS theory.

Identification of 3D gravity with CS theory can be used with some advantage to find the partition function for a black hole in 3D gravity with negative cosmological constant. This in turn yields an expression for entropy of the black hole.

### BTZ Black Hole and Its Partition Function

Only for negative $\Lambda$ we have a black hole solution of the Einstein's equations. This solution, known as the BTZ black hole (Carlip 2003), in Euclidean gravity is given by the metric

$$\mathrm{d}s^2_{\mathrm{E}} = \left(-M + \frac{r^2}{l^2} - \frac{J^2}{4r^2}\right)\mathrm{d}\tau^2 + \left(-M + \frac{r^2}{l^2} - \frac{J^2}{4r^2}\right)^{-1} \mathrm{d}r^2 + r^2\left(\mathrm{d}\phi - \frac{J}{2r}\mathrm{d}\tau\right)^2$$

It is specified by two parameters $M$ and $J$ (the mass and angular momentum). By a coordinate transformation, this metric can be rewritten as $\mathrm{d}s^2_{\mathrm{E}} = (l^2/z^2)(\mathrm{d}x^2 + \mathrm{d}y^2 + \mathrm{d}z^2)$, with $z > 0$. This is the 3D upper-half hyperbolic space and can be rewritten using spherical polar coordinates as

$$\mathrm{d}s^2_{\mathrm{E}} = \frac{l^2}{R^2 \sin^2\chi}\left(\mathrm{d}R^2 + R^2\mathrm{d}\theta^2 + R^2 \sin^2\theta \mathrm{d}\chi^2\right)$$

We have the identifications $(R, \theta, \chi) \sim (R \exp\{2\pi r_+/l\}, \theta + \{2\pi r_-/l\}, \chi)$ where $r_+$ and $r_-$ are the outer and inner horizon radii, respectively. It is clear from this identification that topologically the metric corresponds to a solid torus. Functional integral over this manifold represents a state in the Hilbert space specified by the mass and angular momentum. It is the microcanonical ensemble partition function and its logarithm is the entropy of the black hole.

To evaluate this partition function, the connection 1-form is kept at a constant value on the toroidal boundary through a gauge transformation. We

define local coordinates on the torus boundary $z = x + \tau y$ such that $\int_a \mathrm{d}z = 1$, $\int_b \mathrm{d}z = \tau$, where $a$ ($b$) stands for the contractible (noncontractible) cycle of solid torus and $\tau = \tau_1 + \mathrm{i}\tau_2$ is the modular parameter of the boundary torus. Then connection describing the black hole is

$$A = \left( \frac{-\mathrm{i}\pi \tilde{u}}{\tau_2} \mathrm{d}\bar{z} + \frac{\mathrm{i}\pi u}{\tau_2} \mathrm{d}z \right) T^3 \qquad [15]$$

where $u$ and $\tilde{u}$ are canonically conjugate with commutation relation: $[\tilde{u}, u] = (2/\pi)\tau_2(k+2)^{-1}$. These are related to black hole parameters through holonomies of gauge field $A$ around the $a$- and $b$-cycles (for a classical black hole solution $\Theta = 2\pi$):

$$u = -\frac{\mathrm{i}}{2\pi}\left( -\mathrm{i}\Theta\tau + \frac{2\pi(r_+ + \mathrm{i}|r_-|)}{l} \right)$$

$$\tilde{u} = -\frac{\mathrm{i}}{2\pi}\left( -\mathrm{i}\Theta\bar{\tau} + \frac{2\pi(r_+ + \mathrm{i}|r_-|)}{l} \right)$$

For a fixed value of connection, namely $u$, the functional integral is described by a state $\psi_0$ with no Wilson line in the bulk. The states with Wilson line carrying spin $j/2$ are given by Labastida and Ramallo:

$$\psi_j(u, \tau) = \exp\left\{ \frac{\pi k}{4\tau_2} u^2 \right\} \chi_j(u, \tau)$$

where the Weyl–Kac characters for affine su(2)

$$\chi_j(u, \tau) = \frac{\Theta_{j+1}^{(k+2)}(u, \tau) - \Theta_{-j-1}^{(k+2)}(u, \tau)}{\Theta_1^2(u, \tau) - \Theta_{-1}^2(u, \tau)}$$

and $\Theta$ functions are defined by

$$\Theta_\mu^k(u, \tau) = \sum_{n \in \mathcal{Z}} \exp\left\{ 2\pi \mathrm{i} k \left[ \left( n + \frac{\mu}{2k} \right)^2 \tau + \left( n + \frac{\mu}{2k} \right) u \right] \right\}$$

Given the collection of states $\psi_j$, we write the partition function by choosing an appropriate ensemble for fixed mass and angular momentum. This black hole partition function is:

$$Z_{\mathrm{BH}} = \int \mathrm{d}\mu(\tau, \bar{\tau}) \left| \sum_{j=0}^{k} (\psi_j(0, \tau))^* \psi_j(u, \tau) \right|^2$$

where modular invariant measure is $\mathrm{d}\mu(\tau, \bar{\tau}) = \mathrm{d}\tau\, \mathrm{d}\bar{\tau}/\tau_2^2$. This integral can be worked out for large black hole mass and zero angular momentum in saddle-point approximation. The computation yields (Govindarajan *et al.* 2001):

$$Z_{\mathrm{BH}} = \frac{l^2}{r_+^2} \sqrt{\frac{8 r_+ G}{\pi l^2}} \exp\left( \frac{2\pi r_+}{4G} \right) + \cdots \qquad [16]$$

This gives not only the leading Bekenstein–Hawking behavior of the black hole entropy $S$ but also a subleading logarithmic term:

$$S = \ln Z_{\mathrm{BH}} = \frac{2\pi r_+}{4G} - \frac{3}{2} \ln \frac{2\pi r_+}{4G} + \cdots$$

This is an interesting application of CS theory to 3D gravity. In fact, three-dimensional CS theory also has applications in the study of black holes in four-dimensional gravity: the boundary degrees of freedom of a black hole in 4D are also described by an SU(2) CS theory. This allows a calculation of the degrees of freedom of, for example, Schwarzschild black hole. For large area black holes, this in turn results in an expression for the entropy which, besides a Bekenstein–Hawking area term, has a logarithmic area correction with same coefficient –3/2 as above. This suggests a universal, dimension-independent, nature of the these logarithmic corrections.

# Seiberg–Witten Theory

**Siye Wu**, University of Colorado, Boulder, CO, USA

## Introduction

Gauge theory is the cornerstone of the standard model of elementary particles. The original motivation for studying supersymmetric gauge theories was phenomenological (such as the hierarchy problem). They display a large number of interesting phenomena and become the models for the dynamics of strongly coupled field theories. They also offer valuable insights to nonsupersymmetric models. In $N=1$ gauge theory, the low-energy effective superpotential is holomorphic both in the superfields and in the coupling constants. This powerful holomorphy principle, together with symmetry and various limits, often determines the effective superpotential completely. Such theories often have quantum moduli spaces where the classical singularities are smoothed out, continuous interpolation between Higgs and confinement phases, massless composite mesons and baryons, and dual theories weakly coupled at low energy. For $N=2$ pure gauge theory, the low-energy effective theory is an abelian gauge theory in which both the kinetic term and the coupling constant are determined by a holomorphic prepotential. The electric–magnetic duality is in the ambiguity of the low-energy description. Much physical information, such as the coupling constant, the Kähler metric on the quantum moduli, the monodromy around the singularities, can be incorporated in a family of elliptic curves. This low-energy exact solution is also useful to topological field theory that can be obtained from the $N=2$ theory by twisting. Much of the above was the work of Seiberg and Witten in the mid-1990s. In this article, we review some of the fascinating aspects of $N=1$ and $N=2$ supersymmetric gauge theories.

## $N=1$ Gauge Theory and Seiberg Dualities

### $N=1$ Yang–Mills Theory and QCD

Let $G$ be a compact Lie group and let $P$ be a principal $G$-bundle over the Minkowski space $\mathbb{R}^{3,1}$. In pure gauge theory, the dynamical variable is a connection $A$ in $P$; two connections are equivalent if they are related by a gauge transformation. Let $F \in \Omega^2(\mathbb{R}^{3,1}, \mathrm{ad}\,P)$ be the curvature of $A$. It decomposes into the self-dual and anti-self-dual parts, that is, $F = F^+ + F^-$, where $F^{\pm} = (1/2)(F \mp \sqrt{-1} * F)$. With a suitably normalized nondegenerate bilinear form $\langle \cdot,\cdot \rangle$ on the Lie algebra $\mathfrak{g}$, the classical action is

$$S_{\mathrm{YM}}[A] = \int_{\mathbb{R}^{3,1}} -\frac{1}{2g^2}\langle F \wedge *F\rangle + \frac{\theta}{16\pi^2}\langle F \wedge F\rangle$$
$$= \int_{\mathbb{R}^{3,1}} -\frac{\tau}{8\pi}\langle F^+ \wedge F^+\rangle - \frac{\bar{\tau}}{8\pi}\langle F^- \wedge F^-\rangle$$

Here $g > 0$ is the coupling constant and $\theta \in \mathbb{R}$, the $\theta$ angle, and

$$\tau = \frac{\theta}{2\pi} + \frac{4\pi\sqrt{-1}}{g^2}$$

is a complex number in the upper-half plane that incorporates both. Classically, the theory is conformally invariant and the dynamics is independent of the $\theta$-term. At the quantum level, $\theta(\mathrm{mod}2\pi)$ appears in the path integral and parametrizes inequivalent vacua. The coupling constant runs as energy $\mu$ varies, satisfying the renormalization group equation

$$\mu\frac{\mathrm{d}g}{\mathrm{d}\mu} = -\frac{b_0}{(4\pi)^2}g^3 + o(g^5)$$

where the right-hand side is called the $\beta$-function $\beta(g)$. This introduces, when $b_0 \neq 0$, a mass scale $\Lambda$ given by

$$(\Lambda/\mu)^{b_0} = \mathrm{e}^{-8\pi^2/g(\mu)^2}$$

up to one-loop. Consequently, the classical scale invariance is lost. It is convenient to redefine $\Lambda$ as a complex quantity such that

$$(\Lambda/\mu)^{b_0} = \mathrm{e}^{2\pi\sqrt{-1}\tau(\mu)}$$

For pure gauge theory, $b_0 = (11/3)\check{h}$, where $\check{h}$ is the dual Coxeter number of $\mathfrak{g}$. At high energy ($\mu \to \infty$), the coupling becomes weak ($g \to 0$); this is known as asymptotic freedom. On the contrary, the interaction becomes strong at low energy. It is believed that the theory exhibits confinement and has a mass gap.

QCD, or quantum chromodynamics, is gauge theory coupled to matter fields. Suppose the boson $\phi$ and the fermion $\psi$ are in the (complex) representations $R_b$ and $R_f$ of $G$, respectively. That is, $\phi \in \Gamma(P \times_G R_b)$, or $\phi$ is a section of the bundle $P \times_G R_b$, and $\psi \in \Gamma(S \otimes (P \times_G R_f))$, where $S$ is the spinor bundle over $\mathbb{R}^{3,1}$. The classical action is

$$S_{\mathrm{QCD}}[A,\phi,\psi] = S_{\mathrm{YM}}[A] + \frac{1}{g^2}\int \mathrm{d}^4x \frac{1}{2}|\nabla\phi|^2 + \sqrt{-1}(\psi, \nabla\!\!\!/\,\psi) + \cdots$$

where $\nabla$ is the covariant derivative, $\nabla\!\!\!/$ is the Dirac operator coupled to $A$, and we have omitted possible mass and potential terms. The quantum theory depends sensitively on the representations $R_b$ and $R_f$. In the $\beta$-function, we have

$$b_0 = \tfrac{11}{3}\check{h} - \tfrac{1}{6}\nu(R_b) - \tfrac{2}{3}\nu(R_{\mathrm{f}})$$

where $\nu(R)$ is the Dynkin index of a representation $R$. If $b_0 < 0$, the theory is free in the infrared but strongly interacting in the ultraviolet. If $b_0 > 0$, the converse is true; in particular, the theory exhibits asymptotic freedom. If $b_0 = 0$, the situation depends on the sign of the two or higher-loop contributions.

Pure $N = 1$ supersymmetric gauge theory is one on the superspace $\mathbb{R}^{3,1|(2,2)}$ with a constraint that the curvature vanishes in the odd directions. The dynamical variables are in the superfield strength $W$, a $1|(1,0)$-form valued in ad $P$. In components, the theory is gauge field coupled to a Majorana or Weyl fermion in the adjoint representation. Let $S^{\pm}$ be spinor bundles of positive (negative) chiralities, respectively, and let $\lambda$ be a section of $S^+ \otimes \mathrm{ad}P$. The action, written both in superspace and in ordinary spacetime, is

$$S_{\mathrm{SYM}}^{N=1}[A,\lambda] = \frac{1}{4\pi}\mathrm{Im}\left(\int \mathrm{d}^4x\, \mathrm{d}^2\theta\, \tau\langle W, W\rangle\right) = S_{\mathrm{YM}}[A] + \frac{1}{g^2}\int \mathrm{d}^4x\sqrt{-1}\langle\bar{\lambda}, \nabla\!\!\!/^{+}\lambda\rangle$$

Since $b_0 = 3\check{h}$, the theory is asymptotically free but strongly coupled at low energy. Classically, the theory has a $\mathrm{U}(1)_R$ chiral symmetry. However, due to anomaly, only the subgroup $\mathbb{Z}_{2\check{h}}$ survives at the quantum level. Instanton effect yields gaugino condensation $\langle\lambda\lambda\rangle \sim \Lambda^3$. The symmetry is thus further broken to $\mathbb{Z}_2$, resulting $\check{h}$ inequivalent vacua.

The $N = 1$ QCD has additional chiral superfields $\Phi$ in a representation $R$, including the bosons $\phi \in \Gamma(P \times_G R)$ and the fermions $\psi \in \Gamma(S^+ \otimes (P \times_G R))$. In the absence of superpotential, the action is

$$S_{\mathrm{SQCD}}^{N=1}[A,\lambda,\phi,\psi] = S_{\mathrm{SYM}}^{N=1}[A,\lambda] + \frac{1}{g^2}\int \mathrm{d}^4x\, \mathrm{d}^2\theta\, d^2\bar{\theta}\, \tfrac{1}{2}|\Phi|^2$$

In components, the second term is

$$\frac{1}{g^2}\int \mathrm{d}^4x\left(\tfrac{1}{2}|\nabla\phi|^2 + \sqrt{-1}(\psi, \nabla\!\!\!/^{+}\psi) - \tfrac{1}{2}\phi^*|D|^2 + \cdots\right)$$

where $D: R \to \mathfrak{g}^*$ is the moment map of the Hamiltonian $G$-action on $R$, and we have omitted other terms containing fermionic fields. The moduli space of classical vacua is the symplectic quotient $D^{-1}(0)/G = R//G$. It is the same as the Kähler quotient $R^{\mathrm{s}}/G^{\mathbb{C}}$, where the stable subset $R^{\mathrm{s}} = \{\phi \in R | G^{\mathbb{C}} \cdot \phi \cap D^{-1}(0) \neq \emptyset\}$ is open and dense in $R$. Again, the quantum theory depends on the representation $R$. Since $b_0 = 3\check{h} - (1/2)\nu(R)$, the theory is asymptotically free, infrared free, scale invariant (to one-loop) when $\nu(R) < 6\check{h}, \nu(R) > 6\check{h}, \nu(R) = 6\check{h}$, respectively. The moduli space may be lifted by a superpotential or modified by other quantum effects.

### $\mathrm{SU(N_c)}$ Theories at Low Energy

We now consider $N = 1$ QCD with $G = \mathrm{SU}(N_c)$; $N_c$ is the number of colors. The matter field consists of $N_f$ copies of quarks $Q^i (1 \le i \le N_f)$ in the fundamental representation of $\mathrm{SU}(N_c)$ and $N_f$ copies of antiquarks $Q'_{i'} (1 \le i' \le N_f)$ in the conjugate representation. Using the isomorphism of $\mathfrak{su}(N_c)$ with its dual, the moment map is

$$D(Q, Q') = \text{traceless part of } \sqrt{-1}(QQ^{\dagger} - Q'Q'^{\dagger})$$

So $(Q, Q') \in D^{-1}(0)$ if and only if $QQ^{\dagger} - Q'^{\dagger} = cI_{N_c}$ for some $c \in \mathbb{R}$. If $N_f < N_c$, then $c = 0$ and

$$Q, Q' \sim \begin{pmatrix} a_1 & & \\ & \ddots & \\ & & a_{N_f} \end{pmatrix}$$

for some $a_k \geq 0$. Generically, these $a_k > 0$ and the gauge group $SU(N_c)$ is broken to $SU(N_c - N_f)$. If $N_f \geq N_c$, then

$$Q \sim \begin{pmatrix} a_1 & & \\ & \ddots & \\ & & a_{N_c} \end{pmatrix}, \qquad Q' \sim \begin{pmatrix} a'_1 & & \\ & \ddots & \\ & & a'_{N_c} \end{pmatrix}$$

where $a_k, a'_k \geq 0$ satisfy $a_k^2 - a'^2_k = c$ for some $c \in \mathbb{R}$. The gauge group is completely broken. The low-energy superfields are the mesons $M^i_{i'} = Q^i Q'_{i'}$ and, if $N_f \geq N_c$, the baryons

$$B_{i_{N_c+1}\cdots i_{N_f}} = \frac{1}{N_c!}\epsilon_{i_1\cdots i_{N_f}} Q^{i_1}\cdots Q^{i_{N_c}}$$
$$B'^{i'_{N_c+1}\cdots i'_{N_f}} = \frac{1}{N_c!}\epsilon^{i'_1\cdots i'_{N_f}} Q'_{i'_1}\cdots Q'_{i'_{N_c}}$$

When $N_f < N_c$, Affleck *et al.* (1984) found a dynamically generated superpotential

$$W_{\text{eff}}(\hat{M}) = (N_c - N_f)\left(\frac{\Lambda^{3N_c - N_f}}{\det M}\right)^{1/(N_c - N_f)}$$

generated by instanton effect when $N_f = N_c - 1$ and by gaugino condensation in the unbroken $SU(N_c - N_f)$ theory when $N_f < N_c - 1$. It is also the unique superpotential (up to a multiplicative constant) that is consistent with the global and supersymmetry. The potential pushes the vacuum to infinity. Therefore, contrary to the classical picture, theories with $N_f < N_c$ do not have a vacuum at the quantum level.

When $N_f \geq 3N_c$, the theory is not strongly interacting at low energy, and perturbation methods are reliable. (When $N_f = 3N_c$, the two-loop contribution to the $\beta$-function is negative.) We now look at the range $N_c \leq N_f < 3N_c$. The cases $N_f = N_c, N_c + 1$ and $N_c + 2 \leq N_f < 3N_c$ were studied in Seiberg (1994) and Seiberg (1995), respectively.

When $N_f = N_c$, the classical moduli space is $\det M = BB'$. The quantum theory at low energy consists of the fields $M$, $B$, $B'$ satisfying the constraint $\det M - BB' = \Lambda^{2N_c}$. The quantum moduli space is smooth everywhere, and there are no additional massless particles. So the gluons are heavy throughout the moduli space. This is due to confinement near the origin, where the interaction is strong, and due to the Higgs mechanism far out in the flat direction, where the classical picture is a good approximation. We see a smooth transition between these two effects.

When $N_f = N_c + 1$, there is a dynamically generated superpotential

$$W_{\text{eff}} = \frac{1}{\Lambda^{2N_c - 1}}(B'MB - \det M)$$

The stationary points of $W_{\text{eff}}$ are at $BB' - \wedge^{N_c} M = 0$, $BM = 0, MB' = 0$; these are precisely the constraints that the classical configuration satisfies. However, the moduli space is interpreted differently: it is embedded into a larger space, and the constraints are satisfied only at stationary points. At the singularity $\langle M \rangle = 0$, the whole global symmetry group is unbroken, and $B, B'$ are the new massless fields resolving the singularity. So we have a continuous transition between confinement (without chiral symmetry breaking) and the Higgs mechanism in the semiclassical regime.

When $N_c + 2 \leq N_f \leq (3/2)N_c$, the original theory, called the electric theory, is still strongly coupled in the infrared. Seiberg (1995) proposed that there is a dual, magnetic theory, which is infrared free. The two theories are different classically, but are equivalent at the quantum level. The dual theory is an $N = 1 SU(\tilde{N}_c)$ gauge theory with $\tilde{N}_c = N_f - N_c$, coupled to dual quarks $\tilde{Q}_i, \tilde{Q}'^{i'}$, where $1 \leq i; i' \leq N_f$ are flavor indices. In addition, the mesons $M^i_{i'}$ become fundamental fields. They are not coupled to the $SU(\tilde{N}_c)$ gauge field but interact with the dual quarks through the superpotential

$$W = \mu^{-1} M^i_{i'} \tilde{Q}_i \tilde{Q}'^{i'}$$

The two theories have the same global symmetry and the same gauge-invariant operators. The dual quarks are fundamental in the magnetic theory but are solitonic excitations in the electric theory. At high energy, the electric theory is asymptotically free, while the magnetic theory is strongly coupled. At low energies, the converse is true. Therefore, reliable perturbative calculations can be performed by choosing an appropriate weakly coupled theory.

When $(3/2)N_c < N_f < 3N_c$, the theory has a nontrivial infrared fixed point. This is because up to two-loop,

$$\beta(g) = -\frac{g^3}{16\pi^2}(3N_c - N_f) + \frac{g^5}{128\pi^4}\left(2N_c N_f - 3N_c^2 - \frac{N_f}{N_c}\right) + o(g^7)$$

There is a solution $g_* > 0$ to $\beta(g) = 0$. We have $\beta(g) < 0$ when $0 < g < g_*, \beta(g) > 0$ when $g > g_*$. In the infrared limit, the coupling constant flows to $g = g_*$, where we have a nontrivial, interacting superconformal theory in four dimensions. The conformal dimension becomes anomalous and is equal to 3/2 of the charge of the chiral $U(1)_R$; for example, that of the meson $\mu^{-1}M$ is $3(N_f - N_c)/N_f > 1$ in this range.

### Other Classical Gauge Groups

We now consider $N=1$ supersymmetric gauge theory and QCD with gauge groups $Sp(N_c)$ and $SO(N_c)$. The $Sp(N_c)$ theories, studied by Intriligator and Pouliot (1995), are the simplest examples of the $N=1$ theories. We take $2N_f$ chiral superfields $Q_i (i=1,\ldots,2N_f)$ in the fundamental representation $\mathbb{C}^{2N_c} \cong \mathbb{H}^{N_c}$ of $Sp(N_c)$. The number of copies must be even so that the quantum theory is free from global gauge anomaly. The gauge-invariant quantities are the mesons $M_{ij}=Q_i^a Q_j^b \omega_{ab}$, where $\omega$ is the symplectic form on $\mathbb{C}^{2N_c}$, subject to a constraint $\epsilon^{1,\ldots,2N_c+2} M_{1,2} \cdots M_{2N_c+1,2N_c+2}=0$. Using the decomposition $\mathfrak{u}(2N_c)=\mathfrak{sp}(N_c) \oplus \sqrt{-1}\{\mathbb{H}\text{-self-adjoint matrices}\}$, the moment map $D(Q)$ is the projection of $\sqrt{-1}QQ^\dagger$ on $\mathfrak{sp}(N_c)$. So $D(Q)=0$ implies

$$Q \sim \begin{pmatrix} a_1 & & \\ & \ddots & \\ & & a_{\min\{N_c,N_f\}} \end{pmatrix} \otimes \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$$

where $a_k \geq 0$. At a generic point of the classical moduli space, the gauge group is broken to $Sp(N_c - N_f)$ if $N_c > N_f$; it is completely broken if $N_c \leq N_f$.

Since $b_0 = 3(N_c+1) - N_f$, the quantum theory is infrared free if $N_f \geq 3(N_c+1)$. (When $b_0=0$, the two-loop $\beta$-function is negative.) When $N_f \leq N_c$, there is a dynamically generated superpotential

$$W_{\text{eff}} = (N_c + 1 - N_f) \times \left( \frac{2^{N_c-1} \Lambda^{3(N_c+1)-N_f}}{\text{Pf}\, M} \right)^{1/(N_c+1-N_f)}$$

pushing the vacuum to infinity.

When $N_f = N_c$, the classical moduli space $\text{Pf}M=0$ has singularities. The quantum moduli space is $\text{Pf}\, M = 2^{N_c-1}\Lambda^{2(N_c+1)}$. The singularity is smoothed out and there are no light fields other than the mesons $M$. When $N_f = N_c+1$, all components of $M$ become dynamical in the low-energy theory, and there is a superpotential

$$W_{\text{eff}} = -\frac{\text{Pf}\, M}{2^{N_c-1}\Lambda^{2N_c+1}}$$

At the most singular point $\langle M \rangle = 0$, the global symmetry is unbroken, and all the light fields in $M$ become massless. In both cases, there is a transition between confinement and Higgs mechanism.

When $N_c + 3 \leq N_f \leq (3/2)(N_c+1)$, there is a dual, magnetic theory which is free in the infrared. The dual theory has $2N_f$ quarks $\tilde{Q}^i$ in the fundamental representation of $Sp(\tilde{N}_c)$, where $\tilde{N}_c = N_f - N_c - 2$. In addition, the mesons $M_{ij}$ become elementary and couple to $\tilde{Q}$ through a superpotential $W=(2\mu)^{-1} M_{ij} \tilde{Q}^{ia} \tilde{Q}^{jb} \tilde{\omega}_{ab}$, where $\tilde{\omega}$ is the symplectic form on $\mathbb{C}^{2\tilde{N}_c}$. When $(3/2)(N_c+1) < N_f < 3(N_c+1)$, the theory flows to an interacting superconformal field theory in the infrared.

Theories with the $SO(N_c)$ gauge group were studied by Seiberg (1995) and by Intriligator and Seiberg (1995). Since the fundamental representation is real, there is no constraint on the number $N_f$ of quarks $Q^i (1 \leq i \leq N_f)$. The gauge invariants are the mesons $M^{ij}=Q_a^i Q_b^j \delta^{ab}$ and, if $N_f \geq N_c$, the baryons $B_{i_{N_c+1}\cdots i_{N_f}} = \epsilon_{i_1 \cdots i_{N_f}} Q^{i_1} \cdots Q^{i_{N_c}}/N_c!$ They satisfy rank $M \leq N_c$ and $BB = \wedge^{N_c} M$. Using the decomposition $\mathfrak{u}(N_c) = \mathfrak{so}(N_c) \oplus \sqrt{-1}\{\mathbb{R}\text{-self-adjoint matrices}\}$, the moment map $D(Q)$ is the projection $\sqrt{-1}QQ^\dagger$ on $\mathfrak{so}(N_c)$. If $D(Q)=0$, then up to gauge and global symmetries, $Q$ is of the form

$$Q \sim \begin{pmatrix} a_1 & & \\ & \ddots & \\ & & a_r \end{pmatrix}$$

where $a_1,\ldots,a_r > 0$ if $r = \text{rank}\, Q \leq N_c$ and $a_1,\ldots,a_{N_c-1} > 0$ and $a_{N_c} \neq 0$ if $r = N_c$. Generically, the gauge group is broken to $SO(N_c - N_f)$ if $N_c \geq N_f + 2$ and is totally broken if $N_c < N_f + 2$.

We have $b_0 = 3(N_c-2) - N_f$ if $N_c \geq 5$. For $N_c = 4$, the group is $(SU(2) \times SU(2))/\mathbb{Z}_2$ and $b_0 = 6 - N_f$ for each $SU(2)$ factor. If $N_c = 3$, the group is $SU(2)/\mathbb{Z}_2 b_0 = 6 - 2N_f$. The theory is asymptotically free if $N_f > 3(N_c-2)$ and infrared free if $N_f \geq 3(N_c-2)$.

When $N_f \leq N_c - 5$, there is a dynamically generated superpotential

$$W_{\text{eff}} = \frac{1}{2}(N_c - 2 - N_f) \times \left( \frac{16\Lambda^{3(N_c-2)-N_f}}{\det M} \right)^{1/(N_c-2-N_f)}$$

lifting the classical vacuum degeneracy. The coefficient is fixed by mass deformation and by matching the SU(4) theory when $N_c = 6$.

When $N_f = N_c - 4$, the unbroken gauge group is $SO(4) = (SU(2) \times SU(2))/\mathbb{Z}_2$ on the generic point of the moduli space. The superpotential of the original theory is

$$W_{\text{eff}} = 2(\epsilon_+ + \epsilon_-) \left( \frac{\Lambda^{2(N_c-1)}}{\det M} \right)^{1/2}$$

where the choices $\epsilon_+, \epsilon_- = \pm 1$ correspond to the fact that each of the SU(2) theory has two vacua. There are two physically inequivalent branches: $\epsilon_+ = \epsilon_-$ and $\epsilon_+ = -\epsilon_-$. For $\epsilon_+ = \epsilon_-$, the superpotential pushes the vacuum to infinity. For $\epsilon_+ = -\epsilon_-, W_{\text{eff}} = 0$. In the quantum theory, the singularity is smoothed out and

all the massless fermions are in $M$, even at the origin of the moduli space. Hence the quarks are confined.

When $N_f = N_c - 3$, the unbroken gauge group is SO(3) and the theory has two branches with

$$W_{\text{eff}} = 4(1+\epsilon)\frac{\Lambda^{2N_c-3}}{\det M}$$

where $\epsilon = \pm 1$. For $\epsilon = 1$, the quantum theory has no vacuum. For $\epsilon = -1$, $W_{\text{eff}} = 0$, but there are additional light fields $\tilde{Q}_i$ coupling to $M$ via the superpotential $W \sim (2\mu)^{-1} M^{ij} \tilde{Q}_i \tilde{Q}_j$ near $M = 0$.

When $N_f = N_c - 2$, the low-energy theory is related to the $N = 2$ gauge theory and will be addressed in the subsection "Seiberg–Witten's low-energy solution."

When $N_f \geq N_c - 1$, we define a dual, magnetic theory whose gauge group is $\mathrm{SO}(\tilde{N}_c)$, where $\tilde{N}_c = N_f - N_c + 4$. There are $N_f$ dual quarks $\tilde{Q}_i (1 \leq i \leq N_f)$ in the fundamental representation. This theory is infrared free if $N_f \leq (3/2)(N_c - 2)$. In the effective theory, the mesons $M^{ij}$ become fundamental and couple with the dual quarks through a superpotential $W = (2\mu)^{-1} M^{ij} \tilde{Q}_i \tilde{Q}_j$ if $N_f \geq N_c$; there is an additional term $\det M / 64\Lambda^{2N_c-5}$ if $N_f = N_c - 1$. When $(3/2)(N_c - 2) < N_f < 3(N_c - 2)$, the theory flows to an interacting superconformal field theory in the infrared.

## $N = 2$ Gauge Theory and Seiberg–Witten Duality

### $N = 2$ Yang–Mills Theory

Pure $N = 2$ supersymmetric gauge theory is a special case of $N = 1$ QCD when $R = \mathfrak{g}^{\mathbb{C}}$ is the (complexified) adjoint representation of $G$. The moment map is $D(\phi) = (1/2\sqrt{-1})[\phi, \bar{\phi}] \in \mathfrak{g} \cong \mathfrak{g}^*(\phi \in \mathfrak{g})$. Since the fermionic fields $\lambda$ and $\psi$ are sections of the same bundle, there is a second set of supersymmetry transformations by interchanging the roles of $\lambda$ and $\psi$. This makes the theory $N = 2$ supersymmetric. The classical action is

$$\begin{aligned} S^{N=2}_{\text{SYM}}[A, \lambda, \psi, \phi] = S_{\text{YM}}[A] & \\ + \frac{1}{g^2} \int \mathrm{d}^4x \sqrt{-1} (\langle \bar{\lambda}, \nabla\!\!\!/ \lambda \rangle & \\ + \langle \bar{\psi}, \nabla\!\!\!/ \psi \rangle) + \frac{1}{2} |\nabla\phi|^2 & \\ + \sqrt{-1} (\langle \bar{\phi}, [\lambda, \psi] \rangle + \langle \phi, [\bar{\lambda}, \bar{\psi}] \rangle) & \\ - \frac{1}{8} |[\phi, \bar{\phi}]|^2 & \end{aligned}$$

The energy reaches the minimum when $\phi$ takes a constant value $\phi \in \mathfrak{g}^{\mathbb{C}}$ that can be conjugated by $G$ to the Cartan subalgebra $\mathfrak{t}^{\mathbb{C}}$. ($\mathfrak{t}$ is the Lie algebra of the maximal torus $T$.) The classical moduli space is $\mathfrak{g}^{\mathbb{C}}/G^{\mathbb{C}} = \mathfrak{t}^{\mathbb{C}}/W$, where $W$ is the Weyl group. At a generic $\phi \in \mathfrak{t}^{\mathbb{C}}$, the gauge group is broken to $T$ by the Higgs mechanism. Classically, the massless degrees of freedom are excitations of $\phi$ and components of the gauge field in $\mathfrak{t}$. So the low-energy physics can be described by these massless fields. However, the moduli space is singular when $\phi$ is on the walls of the Weyl chambers. At these values, the unbroken gauge group is larger and there are extra massless fields that resolve the singularities.

Since $b_0 = 2\check{h} > 0$, the quantum theory is asymptotically free but strongly interacting at low energy. It can be shown that $N = 1$ supersymmetry already forbids a dynamically generated superpotential on $\mathfrak{t}^{\mathbb{C}}/W$. Therefore, the vacuum degeneracy is not lifted and the quantum moduli space is still a continuum. However, there are corrections to the part of classical moduli space where strong interactions occur. The quantum theory has a dynamically generated mass scale $\Lambda$. We pick the renormalization scale $\mu$ to be $|\phi|$, the typical energy scale where spontaneous symmetry breaking occurs. Far away from the origin, that is, when $|\phi| \gg |\Lambda|$, the theory is weakly interacting and the classical description of the moduli space is a good approximation. However, when $|\phi|$ is comparable to $|\Lambda|$, the classical language and perturbation methods fail due to strong interaction. At $\phi = 0$, the full gauge symmetry is restored classically. But since the theory becomes strongly interacting at low energy, it cannot be the low-energy solution of the original theory.

The classical $\mathrm{U}(1)_R$ symmetry extends to $\mathrm{U}(2)_R$, mixing $\lambda$ and $\psi$. The $\mathrm{U}(1)_R$ subgroup in $\mathrm{U}(2)_R$ is anomalous except for a subgroup $\mathbb{Z}_{4\check{h}}$. So we have a global $\mathrm{SU}(2)_R \times_{\mathbb{Z}_2} \mathbb{Z}_{4\check{h}}$ symmetry at the quantum level. This is consistent with a continuous moduli space of vacua, if the group $\mathrm{SU}(2)_R$ is to act nontrivially. Also, the space is not a single orbit of the global symmetry group. The generator of $\mathbb{Z}_{4\check{h}}$ acts on $\mathfrak{t}^{\mathbb{C}}$ by a phase $\mathrm{e}^{-\pi\sqrt{-1}/\check{h}}$. The group $\mathbb{Z}_{4\check{h}}$ is spontaneously broken to the subgroup which acts trivially on $\mathfrak{t}^{\mathbb{C}}/W$.

We study the general form of low-energy effective Lagrangian that is consistent with $N = 2$ supersymmetry. We assume that the quantum effect does not modify the topology of the moduli space $\mathfrak{t}^{\mathbb{C}}/W$, though it may alter the singularity and its nature. Suppose $U$ is the quantum moduli. At a generic point in $U$, the residual gauge group is $T$. In the $N = 1$ language, the theory is a supersymmetric gauged sigma model with target space $U$. It contains $N = 1$ vector multiplets $W^I$ and chiral multiplets $\Phi^I$, where $1 \leq I \leq r$, $r = \dim T$ being the rank of $G$. $N = 1$ supersymmetry requires that $U$ is Kähler, with

possible singularities where the effective theory breaks down. $N=2$ supersymmetry requires further that $U$ is special Kähler, that is, there is a flat, torsion-free connection $\nabla$ on $TU$ such that the Kähler form $\omega$ is parallel and such that $d_\nabla J=0$, where the complex structure $J$ is viewed as a 1-form valued in $TU$. See, for example, Freed (1999). Locally, there is a holomorphic prepotential $\mathcal{F}$ and special coordinates $\{z^I\}$. Let $\tilde{z}_I=\partial\mathcal{F}/\partial z^I$ be the dual coordinates and let $\tau_{IJ}=\partial^2\mathcal{F}/\partial z^I\partial z^J=\partial\tilde{z}_I/\partial z^J$. Then $K=\mathrm{Im}(\tilde{z}_I\bar{z}^I)$ is a Kähler potential and $\omega=(\sqrt{-1}/2)$ $\mathrm{Im}(\tau_{IJ})\mathrm{d}z^I\wedge\mathrm{d}\bar{z}^J$ is the Kähler form. The effective action is

$$S_{\mathrm{eff}}^{N=2}[W,\Phi]=\frac{1}{4\pi}\mathrm{Im}\left(\int \mathrm{d}^4x\,\mathrm{d}^2\theta\,\tfrac{1}{2}\tau_{IJ}(\Phi)(W^I,W^J)+\int \mathrm{d}^4x\,\mathrm{d}^2\theta\mathrm{d}^2\bar{\theta}K(\Phi)\right)$$

Note that both the coupling constants $\tau_{IJ}$ and the metric $\mathrm{Im}\tau_{IJ}$ on $U$ are determined by a holomorphic function $\mathcal{F}$, which is the hallmark of $N=2$ supersymmetry.

In the bare theory with abelian gauge group $T$, the action is given by choosing $\mathcal{F}_0(\Phi)=(1/2)\tau_{IJ}\langle\Phi^I,\Phi^J\rangle$, where the $\tau_{IJ}$ (and hence the metric $\mathrm{Im}\tau_{IJ}$) are constants. Due to one-loop and instanton effects, $\mathcal{F}$ is no longer quadratic in the effective theory. Since $\tau$ varies on $U$, it cannot be holomorphic (except at a few singular points), single valued, and having a positive-definite imaginary part. The solution to this apparent contradiction is that each set of special coordinates and the expression of $\mathcal{F}$ is valid only in part of $U$. Solving the $N=2$ gauge theory at low energy means understanding the singularity of $U$ in the strong coupling regime and obtaining the explicit form of $\mathcal{F}$ or $\tau_{IJ}$ in various regions of the moduli space.

### Seiberg–Witten's Low-Energy Solution

We consider $N=2$ gauge theory with $G=\mathrm{SU}(2)$. The Cartan subalgebra is $\mathfrak{t}\cong\mathbb{C}$; each $a\in\mathbb{C}$ determines an element $\phi=(1/2)\left(\begin{smallmatrix}a & 0\\ 0 & -a\end{smallmatrix}\right)$ in $\mathfrak{t}$. The Weyl group $W\cong\mathbb{Z}_2$ acts on $\mathbb{C}$ by $a\mapsto\pm a$. The moduli space of classical vacua is the $u$-plane $\mathbb{C}/\mathbb{Z}_2$ parametrized by $u=\mathrm{tr}\,\phi^2=(1/2)a^2$. When $u\neq 0$, the gauge group is broken to U(1). The generator of $\mathbb{Z}_{4\check{h}}=\mathbb{Z}_8\subset\mathrm{U}(1)_R$ acts as $a\mapsto\sqrt{-1}a, u\mapsto -u$. The $\mathbb{Z}_8$ symmetry is broken to $\mathbb{Z}_4$; the quotient $\mathbb{Z}_2=\mathbb{Z}_8/\mathbb{Z}_4$ acts on the $u$-plane by $u\mapsto\pm u$.

Abelian gauge theory and $N=4$ supersymmetric gauge theory exhibit exact electric–magnetic duality in the sense that the quantum theories are identical if the coupling constant $\tau$ undergoes an $\mathrm{SL}(2,\mathbb{Z})$ transformation. Seiberg and Witten (1994a, b) proposed that this is so for the low-energy effective theory of the $N=2$ gauge theory. An $\mathrm{SL}(2,\mathbb{Z})$ transformation maps one description of the low-energy theory to another, exchanging electricity and magnetism. It is however not an exact duality of the full SU(2) theory. Rather, duality is in the ambiguity of the choice of the low-energy description. More precisely, $\tau$ is a section of a flat $\mathrm{SL}(2,\mathbb{Z})$ bundle over $U$. Thus, $\tau$ is multivalued and exists as a function in local charts only. So we must use different Lagrangians in different regions of the $u$-plane. Around the singularities where $\tau$ is not defined, nontrivial monodromy can appear.

Away from infinity, the electric theory is strongly interacting but the magnetic theory is infrared free. The dual field is $\tilde{a}=\mathrm{d}\mathcal{F}(a)/\mathrm{d}a$, and $\tau_{\mathrm{eff}}(u)=\mathrm{d}\tilde{a}/\mathrm{d}a$. The group $\mathrm{SL}(2,\mathbb{Z})$ is generated by

$$P=\begin{pmatrix}-1 & 0\\ 0 & -1\end{pmatrix},\qquad S=\begin{pmatrix}0 & 1\\ -1 & 0\end{pmatrix}$$
$$T=\begin{pmatrix}1 & 1\\ 0 & 1\end{pmatrix}$$

To see its action on $\left(\begin{smallmatrix}\tilde{a}\\ a\end{smallmatrix}\right)$, we use the central extension of the $N=2$ super-Poincaré algebra. In the classical theory, the central charge is $Z=(n_{\mathrm{e}}+\tau n_{\mathrm{m}})a$ from the boundary terms at infinity. As the electric–magnetic duality transformation $S$ interchanges $n_{\mathrm{e}}$ and $n_{\mathrm{m}}$, we have for any $\gamma\in\mathrm{SL}(2,\mathbb{Z})$, $\gamma:(n_{\mathrm{m}},n_{\mathrm{e}})\mapsto(n_{\mathrm{m}},n_{\mathrm{e}})\gamma^{-1}$. When $n_m=0$, the classical formula $Z=n_{\mathrm{e}}a$ is valid. Invariance of $Z$ under $\mathrm{SL}(2,\mathbb{Z})$ requires that $Z=n_{\mathrm{m}}\tilde{a}+n_{\mathrm{e}}a$ at the quantum level and that $\mathrm{SL}(2,\mathbb{Z})$ acts on $\left(\begin{smallmatrix}\tilde{a}\\ a\end{smallmatrix}\right)$ homogeneously as a column vector.

When $u=(1/2)a^2$ is large, perturbation is reliable. The classical and one-loop results are $a(u)\sim\sqrt{2u}$, $\tilde{a}\sim(\sqrt{-1}/\pi)a\log a^2$. As $u$ goes around infinity, the fields transforms as $a\mapsto -a, \tilde{a}\mapsto -\tilde{a}+2a$. The monodromy is $M_\infty=PT^{-2}$. The mass $M$ of a monopole state is bounded by $M^2=P^\mu P_\mu\geq|Z|^2$, which is precisely the Bogomol'nyi bound. Now as a consequence of the $N=2$ supersymmetry, it receives no quantum corrections as long as supersymmetry is not broken at the quantum level. The states that saturate the bound are the BPS states. The BPS spectrum at $u\in U$ is a subset of $H_1(E_u,\mathbb{Z})\cong\mathbb{Z}^2$ containing the pairs $(n_{\mathrm{m}},n_{\mathrm{e}})$ realized by the dyon charges. Near infinity, the condition is that either $n_{\mathrm{e}}=\pm1, n_{\mathrm{m}}=0$ (for $W_\pm$ particles) or $n_{\mathrm{m}}=\pm1$ (for monopoles or dyons). This spectrum is invariant under the monodromy $M_\infty$.

The nontrivial holonomy at infinity implies the existence of at least one singularity at a finite value $u=u_0$, where extra particles become massless. Seiberg and Witten (1994a, b) propose that these

particles are collective excitations in the perturbative regime. Suppose along a path connecting $u_0$ and some base point near infinity, a monopole of charges $(\pm 1, n_e) = (0, 1)(T^{\mp n_e} S^{\pm 1})^{-1}$ becomes massless at $u_0$. Then by the renormalization group analysis and duality, the monodromy at $u_0$ is $M_{u_0} = (T^{\mp n_e} S^{\pm 1}) T^2 (T^{\mp n_e} S^{\pm 1})^{-1}$. It turns out that there are two singularities $u = \pm \Lambda^2$ with monodromies $M_{\Lambda^2} = ST^2 S^{-1}$ and $M_{-\Lambda^2} = (TS)T^2(TS)^{-1}$. The particles that become massless at $\pm\Lambda^2$ are of charges $(n_m, n_e) = (1, 0)$ and $(1, -1)$, respectively. The only BPS states in the strong coupling regime are those which become massless at the singularities; the others decay as $u$ deforms towards strong interaction.

The monodromies $M_{\pm\Lambda^2}, M_\infty$ (or any two of them) generate the subgroup $\Gamma(2)$. The family of elliptic curves with these monodromies can be identified with $y^2 = (x - \Lambda^2)(x + \Lambda^2)(x - u)$ called the Seiberg–Witten curve. The singularities are at $u = \pm\Lambda^2$ and $u = \infty$, where the curve degenerates. Let

$$\lambda = \frac{\sqrt{2}}{2\pi} \frac{y\, dx}{x^2 - \Lambda^4}$$

be the Seiberg–Witten differential (of second kind on the total space $E$). Then in a suitable basis $(\alpha, \beta)$ of $H_1(E_u/U, \mathbb{Z})$, we have $a = \int_\alpha \lambda, \tilde{a} = \int_\beta \lambda$. At a singularity, if $\nu = n_m \beta + n_e \alpha$ is a vanishing cycle, then the dyon of charges $(n_m, n_e)$ becomes massless. This is because its central charge is $Z = n_m \tilde{a} + n_e a = \int_\nu \lambda$. The monodromy at a singularity where $\nu$ is a vanishing cycle is given by the Picard–Lefshetz formula $M: \gamma \mapsto \gamma - 2(\gamma \cdot \nu)\nu$. At $u = \pm\Lambda^2$, the vanishing cycles are $\beta$ and $\beta - \alpha$, respectively.

We return to the $N = 1$ $SO(N_c)$ gauge theory with $N_f = N_c - 2$. At a generic point in the moduli space, the gauge group is broken to SO(2), which is abelian. Much of the above discussion applies to this case. By $N = 1$ supersymmetry, the effective coupling $\tau_{\text{eff}}$ is holomorphic in $M$ but is not single valued. In fact, $\tau_{\text{eff}}$ depends on $u = \det M$, which is invariant under the (anomaly free) $SU(N_f)$ symmetry. For large $u$, we have $e^{2\pi\sqrt{-1}\tau_{\text{eff}}} = \Lambda^{4N_c - 8}/u^2$ and the monodromy around infinity is $M_\infty = PT^{-2}$. On the other hand, a large expectation value of $M$ of rank $N_c - 3$ breaks the gauge group to SO(3) and the theory is the $N = 2$ theory discussed earlier. Using these facts, Intriligator and Seiberg (1995) identified the family of elliptic curves as $y^2 = x(x - 16\Lambda^{2N_c - 4})(x - u)$. There are two singularities with inequivalent physics. At $u = 0$, the monodromy is $ST^2 S^{-1}$. A pair of monopoles $\tilde{Q}^\pm$ becomes massless. They couple with $M$ through the superpotential $W \sim (2\mu)^{-1} M^{ij} \tilde{Q}_i \tilde{Q}_j$. At $u = 16\Lambda^{2N_c - 4}$, the monodromy is $(T^2 S)T^2(T^2 S)^{-1}$. A pair of dyons $E^\pm$ of charges $\pm 1$ become massless. The effective action is $W_{\text{eff}} \sim (u - 16\Lambda^{2N_c - 4})E^+ E^-$.

Topological gauge theory is a twisted version of $N = 2$ Yang–Mills theory in which the observables at high energy are the Donaldson invariants. The work of Seiberg and Witten (1994a, b) yields new insight to it and has a tremendous impact on the geometry of 4-manifolds. See Witten (1994) for the initial steps.

After the work of Seiberg and Witten (1994a, b), there has been much progress on theories with other gauge groups. If the gauge group is a compact Lie group of rank $r$, the $u$-plane is replaced by $\mathfrak{t}^{\mathbb{C}}/W$; the singularities are modified by quantum effects. The duality group is $Sp(2r, \mathbb{Z})$ or its subgroup of finite index, acting on the coupling matrix $\tau = (\tau_{IJ})$ by fractional linear transformations. For example, for $G = SU(N_c)$, the moduli space is parametrized by gauge invariants $u_2, \ldots, u_{N_c}$ defined by $\det(xI - \phi) = x^{N_c} - \sum_{i=2}^{N_c} u_i x^{N_c - i} = P_{N_c}(x, u_i)$. Classically, the singular locus is a simple singularity of type $A_{N_c - 1}$. At the quantum level, the singularity consists of two copies of such locus shifted by $\pm\Lambda^n$ in the $u_n$ direction. The monodromies correspond to a family of hyperelliptic curves $y^2 = P_{N_c}(x, u_i)^2 - \Lambda^{2N_c}$ of genus $N_c - 1$. The Seiberg–Witten differential is

$$\lambda = \frac{\sqrt{2}}{\pi\sqrt{-1}} \frac{\partial P_{N_c}(x, u_i)}{\partial x} \frac{x\, dx}{y} + \partial(\cdots)$$

The $N_c - 1$ independent eigenvalues $a^i$ of $\phi$ and their duals $\tilde{a}_i = \partial\mathcal{F}/\partial a^i$ are the periods of $\lambda$ along the $2N_c - 2$ homology cycles in the curve. For more details, the reader is referred to Klemm *et al.* (1995) and Argyes and Faraggi (1995).

## $N = 2$ QCD

$N = 2$ supersymmetric QCD is $N = 2$ Yang–Mills theory coupled to $N = 2$ matter. The latter consists of $N = 1$ superfields $Q$ that form a quarternionic representation $R$ of the gauge group $G$. The space $R$ has a $G$-invariant hyper-Kähler structure. The hyper-Kähler moment map $\mu_{\mathbb{H}}: R \to \mathfrak{g}^* \otimes \text{Im}\,\mathbb{H}$ consists of a real moment map $\mu_{\mathbb{R}}: R \to \mathfrak{g}^*$ for the Kähler structure and a complex moment map $\mu_{\mathbb{C}}: R \to (\mathfrak{g}^*)^{\mathbb{C}}$ for the holomorphic symplectic structure. As an $N = 1$ theory, the matter superfields are valued in $R \times \mathfrak{g}^{\mathbb{C}}$ with a $D$-term $D(Q, \Phi) = \mu_{\mathbb{R}}(Q) + (1/2\sqrt{-1})[\Phi, \bar{\Phi}]$ and a superpotential $W(Q, \Phi) = \sqrt{2}\langle \mu_{\mathbb{C}}(Q), \Phi \rangle + m(Q)$, where the mass term $m$ is a $G$-invariant quadratic form on $R$. The classical moduli space of vacua has two branches. On the Coulomb branch where $Q = 0$ and $\Phi \neq 0$, the unbroken gauge group is abelian and the

photons are massless. If $Q \neq 0$ exists in the flat directions, the gauge group is broken according to the value of $Q$; these are the Higgs branches. If $m=0$, the moduli space of classical vacua is the hyper-Kähler quotient $\mu_{\mathbb{H}}^{-1}(0)/G$. The branches of two types touch at the origin, where the full gauge group is restored, and at other subvarieties in $R$. The global symmetry is the subgroup of $U(R)$ that commutes with the $G$-action on $R$ and preserves $m$; it contains $U(2)_R$.

Quantum mechanically, such a theory is free from local gauge anomalies. Consistency under large gauge transformations puts a torsion condition on $R$, such as $\nu(R) = 0(\mathrm{mod}\, 2)$. Since $b_0 = 2\check{h} - (1/2)\nu(R)$, the theory is asymptotically free if $\nu(R) < 4\check{h}$. If $\nu(R) = 4\check{h}$, the quantum theory is scale invariant up to one-loop (and hence to all loops), and is expected to be so nonperturbatively. If $\nu(R) > 4\check{h}$, the quantum theory may not be defined but it can be the low-energy solution of another asymptotically free theory. Due to the axial anomaly, the $U(2)_R$ global symmetry reduces to the subgroup $SU(2)_R \times_{\mathbb{Z}_2} \mathbb{Z}_{4\check{h}-\nu(R)}$. The metric on the Coulomb branch can be corrected by quantum effects, but those on the Higgs branches do not change because of the uniqueness of the hyper-Kähler metric. In the quantum theory, the Higgs branches still touch the Coulomb branch, but the photons of the Coulomb branch are the only massless gauge bosons at the point where they meet.

When $G = SU(N_c)$ we take $N_f$ quarks $Q^i (i = 1, \ldots, N_f)$ in the fundamental representation and $N_f$ antiquarks $\tilde{Q}_i (i = 1, \ldots, N_f)$ in the complex-conjugate representation. The moment map is the same as in $N=1$ QCD whereas the superpotential is $W = \sqrt{2}\tilde{Q}_i \Phi Q^i + \sum_i m_i \tilde{Q}_i Q^i$. Consider the case $G = SU(2)$ as in Seiberg and Witten (1994b). Since $b_0 = 4 - N_f$, the asymptotically free theories have $N_f \leq 3$ whereas the $N_f = 4$ theory is scale invariant. As the representations on $Q^i$ and $\tilde{Q}_i$ are isomorphic, the classical global symmetry is $O(2N_f) \times U(2)_R$ when all $m_i = 0$. The appearance of the even number of fundamental representations is necessary for the consistency of the theory at the quantum level. The $U(1)_R$ symmetry is anomalous if $N_f \neq 4$. When $N_f > 0$, $SO(2N_f)$ is anomaly free, whereas $O(2N_f)/SO(2N_f) = \mathbb{Z}_2$ is anomalous. The anomaly free subgroup of $\mathbb{Z}_2 \times U(1)_R$ is $\mathbb{Z}_{4(4-N_f)}$. Its $\mathbb{Z}_2$ subgroup acts in the same way as $\mathbb{Z}_2 \subset Z(SO(2N_f))$. A nonzero expectation value of $u = \mathrm{tr}\,\phi^2$ further breaks the symmetry to $\mathbb{Z}_4$. The quotient group that acts effectively on the $u$-plane (the Coulomb branch) is $\mathbb{Z}_{4-N_f}$ if $N_f > 0$ and $\mathbb{Z}_2$ if $N_f = 0$. When $N_f = 4$, the $U(1)_R$ symmetry is anomaly free but $\mathbb{Z}_2 = O(8)/SO(8)$ is still anomalous.

The $N_f = 0$ theory is the $N=2$ pure gauge theory. In order to compare it to the $N_f > 0$ theories, we multiply $n_e$ by 2 so that it has integer values on $Q^i$ and $\tilde{Q}_i$, and divide $a$ by 2 to preserve the formula $Z = n_m \tilde{a} + n_e a$. The monodromies around the singularities become $M_{\Lambda^2} = STS^{-1}$, $M_{-\Lambda^2} = (T^2 S)T(T^2 S)^{-1}$, $M_\infty = PT^{-4}$. They generate the subgroup $\Gamma_0(4)$ of $SL(2,\mathbb{Z})$. The coupling constant is

$$\tau = \frac{\theta}{\pi} + \frac{8\pi\sqrt{-1}}{g^2}$$

The Seiberg–Witten curve is $y^2 = x^3 - ux^2 + (1/4)\Lambda_0^4 x$, related to the earlier one $y^2 = (x-u)(x^2 - \Lambda_0^4)$ by an isogeny. Here and below, $\Lambda_{N_f}$ is the dynamically generated scale.

For $N_f > 0$, we consider the case with zero bare masses. The simplest BPS-saturated states are the elementary quarks with mass $\sqrt{2}|a|$, which form the vector representation of $SO(2N_f)$. In addition, the quarks have fermion zero modes in the monopole background. When $n_m = 1$, each $SU(2)$ doublet of quarks has one zero mode. With $N_f$ hypermultiplet, there are $2N_f$ zero modes in the vector representation of $SO(2N_f)$. Upon quantization, the quantum states are in the spinor representation. So the flavor symmetry is really $Spin(2N_f)$. The spectrum may also include states with $n_m > 1$. For $N_f = 2, 3, 4$, the center $Z(Spin(2N_f))$ are $\mathbb{Z}_2 \times \mathbb{Z}_2$, $\mathbb{Z}_4$, $\mathbb{Z}_2 \times \mathbb{Z}_2$, whose generators act on states of charges $(n_m, n_e)$ by $((-1)^{n_e+n_m}, (-1)^{n_e})$, $\sqrt{-1}^{n_m+2n_e}$, $((-1)^{n_m}, (-1)^{n_e})$, respectively.

Suppose at a singularity on the $u$-plane, the low-energy theory is QED with $k$ hypermultiplets. Let $m_i$ be the bare mass and $S_i$, the $U(1)$ charge of the $i$th hypermultiplet. With the expectation value of $\phi$, the actual masses are $|\sqrt{2}a + m_i| (1 \leq i \leq k)$. As the states form a small representation of the $N=2$ algebra, the central charge is modified as $Z = n_m \tilde{a} + n_e a + S \cdot m/\sqrt{2}$, where $m = (m_1, \ldots, m_k)$ and $S = (S_1, \ldots, S_k)$. Under a duality transformation $M \in SL(2,\mathbb{Z})$, the column vector $(m/\sqrt{2}, \tilde{a}, a)$ is multiplied by a matrix of the form $\hat{M} = \begin{pmatrix} I_k & 0 \\ * & M \end{pmatrix}$. (For example, if $M = T$, $\hat{M}$ can be derived by one-loop analysis.) So the row vector $W = (S, n_m, n_e)$ transforms as $W \mapsto W\hat{M}^{-1}$. The transformation on $(n_m, n_e)$ is not homogeneous when there are hypermultiplets. This phenomenon persists even when all the bare masses $m_i$ are zero.

When $N_f = 1$, the global symmetry of the $u$-plane is $\mathbb{Z}_3$. There are three singularities related by this symmetry, where monopoles with charges $(n_m, n_e) = (1,0), (1,1)$, and $(1,2)$ become massless. The low-energy theory at each singularity is QED with a single light hypermultiplet. Besides the photon, no other flat directions exist. This is consistent with the absence of Higgs branch in the original theory. The monodromies at the singularities are $STS^{-1}$,

$(TS)T(TS)^{-1}, (T^2S)T(T^2S)^{-1}$, respectively, and the corresponding Seiberg–Witten family of curves is $y^2 = x^2(x-u) - (1/64)\Lambda_1^6$. The Seiberg–Witten differential is

$$\lambda = -\frac{\sqrt{2}}{4\pi}\frac{y\,\mathrm{d}x}{x^2}$$

When $N_f = 2$, there are two singularities related by the global symmetry $\mathbb{Z}_2$ of the $u$-plane. The massless states at one singularity have $(n_\mathrm{m}, n_\mathrm{e}) = (1,0)$ and form a spinor representation of SO(4) while those at the other have $(n_\mathrm{m}, n_\mathrm{e}) = (1,1)$ and form the other spinor representation. The low-energy theory at each singularity is QED with two light hypermultiplets. There are additional flat directions along which $\mathrm{SO}(4) \times \mathrm{SU}(2)_R$ is broken. They form the two Higgs branches that touch the $u$-plane at the two singularities rather than at the origin. The metric and pattern of symmetry breaking are the same as classically. The monodromies are $ST^2S^{-1}, (TS)T^2(TS)^{-1}$. The Seiberg–Witten curve is $y^2 = (x^2 - u) - (1/64)\Lambda_2^4)(x-u)$ and the differential is

$$\lambda = -\frac{\sqrt{2}}{4\pi}\frac{y\,\mathrm{d}x}{x^2 - \Lambda_2^4/64}$$

When $N_f = 3$, the $u$-plane has no global symmetry. There are two singularities. At one of them, a single monopole bound state with $(n_\mathrm{m}, n_\mathrm{e}) = (2,1)$ becomes massless and there are no other light particles. At the other singularity, the massless states have $(n_\mathrm{m}, n_\mathrm{e}) = (1,0)$ and form a (four-dimensional) spinor representation of SO(6) with a definite chirality. Thus, the low-energy theory is QED with four light hypermultiplets. Along the flat directions, the $\mathrm{SO}(6) \times \mathrm{SU}(2)_R$ symmetry is further broken. This corresponds to a single Higgs branch touching the $u$-plane at the singularity. Again, the metric on the Higgs branch is not modified by quantum effects. The monodromies at the two singularities are $(ST^2S)T(ST^2S)^{-1}$ and $ST^4S^{-1}$, respectively. The Seiberg–Witten curve is $y^2 = x^2(x-u) - (1/64)\Lambda_3^2(x-u)^2$ and the differential is

$$\lambda = \frac{\sqrt{2}}{\pi\Lambda_3}\log\left(y + \sqrt{-1}\frac{\Lambda_3}{8}\left(x - u - \frac{32}{\Lambda_3^2}x^2\right)\right)\mathrm{d}x$$

When $N_f = 4$, the theory is characterized by classical coupling constant $\tau$, and there are no corrections to $a = (1/2)\sqrt{2u}, \tilde{a} = \tau a$. There is only one singularity at $u = 0$, where the monodromy is $P$. Seiberg and Witten (1994b) postulate that the full quantum theory is $\mathrm{SL}(2,\mathbb{Z})$ invariant, just like the $N = 4$ pure gauge theory. The elementary hypermultiplet has $(n_\mathrm{m}, n_\mathrm{e}) = (0,1)$ and form the vector representation $v$ of SO(8). Fermion zero modes give rise to hypermultiplets with $(n_\mathrm{m}, n_\mathrm{e}) = (1,0), (1,1)$ that transform under the spinor representations $s$, $c$ of Spin(8). $\mathrm{SL}(2,\mathbb{Z})$ acts on the spectrum via a homomorphism onto the outer-automorphism group $S_3$ of Spin(8), which then permutes $v$, $s$, and $c$. So duality is mixed in an interesting way with the SO(8) triality. In $v$, $s$, and $c$, the center $\mathbb{Z}_2 \times \mathbb{Z}_2$ acts as $((-1)^{n_\mathrm{m}}, (-1)^{n_\mathrm{e}}) = (1,-1), (-1,1), (-1,-1)$, respectively. The full $\mathrm{SL}(2,\mathbb{Z})$ invariance predicts the existence of multimonopole bound states: for every pair of relatively prime integers $(p, q)$, there are eight states with $(n_\mathrm{m}, n_\mathrm{e}) = (p,q)$ that form a representation of Spin(8) on which the center acts as $((-1)^p, (-1)^q)$.

Solutions when the bare masses are nonzero are also obtained by Seiberg and Witten (1994b). The masses can be deformed to relate theories with different values of $N_f$. $N = 2$ QCD with a general classical gauge group has also been studied. By adding to these theories a mass term $m\,\mathrm{tr}\,\Phi^2$ that explicitly breaks the supersymmetry to $N = 1$, the dualities of Seiberg can be recovered. For $\mathrm{SU}(N_c), \mathrm{SO}(N_c)$ and $\mathrm{Sp}(2N_c)$ gauge groups, see Hanany and Oz (1995), Argyes *et al.* (1996), Argyes *et al.* (1997) and references therein.

# Semiclassical Spectra and Closed Orbits

**Y Colin de Verdière**, Université de Grenoble 1, Saint-Martin d'Hères, France

## Introduction

The purpose of this article is to describe the so-called "semiclassical trace formula" (SCTF) relating the "spectrum" of a semiclassical Hamiltonian to the "periods of closed orbits" of its classical limit. SCTF formula expresses the asymptotic behavior as $\hbar \to 0$ ($\hbar = h/2\pi$) of the regularized density of states as a sum of oscillatory contributions associated to the closed orbits of the classical limit.

We will mainly present the case of the Schrödinger operator on a Riemannian manifold which contains the purely Riemannian case.

We start with a section about the history of the subject. We then give a statement of the results and a heuristic proof using Feynman integrals. This proof can be transformed into a mathematical proof which we will not give here. After that we describe some applications of the SCTF.

## About the History

SCTF has several origins: on one side, Selberg trace formula (1956) is an exact summation formula concerning the case of locally symmetric spaces; this formula was interpreted by H Huber as a formula relating eigenvalues of the Laplace operator and lengths of closed geodesics (also called the "lengths spectrum") on a closed surface of curvature –1.

On the other side, around 1970, two groups of physicists developed independently asymptotic trace formulas:

- M Gutzwiller for the Schrödinger operator, using the quasiclassical approximation of the Green function (the "van Vleck's formula"); it is interesting to note that the word "trace formula" is not written, but Gutzwiller instead speaks of a new "quantization method" (the old one being "Einstein–Brillouin–Keller (EBK)" or "Bohr–Sommerfeld rules").
- R Balian and C Bloch, for the eigenfrequencies of a cavity, use what they call a "multiple reflection expansion." They asked about a possible application to Kac's problem.

At the same time, under the influence of Mark Kac's famous paper "Can one hear the shape of a drum?," mathematicians became quite interested in inverse spectral problems, mainly using heat kernel expansions (for the state of the art around 1970, see Berger *et al.* (1971)).

The SCTF was put into its final mathematical form for the Laplace operator on closed manifolds by three groups of people around 1973–75:

- Y Colin de Verdière in his thesis was using the short-time expansion of the Schrödinger kernel and an approximate Feynman path integral. He proved that the spectrum of the Laplace operator determines generically the lengths of closed geodesics.
- J Chazarain derived the qualitative form of the trace for the wave kernel using Fourier integral operators.

- Using the full power of the symbolic calculus of Fourier integral operators, H Duistermaat and V Guillemin were able to compute the main term of the singularity from the Poincaré map of the closed orbit. Their paper became a canonical reference on the subject.

  After that, people were able to extend SCTF to:

- general semiclassical Hamiltonians (Helffer–Robert, Guillemin–Uribe, Meinrenken),
- manifolds with boundary (Guillemin–Melrose),
- surfaces with conical singularities and polygonal billiards (Hillairet), and
- several commuting operators (Charbonnel–Popov).

Recently, some researchers have remarked about the nonprincipal terms in the singularities expansion which come from the semiclassical Birkhoff normal form (Zelditch, Guillemin).

## Selberg Trace Formula

We consider a compact hyperbolic surface $X$. "Hyperbolic" means that the Riemannian metric is locally $(\mathrm{d}x^2+\mathrm{d}y^2)/y^2$ or is of constant curvature –1. Such a surface is the quotient $X=\boldsymbol{H}/\Gamma$ where $\Gamma$ is a discrete co-compact subgroup of the group of isometries of the Poincaré half-plane $\boldsymbol{H}$. Closed geodesics of $X$ are in bijective correspondence with nontrivial conjugacy classes of $\Gamma$. More precisely, the set of loops $C(S^1,X)$ splits into connected components associated to conjugacy classes and each component of nontrivial loops contains exactly one periodic geodesic.

**Theorem 1** (Selberg trace formula). *If $\rho$ is a real-valued function on $\mathbb{R}$ whose Fourier transform $\hat{\rho}$ is compactly supported and $\lambda_j=1/4+\mu_j^2$ is the spectrum of the Laplace operator on $X$, we have*:

$$\sum_{j=1}^{\infty}\rho(\mu\pm\mu_j)=\frac{A}{2\pi}\int_{\mathbb{R}}\rho(\mu+s)s\tanh\pi s\,\mathrm{d}s + \sum_{\gamma\in\mathcal{P}}\sum_{n=1}^{\infty}\frac{l_\gamma}{2\pi\sinh(nl_\gamma/2)} \times \mathrm{Re}(\hat{\rho}(nl_\gamma)\mathrm{e}^{\mathrm{i}n\mu l_\gamma})$$

*where $A$ is the area of $X$, $\mathcal{P}$ the set of primitive conjugacy classes of $\Gamma$ and, for $\gamma\in\mathcal{P}$, $l_\gamma$ is the length of the unique closed geodesic associated to $\gamma$.*

A nice recent presentation of the Selberg trace formula can be found in Marklof (2003).

## Semiclassical Schrödinger Operators on Riemannian Manifolds

If $(X, g)$ is a (possibly noncompact) Riemannian manifold and $V: X\to\mathbb{R}$ a smooth function which satisfies $\liminf_{x\to\infty}V(x)=E_\infty>-\infty$, the differential operator $\hat{H}=(1/2)\hbar^2\Delta+V$ is semibounded from below and admits self-adjoint extensions. For all those extensions, the spectrum is discrete in the interval $]-\infty,E_\infty[$ and eigenfunctions $\hat{H}\varphi_j=E_j\varphi_j$ are localized in the domain $V\le E_j$. If $X$ is compact and $V=0$, we recover the case of the Laplace operator.

We will denote this part of the spectrum by

$$\inf V<E_1(\hbar)<E_2(\hbar)\le\cdots\le E_j(\hbar)\le\cdots<E_\infty$$

For the Laplace operator, we have $E_j=\hbar^2\lambda_j$, where $\lambda_1\le\lambda_2\le\cdots\le\lambda_j\le\cdots$ is the spectrum of the Laplace operator.

The SCTF can also be derived the same way for Schrödinger operators with magnetic field. One can even extend it to Hamiltonian systems which are not obtained by Legendre transform from a regular Lagrangian. In this case, Morse indices have to be replaced by the more general Maslov indices.

## Classical Dynamics

### Newton Flows

Euler–Lagrange equations for the Lagrangian $\mathcal{L}(x,v):=(1/2)\|v\|_g^2-V(x)$ admit a Hamiltonian formulation on $T^\star X$ whose energy is given by $H=(1/2)\|\xi\|_g^2+V(x)$. We will denote by $X_H$ the Hamiltonian vector field

$$X_H:=\sum_j\frac{\partial H}{\partial\xi_j}\partial_{x_j}-\frac{\partial H}{\partial x_j}\partial_{\xi_j}$$

Preservation of $H$ by the dynamics shows immediately that the Hamiltonian flow $\Phi_t$ restricted to $H<E_\infty$ is complete.

The Hamiltonian $H$ is the "classical limit" of $\hat{H}$; in more technical terms, $H$ is the semiclassical principal symbol of $\hat{H}$.

If $V=0$, $H=(1/2)g^{ij}\xi_i\xi_j$ and the flow is the geodesic flow.

### Periodic Orbits

**Definition 1** *A* periodic orbit $(\gamma,T)$ (also denoted p.o.) of the Hamiltonian $H$ consists of an orbit $\gamma$ of $X_H$ which is homeomorphic to a circle and a nonzero real number $T$ so that $\Phi_T(z)=z$ for all $z\in\gamma$. We will denote by $T_0(\gamma)>0$ (the primitive period) the smallest $T>0$ for which $\Phi_T(z)=z$.

If $(T, E)$ are given, $W_{T,E}$ is the set of $z$'s so that $H(z) = E$ and $\Phi_T(z) = z$.

- The (linear) Poincaré map $\Pi_\gamma$ of a p.o. $(\gamma, T)$ with $H(\gamma) = E$: we restrict the flow to $S_E := \{H = E\}$ and take a hypersurface $\Sigma$ inside $S_E$ transversal to $\gamma$ at the point $z_0$. The associated return map $P$ is a local diffeomorphism fixing $z_0$. Its linearization $\Pi_\gamma := P'(z_0)$ is the linear Poincaré map, an inversible (symplectic) endomorphism of the tangent space $T_{z_0}\Sigma$.
- The Morse index $\iota(\gamma)$: p.o. $(\gamma, T)$ is a critical point of the action integral $\int_0^T \mathcal{L}(\gamma(s), \dot\gamma(s))\,ds$ on the manifold $C^\infty(\mathbb{R}/T\mathbb{Z}, X)$. It always has a finite Morse index (Milnor 1967) which is denoted by $\iota(\gamma)$. For general Hamiltonian systems, the Morse index is replaced by the Conley–Zehnder index.
- The nullity index $\nu(\gamma)$ is the dimension of the space of infinitesimal deformations of the p.o. $\gamma$ by p.o. of the same energy and period. We always have $\nu(\gamma) \geq 1$ and $\nu(\gamma) = 1 + \dim\ker(\mathrm{Id} - \Pi_\gamma)$.

**Example 1** (Geodesic flows)

- Riemannian manifold with sectional curvature $< 0$: in this case, we have for all periodic geodesics $\iota(\gamma) = 0, \nu(\gamma) = 1$.
- Generic metrics: for a generic metric on a closed manifold, we have $\nu(\gamma) = 1$ for all periodic geodesics.
- For flat tori of dimension $d$: we have $\iota(\gamma) = 0$ and $\nu(\gamma) = d$.
- For sphere of dimension 2 with constant curvature: if $\gamma_n$ is the $n$th iterate of the great circle, we have $\iota(\gamma_n) = 2|n|$ and $\nu(\gamma_n) = 3$.

It is a beautiful result of J-P Serre that any pair of points on a closed Riemannian manifold are endpoints of infinitely many distinct geodesics. Counting geometrically distinct periodic geodesics is much harder especially for simple manifolds like the spheres. It is now known that every closed Riemannian manifold admits infinitely many geometrically distinct periodic geodesics (at least, in some cases, for generic metrics, (Berger 2000 chap. V). There exists significant knowledge concerning more general Hamiltonian systems as well.

### Nondegeneracy

There are several possible nondegeneracy assumptions. They can be formulated "à la Morse–Bott" (critical point of action integrals) or purely symplectically.

**Definition 2** Two submanifolds $Y$ and $Z$ of $X$ intersect cleanly iff $Y \cap Z$ is a manifold whose tangent space is the intersection of the tangent spaces of $Y$ and $Z$.

Fixed points of a smooth map are clean if the graph of the map intersects the diagonal cleanly.

**Definition 3** We will denote by (ND) the following property of the p.o. $(\gamma_0, T_0)$: the fixed points of the associated (nonlinear) Poincaré map $P$ are clean.

The set $W_{T,E}$ is ND if all p.o.'s inside are ND. $W_{T,E}$ is then a manifold of dimension $\nu(\gamma)$.

**Example 2**

- *Generic case*: $\nu = 1$; (ND) is equivalent to "1 is not an eigenvalue of the linear Poincaré map." In this case, we can deform the p.o. smoothly by moving the energy. This family of p.o.'s is called a cylinder of p.o.'s. The period $T(E)$ is then a smooth function of $E$.
- *Completely integrable systems*: $\nu = d$; (ND) is then a consequence of the so-called "isoenergetic KAM condition": assuming the Hamiltonian is expressed as $H(I_1, \ldots, I_d)$ using action-angle coordinates, this condition is that the mapping $I \to [\nabla H(I)]$ from the energy surface $H = E$ into the projective space is a local diffeomorphism. This condition implies that Diophantine invariant tori are not destructed by a small perturbation of the Hamiltonian.
- *Maximally degenerated systems*: it is the case where all orbits are periodic ($\nu = 2d - 1$). For example, the two-body problem with Newtonian potential and the geodesic flows on compact rank-1 symmetric spaces.

### Canonical Measures and Symplectic Reduction

Under the hypothesis (ND), the manifold $W_{T,E}$ admits a canonical measure $\mu_c$, invariant by $\Phi_t$. In the case $\nu = 1$, this measure is given by $|dt|/\sqrt{\det(\mathrm{Id} - \Pi)}$.

By using a Poincaré section, it is enough to understand the following fact: if $A$ is a symplectic linear map, the space $\ker(\mathrm{Id} - A)$ admits a canonical Lebesgue measure.

We start with the following construction: let $L_1$ and $L_2$ be two Lagrangian subspaces of a symplectic space $E$ and $\omega_j, j = 1, 2$, be half-densities on $L_j$, denoted by $\omega_j \in \Omega^{1/2}(L_j)$. If $W = L_1 \cap L_2$, we have the following canonical isomorphisms: $\Omega^{1/2}(L_j) = \Omega^{1/2}(W) \otimes \Omega^{1/2}(L_j/W)$. So $\Omega^{1/2}(L_1) \otimes \Omega^{1/2}(L_2) = \Omega^{1/2}(L_1/W) \otimes \Omega^{1/2}(L_2/W) \otimes \Omega^1(W)$. $M_j = L_j/W$ are two Lagrangian subspaces of the reduced space $W^o/W$ whose intersection is 0. Hence, by using the Liouville measure on it, we get $\Omega^{1/2}(M_1) \otimes \Omega^{1/2}(M_2) = \mathbb{C}$. Hence, we get a density $\omega_1 \star \omega_2$ on $W$. It turns out that the previous calculation is one of the main algebraic pieces of the symbolic calculus of

Fourier integral operators and the density $\omega_1 \star \omega_2$ arises in stationary-phase computations.

The graph of a symplectic map is equipped with a half-density by pullback of the Liouville half-density. So we can apply the previous construction to the intersection of the graph of $A$ and the graph of the identity map.

### Actions

**Definition 4** If $(\gamma, T)$ is a p.o., we define the following quantity which is called action of $\gamma$:

$$A(\gamma) = \int_\gamma \xi \, dx$$

In the (ND) case, $A(\gamma)$ is constant on each connected component of $W_{T,E}$.

In the generic case and if $T'(E) \neq 0$ (cylinder of p.o.), p.o.'s of the cylinder are also parametrized by $T$ (i.e., we note by $\gamma_E$ the p.o. of the cylinder of energy $E$ and $\gamma_T$ the p.o. of period $T$). If $a(E) = A(\gamma_E)$ and $b(T) = -\int_0^T \mathcal{L}(\gamma_T(s), \dot{\gamma}_T(s)) ds$, $a(E)$ and $b(T)$ are Legendre transforms of each other.

## Playing with Spectral Densities

We will define the "regularized spectral densities." The general idea is as follows: we want to study an $\hbar$-dependent sequence of numbers $E_j(\hbar)$ (a spectrum) in some interval $[a, b]$. We introduce a non negative function $\rho \in \mathcal{S}(\mathbb{R})$ which satisfies $\int \rho(t) dt = 1$, and also $D_{\rho,\varepsilon,\hbar}(E) = \sum \rho_\varepsilon(E - E_j)$, where $\rho_\varepsilon(E) = \varepsilon^{-1}\rho(E/\varepsilon)$. It gives the analysis of the spectrum at the scale $\varepsilon$. Of course, we will adapt the scaling $\varepsilon$ to the small parameter $\hbar$. If the scaling is of the size of the mean spacing of the spectrum, we will get a very precise resolution of the spectrum.

The general philosophy is:

- If $\hbar$ is the semiclassical parameter of a semiclassical Hamiltonian, the mean spacing of the eigenvalues is of order $\hbar^d$ (Weyl's law). The trace formula gives the asymptotic behavior of $D_{\rho,\varepsilon,\hbar}(E)$ for $\varepsilon \sim \hbar$ (and hence $\varepsilon >> \overline{\Delta E}$ except if $d = 1$). This behavior is not "universal" and thus contains a significant amount information of (in our case, on periodic trajectories).
- Better resolution of the spectrum needs the use of the long-time behavior of the classical dynamics and is conjecturally universal. It means that eigenvalues seen at very small scale behave like eigenvalues of an ensemble of random matrices, the most common one being the Wigner Gaussian orthogonal ensemble (GOE) and Gaussian unitary ensemble (GUE).

We fix some interval $[a, b]$ with $b < E_\infty$.

We define $D(E) := \sum_{a \leq E_j \leq b} \delta(E_j)$ as the sum of Dirac measures at the points $E_j$ and its $\hbar$-Fourier transform as

$$Z(t) = \text{trace}'(e^{-it\hat{H}/\hbar}) := \sum{}' \exp(-itE_j/\hbar) \quad [1]$$

where $\sum'$ is the sum over $E_j \in [a, b]$.

The Duistermaat–Guillemin trick relates the previous behavior to asymptotics of the regularized density of eigenvalues. Let us give a function $\rho \in \mathcal{S}(\mathbb{R})$ so that $\hat{\rho}(t) = \int e^{-itE} \rho(E) dE$ is compactly supported and

$$\hat{\rho}(t) = 1 + O(t^\infty), \quad t \to 0 \quad [2]$$

(all moments of $\rho$ vanish). We introduce, for $E \in [a, b]$, $D_\rho(E) := \sum_j' \frac{1}{\hbar} \rho(E - E_j/\hbar)$. $D_\rho(E)$ is independent modulo $O(\hbar^\infty)$ of $a, b$. We have

$$D_\rho(E) = \frac{1}{2\pi\hbar} \int \hat{\rho}(t) Z(t) \, dt$$

The idea is now to start from a semiclassical approximation of $U(t) = e^{-it\hat{H}/\hbar}$ and to insert it into eqn [1]. We need only a uniform approximation of $U(t)$ for $t \in \text{Support}(\hat{\rho})$. From the asymptotic expansion of $Z(t)$, we will deduce the asymptotic expansion of $D_\rho$, the regularized eigenvalue density.

## The Smoothed Density of States

The following statement expressing the smoothed density of eigenvalues is the main result of the subject. Under the (ND) assumption, it gives the existence of an asymptotic expansion for $D_\rho(E)$:

**Theorem 2** *If $E$ is not a critical value of $H$ and the* (ND) *condition is satisfied for all p.o.'s of energy $E \in [a, b]$ and period inside the support of $\hat{\rho}$,*

$$D_\rho(E) = D_{\text{Weyl}}(E) + \sum D_{W(T,E)} + O(\hbar^\infty) \quad [3]$$

*where*:

(i)
$$D_{\text{Weyl}}(E) = (2\pi\hbar)^{-d} \left( \sum_{j=0}^{\infty} a_j(E) \hbar^j \right)$$

*with* $a_0(E) = \int_{H=E} dL/dH$

(ii) *The sum is over all the manifolds $W_{T,E}$ so that* $T \in \text{Support}(\hat{\rho})$.

(iii)
$$D_{W(T,E)} = \frac{\varepsilon}{(2\pi i\hbar)^{(\nu(\gamma)+1)/2}} e^{-i\iota(\gamma)\pi/2} \times e^{iA(\gamma)/\hbar} \sum_{j \geq 0} b_j(E) \hbar^j$$

*with*

$$b_0(E) = \hat{\rho}(T)\int_{W_{T,E}} d\mu_c$$
$$\varepsilon = \begin{cases} 1 & \text{if } T'(E) > 0 \\ i & \text{if } T'(E) < 0 \end{cases}$$

*If* $\nu(\gamma) = 1$, *we get* $b_0 = \hat{\rho}(T_\gamma)T_0|\det(\mathrm{Id} - \Pi_\gamma)|^{-1/2}$.

## The Weyl Expansion

If Support($\hat{\rho}$) is contained in $[-T_{\min}, T_{\min}]$, where $T_{\min}$ is the smallest period of a p.o. $\gamma$ with $H(\gamma) = E$, and, if $E$ is not a critical value of $H$, formula [3] reduces to

$$D_\rho(E) \sim (2\pi\hbar)^{-d}\left(\sum_{j=0}^{\infty} a_j(E)\hbar^j\right)$$

From the previous formula, it is possible to deduce the following estimates:

**Theorem 3** *If a, b are not critical values of H*:

$$\#\{j | a \le E_j(\hbar) \le b\} = (2\pi\hbar)^{-d}\text{volume}(a \le H \le b)(1 + O(\hbar))$$

This remainder estimate is optimal and was first shown in rather great generality by Hörmander (1968).

## Derivation from the Feynman Integral

### The Feynman Integral

R Feynman (Feynman and Hibbs 1965) found a geometric representation of the propagator, that is, the kernel $p(t,x,y)$ of the unitary group $\exp(-it\hat{H}/\hbar)$ using an integral (FPI := Feynman path integral) on the manifold $\Omega_{t,x,y} := \{\gamma : [0,t] \to X | \gamma(0) = x, \gamma(t) = y\}$ of paths from $x$ to $y$ in the time $t$; if $\mathcal{L}(\gamma, \dot{\gamma})$ is the Lagrangian, we have, for $t > 0$:

$$p(t,x,y) = \int_{\Omega_{t,x,y}} \exp\left(\frac{i}{\hbar}\int_0^t \mathcal{L}(\gamma(s), \dot{\gamma}(s))\, ds\right)|d\gamma|$$

where $|d\gamma|$ is a "Riemannian measure" on the manifold $\Omega_{t,x,y}$ with the natural Riemannian structure.

There is no justification FPI as a useful mathematical tool. Nevertheless, FPI gives good heuristics and right formulas.

### The Trace and Loop Manifolds

Let us try a formal calculation of the partition function and its semiclassical limit. We get

$$Z(t) = \int_X |dx| \int_{\Omega_{x,x,t}} \exp\left(\frac{i}{\hbar}\int_0^t \mathcal{L}(\gamma(s), \dot{\gamma}(s))ds\right)|d\gamma|$$

If we denote by $\Omega_t$ the manifold of paths $\gamma : \mathbb{R}/t\mathbb{Z} \to X$, (loops) and we apply Fubini (sic !), we get

$$Z(t) = \int_{\Omega_t} \exp\left(\frac{i}{\hbar}\int_0^t \mathcal{L}(\gamma(s), \dot{\gamma}(s))\, ds\right)|d\gamma|$$

### The Semiclassical Limit

We want to apply stationary phase in order to get the asymptotic expansion of $Z(t)$; critical points of $J_t : \Omega_t \to \mathbb{R}$ are the p.o.'s of the Euler–Lagrange flow and hence of the Hamiltonian flow of period $t$. We require the ND assumption (Morse–Bott), the Morse index, and the determinant of the Hessian:

1. The ND assumption is the original Morse–Bott one in Morse theory: we have smooth manifolds of critical points and the Hessian is transversally ND.
2. The Morse index is the Morse index of the action functional on periodic loops: $L(\gamma) := \int_0^t \mathcal{L}(\gamma(s), \dot{\gamma}(s))ds$.
3. The Hessian is associated to a periodic Sturm–Liouville operator for which many regularizations have already been proposed.

In this manner, we get a sum of contributions given by the components $W_{j,t}$ of $W_t$:

$$Z_j(t) = (i\hbar)^{-\nu_j/2} e^{(i/\hbar)L(\gamma)} c_j(\hbar)$$

with $c_j(\hbar) \sim \sum_{l=0}^{\infty} c_{j,l}\hbar^l$ and

$$c_{j,0} = \frac{e^{-i\mu(\pi/2)}}{|\delta|^{1/2}}$$

where $\mu$ is the Morse index and $\delta$ is a regularized determinant.

## The Integrable Case

As observed by Berry–Tabor, the trace formula in this case comes from Poisson summation formula using action-angle coordinates. Asymptotic of the eigenvalues to any order can then be given in the so-called quantum integrable case by Bohr–Sommerfeld rules.

## The Maximally Degenerated Case

Let us assume that $(X, g)$ is a compact Riemannian manifold for which all geodesics have the same smallest period $T_0 = 2\pi$. Then we have the following clustering property:

**Theorem 4** *There exists some constant C and some integer $\alpha$ so that*

(i) *the spectrum of $\Delta$ is contained in the union of the intervals*

$$I_k = \left[\left(k + \frac{\alpha}{4}\right)^2 - C, \left(k + \frac{\alpha}{4}\right)^2 + C\right], \quad k = 1, 2, \ldots$$

(ii) $N(k) = \#\text{Spectrum}(\Delta) \cap I_k$ *is a polynomial function of k for k large enough.*

The property (ii) is consequence of the trace formula.

## Applications to the Inverse Spectral Problem

We will now restrict ourselves to the case of the Laplace operator on a compact Riemannian manifold $(X, g)$. The main result is as follows:

**Theorem 5** (*Colin de Verdière*). *If X is given, there exists a generic subset $\mathcal{G}_X$, in the sense of Baire category, of the set of smooth Riemannian metrics on X, so that, if $g \in \mathcal{G}_X$, the length spectrum of $(X, g)$ can be recovered from the Laplace spectrum. The set $\mathcal{G}_X$ contains all metrics with $<0$ sectional curvature and (conjecturally) all metrics with $<0$ sectional curvature.*

We can take for $\mathcal{G}_X$ the set of metrics for which all periodic geodesics are nondegenerate and the length spectrum is simple.

Some cancelations may occur between the asymptotic expansions of two ND periodic trajectories with the same actions if the Morse indices differ by 2 mod 4.

## The Case with Boundary

If $(X, g)$ is a smooth compact manifold with boundary, one introduces the broken geodesic flow by extending the trajectories by reflection on the boundary. SCTFs have been extended to that case by Guillemin and Melrose. Periodic geodesics which are transversal to the boundary contribute to the density of states in the same way as for periodic manifolds. Periodic geodesics inside the boundary are in general accumulation of periodic geodesics near the boundary: their contributions is therefore very complicated analytically.

## Bifurcations

Let us denote by $C_H \subset \mathbb{R}^2_{T,E}$, the set of pairs $(T,E)$ for which $W_{T,E}$ is not empty. The previous results apply to the "smooth" part of the set $C_H$. Among other interesting points are points $(0,E)$ with critical value $E$ of $H$ (Brummelhuis–Paul–Uribe) and points corresponding to bifurcation of p.o. when moving the energy.

Detailed studies of some of these points have been done, for example, the results of suitable applications of the theory of singularities of functions of finitely many variables, their deformations (catastrophe theory), and applications to stationary-phase method, and a significant body of knowledge on these subjects now exists.

## SCTF and Eigenvalue Statistics

One of the main open mathematical problems is: "can one really use appropriate forms of the SCTF as quantization rules and use it in order to derive eigenvalues statistics?"

This problem is related to the fine-scale study of the eigenvalue spacings ($\varepsilon << \hbar$). It is one of the important unsolved problems of the so-called "quantum chaos." Many people think that progress in this field will allow us to solve the Bohigas–Giannoni–Schmit conjecture: "if the geodesic flow is hyperbolic, eigenvalue distribution follows random matrix asymptotics."

# Semilinear Wave Equations

**P D'Ancona**, Università di Roma "La Sapienza," Rome, Italy

## Introduction

A semilinear wave equation is an equation of the form

$$\Box u = F(u, u'), \quad u : \Omega \subseteq \mathbb{R} \times \mathbb{R}^n \to \mathbb{R} \qquad [1]$$

where $F : \mathbb{R}^{n+2} \to \mathbb{R}$ is a smooth function, the d'Alembert operator $\Box$ is defined as

$$\Box = D_t^2 - D_{x_1}^2 \cdots - D_{x_n}^2, \quad D_t = \frac{\partial}{\partial t}, D_{x_j} = \frac{\partial}{\partial x_j} \qquad [2]$$

and $u'$ denotes the vector of all first-order derivatives of $u$:

$$u' = (D_t u, D_{x_1} u, \ldots, D_{x_n} u) \equiv (u_t, u_{x_1}, \ldots, u_{x_n})$$

Sometimes the term "semilinear" is used in a more restrictive sense and refers to the special class of equations

$$\Box u = f(u) \qquad [3]$$

The very particular case $f(u) = -mu, m > 0$, corresponds to the Klein–Gordon equation, used to model relativistic particles. True nonlinear terms of the form $f(u) = -mu - u^3, m \geq 0$ (meson equation), or $f(u) = -\sin u$ (sine-Gordon equation) have been proposed as models of self-interacting fields with a local interaction. Notice that for the physical applications it is natural to consider complex-valued functions $u(t, x)$; in the general case of eqn [1], this actually means that we are considering a $2 \times 2$ system in $\Re u$ and $\Im u$. However, the natural physical requirement of gauge invariance restricts the possible nonlinearities to the functions satisfying the condition

$$f(e^{i\theta} u) = f(u) e^{i\theta}, \quad \forall \theta \in \mathbb{R} \qquad [4]$$

Thus, in particular $f(0) = 0$ and we see that $f$ must be of the form $f(u) = g(|u|^2)u$ for some $g$. Since the gauge-invariant wave equation

$$\Box u = g(|u|^2)u \qquad [5]$$

has essentially the same properties as the real-valued equation [3], it is not too restrictive to study only real-valued functions as we shall mostly do in the following.

The more general equations of the form [1], involving the derivatives of $u$, are encountered in several physical theories, including the nonlinear $\sigma$-models and general relativity.

However, beyond the concrete physical applications, eqn [1] is important since it is a simplified but relevant model of much more general equations and systems of mathematical physics; despite its simple structure, the semilinear wave equation presents already all the main difficulties and phenomena of nonlinear wave interaction, and it represents an ideal laboratory for such problems.

In this article we plan to give a concise but, as far as possible, comprehensive review of the main research directions concerning eqn [1], and in particular we shall focus on the global existence of both large and small nonlinear waves, and the problem of local existence for low-regularity solutions. A large part of the theory extends to nonlinear perturbations of the form $\Box u = F(u, u', u'')$ and to the fully nonlinear case; we have no space here to give an account of these developments and we must refer the reader to the books and papers cited in the "Further reading" section.

## Classical Results

Equations [1] and [3] are hyperbolic with respect to the variable $t$. This is a precise way of stating that the "correct" problem for it is an initial-value problem (IVP) with data at some fixed time, or

more generally on some spacelike surface: this means that we assign two functions $u_0(x), u_1(x)$, called the "initial data," and we look for a function $u(t,x)$ satisfying the IVP:

$$\Box u = F(u,u'), \quad u(0,x) = u_0(x), \quad u_t(0,x) = u_1(x) \qquad [6]$$

This setting is in agreement with the physical picture of an evolution problem: the data represent the complete state of a system at a fixed time, and they uniquely determine the evolution of the system, which is described by the differential equation.

This rough statement of the problem is sufficient when working with smooth functions, as in the classical approach. By purely classical methods, that is, energy inequalities and nonlinear estimates, it is not difficult to prove the following local existence result, where $H^k = H^k(\mathbb{R}^n)$ denotes the Sobolev space of functions with $k$ derivatives in $L^2(\mathbb{R}^n)$:

**Theorem 1** *Assume $F$ is $C^\infty$. Let $(u_0,u_1) \in H^k \times H^{k-1}$ for some $k > 1 + n/2$. Then there exists a time $T = T(\|u_0\|_{H^k} + \|u_1\|_{H^{k-1}}) > 0$ such that problem [6] has a unique solution belonging to $(u,u_t) \in C([-T,T]; H^k) \times C([-T,T]; H^{k-1})$.*

*If $F = F(u)$ depends only on $u$, the result holds for all $k > n/2$.*

**Proof** We decided to include a sketchy but complete proof of this result since it shows the basic approach to nonlinear wave equations: many results of the theory, even some of the most delicate ones, are obtained by suitable variations of the contraction method, and are similar in spirit to this classical theorem.

Assume for a moment that the equation is linear so that $F = F(t,x)$ is a given smooth function of $(t,x)$. For the linear equation $\Box u = F$, we can construct a solution $u$ using explicit formulas. Moreover, $u$ satisfies the energy inequality

$$E_k(t) \le E_k(0) + \int_0^t \|F(s,\cdot)\|_{H^{k-1}}\, ds \qquad [7]$$

where the energy $E_k(t)$ is defined as

$$E_k(t) = \|u(t,\cdot)\|_{H^k} + \|u_t(t,\cdot)\|_{H^{k-1}} \qquad [8]$$

Now we introduce the space $X_T = C([-T,T]; H^k) \cap C^1([-T,T]; H^{k-1})$, the space $Y_T = C([-T,T]; H^{k-1})$, the mapping $\Phi : F \to u$ that takes the function $F(t,x)$ into the solution of $\Box u = F$ (with fixed data $u_0, u_1$), and the mapping $\Psi(u) = F(u,u')$ which is the original right-hand side of the equation.

The energy inequality tells us that $\Phi$ is bounded from $Y_T$ to $X_T$. Actually, for $M$ large enough with respect to $E_k(0)$ (the $H^k$ norm of the data), $\Phi$ takes any ball $B_Y(0,N)$ of $Y_T$ into the ball $B_X(0, M + NT)$ of $X_T$. Moreover, if we apply [7] to the difference of two equations $\Box u = F$ and $\Box v = G$, we also see that $\Phi$ is Lipschitz continuous from $Y_T$ to $X_T$, with a Lipschitz constant $CT$.

On the other hand, $\Psi(u) = F(u,u')$ takes $X_T$ to $Y_T$, provided $k > 1 + n/2$; we can even say that it is Lipschitz continuous from $B_X(0,M)$ to $B_Y(0, C(M))$ for some function $C(M)$, with a Lipschitz constant $C_1(M)$ also depending on $M$. This follows easily from Moser type estimates like

$$\|F(u,u')\|_{H^{k-1}} \le \phi(\|u\|_{L^\infty})\|u\|_{H^k}, \quad k > \frac{n}{2} + 1$$

or

$$\|F(u)\|_{H^k} \le \phi(\|u\|_{L^\infty})\|u\|_{H^k}, \quad k > \frac{n}{2}$$

Now it is easy to conclude: the composition $\Phi \circ \Psi$ maps $X_T$ into itself, and actually is a contraction of $B_X(0,M)$ into itself provided $M$ is large enough with respect to the data, and $T$ is small enough with respect to $M$. The unique fixed point is the required solution. $\Box$

The wave operator has an additional important property called the finite speed of propagation, which can be stated as follows: given the IVP

$$\Box u = 0, \qquad u(0,x) = u_0(x), \qquad u_t(0,x) = u_1(x)$$

if we modify the data "outside" a ball $B(x_0,R) \subset \mathbb{R}^n$, the values of the solution inside the cone

$$K(x_0,R) = \{(t,x) : t \ge 0,\ |x - x_0| < R - t\}$$

do not change. Notice that $K(x_0,R)$ is the cone with basis $B(x_0,R)$ and tip $(R,x_0)$; the slope of its mantle represents the speed of propagation of the signals, which for the wave operator $\Box$ is equal to 1. The property extends without modification to the semilinear problem [6], at least for the smooth solutions given by Theorem 1. Actually, it is not difficult to modify the proof of the theorem to work on cones instead of bands $[-T,T] \times \mathbb{R}^n$; in other words, given a ball $B = B(x_0,R)$, we can assign two data $u_0 \in H^k(B)$, $u_1 \in H^{k-1}(B) (k > n/2 + 1)$ and prove the existence of a local solution on the cone $K(x_0,R)$ for some time interval $t \in [0,T]$.

In general, the finite speed of propagation allows us to localize in space most of the results and the estimates; as a rule of thumb, we expect that what is true on a band $[0,T] \times \mathbb{R}^n$ should also be true on any truncated cone $K(x_0,R) \cap \{0 \le t \le T\}$.

## Symmetries

The linear wave equation can be written as the Euler–Lagrange equation of a suitable Lagrangian. This is still true for the semilinear perturbations of the form

$$\square u + f(u) = 0 \qquad [9]$$

Indeed, denoting with $F(s) = \int_0^s f(\sigma)\,d\sigma$ the primitive of $f$, the Lagrangian of [9] is

$$\mathcal{L}(u) = \iint \left[ -\frac{1}{2}|u_t|^2 + \frac{1}{2}|\nabla_x u|^2 + F(u) \right] dt\,dx \qquad [10]$$

The functional $\mathcal{L}$ is not positive definite; hence, the variational approach gives only weak results. However, this point of view allows us to apply Noether's principle: any invariance of the functional is related to a conservation law of the equation. These conserved quantities can also be obtained by taking the product of the equation by a suitable multiplier, although this method is far from obvious in many cases. We describe here this circle of ideas briefly.

The functional $\mathcal{L}$ is invariant under the Poincaré group, generated by time and space translations and the Lorentz transformations ($\lambda > 1, c \neq 0$):

$$t \mapsto \frac{\lambda t - x_j/c}{\sqrt{\lambda^2 - 1}}, \qquad x_j \mapsto \frac{\lambda x_j - ct}{\sqrt{\lambda^2 - 1}} \qquad [11]$$

The infinitesimal generators of the translations are simply the partial derivatives $D_t$ and $D_{x_j}$. The Lorentz transformations can be decomposed as a rotation followed by a boost, and indeed a corresponding complete set of infinitesimal generators are the operators

$$\Gamma_{jk} = x_j D_k - x_k D_j, \qquad \Gamma_j = x_j D_t + t D_j \qquad [12]$$

All the operators in the Poincaré group commute with $\square$ exactly.

The conservation law related to time translations (time derivative) is the fundamental "conservation of energy"

$$E(t) = \int \left[ \frac{1}{2}u_t^2 + \frac{1}{2}|\nabla_x u|^2 + F(u) \right] dx = E(0) \qquad [13]$$

while spatial translations (spatial derivatives) lead to the conservation of momenta

$$\int u_t u_{x_j}\, dx = \text{const.}, \quad j = 1, \ldots, n$$

On the other hand, infinitesimal rotations and boost [12] are connected to the conservation of angular momenta

$$\int [x_k D_j u - x_j D_k u] \cdot D_t u\, dx = \text{const.}, \quad j,k = 1, \ldots, n \qquad [14]$$

and

$$\int [x_k e(u) + D_k u\, D_t u]\, dx = \text{const.}, \quad k = 1, \ldots, n \qquad [15]$$

where

$$e(u) = \tfrac{1}{2}u_t^2 + \tfrac{1}{2}|\nabla_x u|^2 + F(u) \qquad [16]$$

is the energy density.

The Poincaré group does not exhaust the invariance properties of the free wave equation. Among the other transformations which commute or almost commute with $\square$, we mention the spacetime dilations and inversions (which together with translations and Lorentz transformations generate the larger conformal group), the scaling $u \mapsto \lambda u$, the spatial dilations, and, in the complex-valued case, the gauge transformation $u \mapsto e^{i\theta} u$. In this way several useful conservation laws can be obtained, including the conformal energy identities of K Morawetz.

## Strichartz Estimates

Energy estimates are very useful tools but they have some major shortcomings. The main one is clearly the large number of derivatives necessary to estimate the nonlinear term. This is why the modern theory of semilinear wave equations relies mainly on different tools, which go under the umbrella name of Strichartz estimates and express the decay properties of solutions when measured in $L^p$ or related norms. In this section we summarize these estimates in their most general form, and try to give a feeling of the techniques involved.

Consider the following IVP for a homogeneous linear wave equation:

$$\square u = 0, \qquad u(0,x) = 0, \qquad u_t(0,x) = f(x) \qquad [17]$$

The conservation of energy states that

$$\|u_t(t,\cdot)\|_{L^2}^2 + \|\nabla_x u(t,\cdot)\|_{L^2}^2 \equiv \|f\|_{L^2}^2 \qquad [18]$$

for all times $t$. Thus, we see that $L^2$-type norms of the solution do not decay. The interesting fact is that if we measure the solution $u$ in a different $L^p$-norm, $p > 2$, the norm decays as $t \to \infty$, and the decay is fastest for the $L^\infty$-norm.

To appreciate the dispersive phenomena at their best, let us assume that the Fourier transform of the data is localized in an annulus of order 1:

$$\operatorname{supp} \hat{f}(\xi) \subset \{1/2 \leq |\xi| \leq 2\} \qquad [19]$$

Then the corresponding solution $u(t,x)$ has the same property, and we see that

$$\|u\|_{L^2} = \|\hat{u}\|_{L^2} \le 2\||\xi|\hat{u}\|_{L^2} \equiv 2\|\nabla u\|_{L^2} \le 4\|u\|_{L^2}$$

We condense the last line in the shorthand notation

$$\|u\|_{L^2} \simeq \|\nabla u\|_{L^2}$$

We shall also write

$$\|v\|_X \lesssim \|w\|_Y \iff \|v\|_X \le C\|w\|_Y \quad \text{for some } C$$

We can now rewrite the conservation of energy [20] in a very simple form; for localized data (and hence a localized solution) as in [19], we have

$$\|u(t,\cdot)\|_{L^2} \lesssim \|f\|_{L^2} \qquad [20]$$

The basic $L^\infty$-estimate for a solution of [17] with localized data as in [19] is simply

$$\|u(t,\cdot)\|_{L^\infty} \lesssim t^{-(n-1)/2}\|f\|_{L^1} \qquad [21]$$

This estimate is well known since the 1960s; it can be proved easily by several techniques, notably by the stationary-phase method. Property [21] measures the fact that as time increases, the total energy of the solution remains constant but spreads over a region of increasing volume, due to the propagation of waves. If we interpolate between [20] and [21], we obtain the full set of dispersive estimates

$$\|u(t,\cdot)\|_{L^q} \lesssim t^{-(n-1)(1/2-1/q)}\|f\|_{L^p}$$
$$\frac{1}{q}+\frac{1}{p}=1, \quad 2 \le q \le \infty \qquad [22]$$

Recall that we are working with localized solutions on the annulus $|\xi| \sim 1$; it is easy to extend the above estimates to general solutions by a rescaling argument, exploiting the fact that, if $u(t,x)$ is a solution of the homogeneous wave equation, $u(\lambda t, \lambda x)$ is also a solution for any constant $\lambda$. Indeed, if $\hat{f}$ (and hence $\hat{u}$) is supported in the annulus $2^{j-1} \le |\xi| \le 2^{j+1}$, $j \in \mathbb{Z}$, by rescaling [21], we obtain

$$\|u(t,\cdot)\|_{L^\infty} \lesssim t^{-(n-1)/2}2^{j(n-1)/2}\|f\|_{L^1} \qquad [23]$$

If $f$ is any smooth function, not localized in frequency, we can still write it as a series

$$f = \sum_{j\in\mathbb{Z}} f_j$$

where $\operatorname{supp} \hat{f}_j \subset \{2^{j-1} \le |\xi| \le 2^{j+1}\}$. The quantity

$$\|f\|_{\dot{B}^s_{1,1}} = \sum_{j\in\mathbb{Z}} 2^{js}\|f_j\|_{L^1}$$

is by definition the $\dot{B}^s_{1,1}$ Besov norm of $f$. Thus, summing the estimates [23] over $j$, we conclude that a general solution of [17] satisfies the dispersive estimate

$$\|u(t,\cdot)|_{L^\infty} \lesssim t^{-(n-1)/2}\|f\|_{\dot{B}^{(n-1)/2}_{1,1}} \qquad [24]$$

The Strichartz estimates can be obtained as a consequence of the above dispersive estimates, plus some subtle functional analytic arguments. In the general form we give here, they were proved by J Ginibre and G Velo, and in the most difficult endpoint cases by Keel and T Tao. The solution of the homogeneous problem [17] studied above can be written as

$$u(t,x) = \frac{\sin(t|D|)}{|D|}f, \quad |D| \equiv \mathcal{F}^{-1}|\xi|\mathcal{F}$$

(here $\mathcal{F}$ denotes the Fourier transform). On the other hand, the solution of the complete nonhomogeneous problem

$$\Box u = F(t,x), \quad u(0,x) = u_0, \quad u_t(0,x) = u_1(x) \qquad [25]$$

can be written by Duhamel's formula as

$$u(t,x) = \frac{\partial}{\partial t}\frac{\sin(t|D|)}{|D|}u_0 + \frac{\sin(t|D|)}{|D|}u_1 + \int_0^t \frac{\sin((t-s)|D|)}{|D|}f\,ds$$

and we see that the above estimates [22] apply to all the operators appearing here. If we consider problem [25] and we assume that the data $F(t,x), u_0, u_1$ are localized in frequency so that $\hat{F}(t,\xi), \hat{u}_0, \hat{u}_1$ have support in the annulus $|\xi| \sim 1$, the Strichartz estimate takes the following form:

$$\|u\|_{L^p_I L^q} \lesssim \|u_0\|_{L^2} + \|u_1\|_{L^2} + \|F\|_{L^{\tilde{p}'}_I L^{\tilde{q}'}} \qquad [26]$$

Here the dimension is $n \ge 2$; $L^p_I L^q$ denotes the space with norm

$$\|u\|_{L^p_I L^q} = \left(\int_I \|u(t,\cdot)\|^p_{L^q(\mathbb{R}^n)}\,dt\right)^{1/p}, \quad I = [0,T]$$
$$\text{or } I = \mathbb{R}$$

the indices $p, q$ satisfy the conditions

$$\frac{1}{p}+\frac{1}{q}\frac{n-1}{2} \le \frac{1}{2}\frac{n-1}{2},$$
$$p \in [2,\infty], \ (n,p,q) \ne (3,2,\infty) \qquad [27]$$

while $\tilde{p}, \tilde{q}$ satisfy an identical condition (and $p'$ denotes the conjugate index to $p$). The constant in inequality [26] is uniform with respect to the interval $I$.

To get the most general form of the estimates, some additional function space trickery is required. As before, a simple rescaling argument extends estimate [26] to the case of data $F, u_0, u_1$, whose spatial Fourier transforms are localized in the annulus $2^{j-1} \leq |\xi| \leq 2^{j+1}$; we obtain

$$2^{j(1/p+n/q)}\|u\|_{L_I^p L^q} \lesssim 2^{jn/2}\|u_0\|_{L^2} + 2^{j(n/2-1)}\|u_1\|_{L^2} + 2^{j(1/\tilde{p}'+n/\tilde{q}'-2)}\|F\|_{L_I^{\tilde{p}'} L^{\tilde{q}'}}$$

Finally, if the data are arbitrary, we may decompose them as series of localized functions, and summing the corresponding estimates we obtain the general Strichartz estimates for the wave equation [25]: for all $(p, q)$ and $(\tilde{p}, \tilde{q})$ as in [27],

$$\|u\|_{L_I^p \dot{B}^{1/p+n/q}_{q,2}} \lesssim \|u_0\|_{\dot{H}^{n/2}} + \|u_1\|_{\dot{H}^{n/2-1}} + \|F\|_{L_I^{\tilde{p}'} \dot{B}^{1/\tilde{p}'+n/\tilde{q}'-2}_{\tilde{q}',2}} \quad [28]$$

Here, given a decomposition $f = \sum_{j\in\mathbb{Z}} f_j$, the homogeneous Besov and Sobolev norms are defined, respectively, by the identities (obvious modification for $r=\infty$):

$$\|f\|^r_{\dot{B}^s_{q,r}} = \sum_{j\in\mathbb{Z}} 2^{jsr}\|f_j\|^r_{L^q},$$
$$\|u\|_{\dot{H}^s} = \||\xi|^s\hat{u}\|_{L^2} \simeq \|u\|_{\dot{B}^s_{2,2}}$$

It is easy to convert the estimates [28] into a form that uses only the more traditional norms

$$\|f\|_{\dot{H}^s_q} \equiv \||D|^s f\|_{L^q}, \qquad |D|^\sigma \equiv \mathcal{F}^{-1}|\xi|^\sigma\mathcal{F}$$

since by the Besov–Sobolev embedding we have

$$\dot{B}^s_{q,2} \subseteq \dot{H}^s_q \text{ for } 2 \leq q < \infty,$$
$$\dot{B}^s_{q,2} \supseteq \dot{H}^s_q \text{ for } 1 < q \leq 2$$

Notice that if we apply to the equation and the data the operator $|D|^\sigma = \mathcal{F}^{-1}|\xi|^\sigma\mathcal{F}$, which commutes with $\square$, the Strichartz estimate [28] can be rewritten in an apparently more general form:

$$\|u\|_{L_I^p \dot{B}^{1/p+n/q+\sigma}_{q,2}} \lesssim \|u_0\|_{\dot{H}^{n/2+\sigma}} + \|u_1\|_{\dot{H}^{n/2-1+\sigma}} + \|F\|_{L_I^{\tilde{p}'} \dot{B}^{1/\tilde{p}'+n/\tilde{q}'-2+\sigma}_{\tilde{q}',2}} \quad [29]$$

In particular, it is possible to choose the indices in such a way that no derivatives appear on $u$ and $F$: this choice gives

$$\|u\|_{L^p(\mathbb{R}^{n+1})} \lesssim \|u_0\|_{\dot{H}^{1/2}} + \|u_1\|_{\dot{H}^{-1/2}} + \|F\|_{L^{p'}(\mathbb{R}^{n+1})}$$
$$p = \frac{2(n+1)}{n-1}$$

which is the estimate originally proved by Strichartz.

## Global Large Waves

As for ordinary differential equations (ODEs), the local solutions constructed in Theorem 1 can be extended to a maximal time interval $[0, T^*]$, and a natural question arises: are these maximal solutions global, that is, is $T^* = \infty$?

For generic nonlinearities and large data, the answer is negative; in a dramatic way, in general the norm $\|u(t, \cdot)\|_{L^\infty}$ is unbounded as $t\uparrow T^* < \infty$. The reason for this is simple: using the finite speed of propagation, we can localize the equation and work on a cone; then if we take constant functions as initial data, the solution inside the cone does not depend on $x$, and the equation restricted to the cone effectively reduces to an ODE:

$$\square u = f(u) \iff y''(t) = f(y), \quad y(t) \equiv u(t,x) \quad [30]$$

By this remark it is elementary to construct solutions of the IVP [6] that blow up in a finite time.

This construction does not apply if the equation has some positive conserved quantity. Indeed, consider a general gauge-invariant equation

$$\square u + g(|u|^2)u = 0, \quad u(0,x) = u_0(x), \quad u_t(0,x) = u_1(x) \quad [31]$$

for some smooth function $g(s)$. Writing $G(s) = \int_0^s g(\sigma)\,d\sigma$, multiplying the equation by $\overline{u}_t$, and integrating over $\mathbb{R}^n$, it is easy to check that the nonlinear energy

$$E(t) = \int \left[|u_t|^2 + |\nabla_x u|^2 + G(|u|^2)\right] dx \equiv E(0) \quad [32]$$

is constant in time, provided the solution $u$ is smooth enough. When $G(s)$ has no definite sign, we can proceed as above and construct solutions that blow up in finite time; this is usually called the "focusing" case. However, if we assume that $G(s) \geq 0$ ("defocusing" case), the energy $E(t)$ is non-negative. The corresponding ODE, which is $y'' + g(y^2)y = 0$, has only global solutions, and one may guess that also the solutions of [31] can be extended to global ones.

This innocent-looking guess turns out to be one of the most difficult problems of the theory of nonlinear waves, and is actually largely unsolved at present.

The only general result for eqns [31] is Segal's theorem, stating that the IVP has always a global weak solution:

**Theorem 2** *Let $g(s)$ be a $C^1$ non-negative function on $[0, +\infty)$, write $G(s) = \int_0^s g(\sigma)\,d\sigma$ and assume that for some constant C*

$$sg(s^2) \leq CG(s^2), \qquad \lim_{s\to+\infty} G(s) = +\infty \quad [33]$$

*Then for any* $(u_0, u_1) \in H^1 \times L^2$ *such that* $G(|u_0|^2) \in L^1$, *the IVP* [31] *has a global solution* $u(t, x)$ *in the sense of distributions, such that* $u' \in L^\infty(\mathbb{R}, L^2(\mathbb{R}^n))$ *and* $F(u) \in L^\infty(\mathbb{R}, L^1(\mathbb{R}^n))$.

The proof (see Shatah and Struwe (1998)) is delicate but elementary in spirit: by truncating the nonlinear term, we can approximate the problem at hand with a sequence of problems with global solution; then the conservation law [32] yields some extra compactness, which allows us to extract a subsequence converging to a solution of the original equation.

Thus we see that, despite its generality, this result does not shed much light on the difficulties of the problem. Indeed, the weak solution obtained might not be unique, nor smooth, and in these questions the real obstruction to solving [31] is hidden.

Notice that in the one-dimensional case $n = 1$ the solution is always unique and smooth when the data are smooth, since in this case $E(t)$ controls the $L^\infty$-norm of $u$. For higher dimensions $n \geq 2$, something more can be proved if we assume that the nonlinear term has a polynomial growth:

$$sg(s^2) = |s|^{p-1}s \quad \text{for } s \text{ large, } p > 1 \qquad [34]$$

In particular, the defocusing wave equation with a power nonlinearity

$$\Box u + |u|^{p-1}u = 0 \qquad [35]$$

has been studied extensively. Notice that when $p$ is close to 1, the term $|u|^{p-1}u$ becomes singular near 0; this introduces additional difficulties in the problem; for this reason, it is better to consider a smooth term as in [34].

We can summarize the best-known results concerning [31] under [34] as follows. Let $p_0(n)$ be the number

$$p_0(1) = p_0(2) = \infty$$
$$p_0(n) = 1 + \frac{4}{n-2} \quad \text{for } n \geq 3$$

Then

- in the subcritical case $1 \leq p < p_0(n)$, for any data $(u_0, u_1) \in H^1 \times L^2$, there exists a unique solution $u \in C(\mathbb{R}; H^1)$ such that $u' \in C(\mathbb{R}; L^2)$;
- the same result holds in the critical case $p = p_0(n)$ for $n \geq 3$; and
- when $3 \leq n \leq 7, 1 \leq p \leq p_0(n)$, the solution is smoother if the data are smoother.

These results have been achieved in the course of more than 30 years through the works of several authors (it is indispensable to mention at least the names of K Jörgens, I Segal, W Strauss, W von Wahl, P Brenner, H Pecher, J Ginibre, G Velo, R Glassey and the more recent contributions of J Shatah, M Struwe, L Kapitanski, M Grillakis, omitting many others). Actually modern proofs are remarkably simple, and are based again on a variation of the fixed-point argument. Roughly speaking, the linear equation $\Box u + g(|v|^2)v = 0$ defines a mapping $v \mapsto u$; the Strichartz estimates localized on a cone imply that this mapping is Lipschitz continuous in suitable spaces, the Lipschitz constant being estimated by the nonlinear energy of the solution restricted to the cone. In order to show that this mapping is actually a contraction, it is sufficient to prove that the localized energy tends to zero near the tip of the cone, that is, it cannot concentrate at a point. Once this is known, it is easy to continue the solution beyond any maximal time of existence and prove the global existence and uniqueness of the solution.

In the supercritical case $p > p_0(n)$, very little is known at present; there is some indication that the problem is much more unstable than in the subcritical case (Kumlin, Brenner, Lebeau), and there is some numerical evidence in the same direction.

## Global Small Waves

It was noted already in the 1960s (Segal, Strauss) that the equation in dimension $n \geq 2$

$$\Box u = f(u), \quad u(0,x) = \varepsilon u_0(x), \quad u_t(0,x) = \varepsilon u_1(x)$$
$$f(u) = O(|u|^\gamma) \quad \text{for } u \sim 0$$

with small data can be considered as a perturbation of the free wave equation and admits global solutions. The phenomenon may be regarded as follows: the wave operator tends to spread waves and reduce their size (see [21]); the nonlinear term tends to concentrate the peaks and make them higher, but at the same time it makes small waves smaller. If the rate of dispersion is fast enough, the initial data are small enough, and the power of the nonlinear term is high enough, the peaks have no time to concentrate, and the solution quickly flattens out to 0. Notice that in dimension 1 there is no dispersion, and this kind of mechanism does not occur.

It was, however, F John who initiated the modern study of this question by giving the complete picture in dimension 3: for the IVP

$$\Box u = |u|^\gamma, \quad u(0,x) = \varepsilon u_0(x)$$
$$u_t(0,x) = \varepsilon u_1(x), \quad n = 3$$

he proved that, for fixed $u_0, u_1 \in C_0^\infty$,

- if $\gamma > 1 + \sqrt{2}$ and $\varepsilon$ is small enough, the solution is global and
- if $1 < \gamma < 1 + \sqrt{2}$ and the data are not identically zero, the solutions blow up in a finite time for all $\varepsilon$ (i.e., the $L^\infty$-norm is unbounded).

Later Schaeffer proved that blow-up occurs also at the critical value $\gamma = 1 + \sqrt{2}$.

W Strauss guessed the correct critical value for all dimensions – $\gamma_0(n)$ is the positive root of the algebraic equation

$$\left(\frac{n-1}{2}\gamma - \frac{n+1}{2}\right)\gamma = 1$$

and conjectured that the same picture as in dimension 3 is valid for all dimensions $n \geq 2$.

Soon Sideris proved that, for $1 < \gamma < \gamma_0(n)$ and the quite general and small data, one always has blow-up. Also it was proved by Klainerman, Shatah, Christodoulou, and others that the positive part of the conjecture was true for $\gamma > \gamma_0(n)$, with a small gap near the critical value. The gap was closed by Georgiev, Lindblad, Sogge, who proved global existence for all $\gamma > \gamma_0(n)$. We also mention that the solution at the critical value $\gamma = \gamma_0(n)$ always seems to blow up; this is settled for low dimension (Schaeffer, Yordanov, Zhang and others), but the question is still not completely clear for large dimensions.

This problem has spurred a great deal of creativity, eventually leading to very fruitful results: the different approaches have proved useful in a variety of problems, sometimes quite different from the original semilinear equation. We mention a few:

- The weighted estimates of F John are estimates of the solution in spacetime $L^p$ norms with weights of the form $(1 + |t| + |x|)^\alpha (1 + ||t| - |x||)^\beta$. An extension of this method was also used in the final complete proof of the conjecture.
- The vector field approach of S Klainerman. If we regard energy estimates as norms generated by the plain derivatives, it is natural to extend them to more general norms generated by vector fields commuting, or quasicommuting, with the wave operator. The conservation of energy expressed in these generalized norms has a built-in decay that allows us to prove global existence of small waves. This circle of ideas led very far, and we might even regard Christodoulou and Klainerman's proof of the stability of Minkowski space for the Einstein equation as an extreme consequence of this approach.
- The normal forms of J Shatah. The idea is to apply a nonlinear (and nonlocal) transformation to the equation in order to increase the power $\gamma$. This method is effective for a variety of equations, including the semilinear wave, Klein–Gordon, and Schrödinger equations.
- The conformal transform method of D Christodoulou. The Penrose transform takes the wave operator on $\mathbb{R}^{1+n}$ to the wave operator on a bounded subset of $\mathbb{R} \times \mathbb{S}^n$, the so-called Einstein diamond (here $\mathbb{S}^n$ is the $n$-dimensional sphere). Thanks to the fact that a problem of global existence is converted into a problem of local existence, the proof reduces to showing that the lifespan of the local solution becomes large enough to cover the whole diamond when $\varepsilon$ decreases.

A similar theory has been developed for the more general semilinear equation

$$\Box u = F(u, u'), \quad F(u, u') = O(|u, u'|^\gamma) \text{ for } u \sim 0$$

but the results are less complete. The general picture is similar: for $\gamma \geq 2$ when $n \geq 4$, and for $\gamma \geq 3$ when $n = 3$, one has global small solutions, while for $\gamma$ close to 1 one in general has blow-up.

A very interesting phenomenon in this context was discovered by S Klainerman: some nonlinearities with a special structure, called "null structure," behave better than the others. This structure is clearly related to the wave operator, and in the end it can be precisely explained in terms of interaction of waves in phase space. We illustrate these ideas in the most interesting special case. Consider the equation in three dimensions

$$\Box u = F(D_t u, D_x u), \quad F = O(|u'|^\gamma), \ n = 3$$

In the "cubic" case $\gamma = 3$, one has global existence for all data small enough. On the other hand, in the "quadratic" case $\gamma = 2$, it is possible to construct examples where the solution blows up in a finite time no matter how small the data. Now, assume that the nonlinear term has the following structure:

$$F(u') = aQ_0(u') + \sum_{0 \leq j < k \leq 3} c_{jk} Q_{jk}(u') + O(|u'|^3) \quad [36]$$

which is called a "null structure". Here $a, c_{jk}$ are constants, and the quadratic forms $Q$ are the following:

$$Q_0(u') = |D_t u|^2 - |D_{x_1 u}|^2 - |D_{x_2 u}|^2 - |D_{x_3 u}|^2 \quad [37]$$

$$Q_{0j}(u') = D_t u \cdot D_{x_j} u - D_{x_j} u \cdot D_t u, \quad j = 1, 2, 3 \quad [38]$$

$$Q_{jk}(u') = D_{x_j} u \cdot D_{x_k} u - D_{x_k} u \cdot D_{x_j} u \quad j, k = 1, 2, 3, \ j < k \quad [39]$$

Then the problem has a global solution for all small enough data. The extensions and applications of this idea are very wide (see the "Further reading" section for further information). Another situation where the null structure plays an important role is discussed in the next section.

## Low Regularity

Theorem 1, although optimal in the classical framework, is not satisfactory for a few reasons. From a physicist's point of view, requiring $n/2+1$ derivatives of the data is not meaningful, since the measurable quantities involve only low-order derivatives, the most important one being the energy, that is, the $H^1$-norm of the solution. Moreover, the wave equation has a rich set of conserved quantities, symmetries and decay properties which may be useful to prove stronger results, and in particular the global existence. However, many of these structures appear only at a low-regularity level ($H^1$ or even $L^p$); in order to exploit them it is essential to work with low-regularity solutions.

As an example, if we were able to prove Theorem 1 for $k=1$, then we could deduce that the local solutions can be extended to global ones in all cases when the $H^1$-norm is conserved. For instance, this would allow us to solve globally the equations of the form

$$\Box u + G'(|u|^2)u = 0, \quad G(s) \geq 0$$

The problem of the lowest value of $s$ such that a unique local solution exists in $H^s$ is quite difficult, and still not completely solved. In order to state the results we precise the definition of solution as follows: the IVP is said to be locally well posed in $H^s$, if, for all $(u_0, u_1)$ in a bounded set $B$ of $H^s \times H^{s-1}$, there exist a $T>0$, a Banach space $X_T$ (depending on $B$) continuously embedded in $C([0,T]; H^s)$, and a unique solution $u \in X_T$, such that the map $(u_0, u_1) \mapsto u$ is continuous from $B$ to $X_T$.

For the wave equation with a power nonlinearity

$$\Box u = |u|^p \qquad [40]$$

or more generally

$$\Box u = F(u), \quad F(u) = 0$$
$$|F(u) - F(v)| \leq C|u-v|(|u|^{p-1} + |v|^{p-1}) \qquad [41]$$

the picture is almost complete. Indeed, by using the scaling

$$t \mapsto \lambda t, \qquad x \mapsto \lambda x \qquad [42]$$

and the Lorentz transformation

$$t \mapsto \frac{\lambda t - x_1}{\sqrt{\lambda^2 - 1}}, \qquad x \mapsto \frac{t - \lambda x_1}{\sqrt{\lambda^2 - 1}} \qquad [43]$$

it is possible to show by explicit constructions that

- the equation is not locally well posed for $p(n/2 - s) \leq (n/2 + 2 - s)$ (scaling) and
- the equation is not locally well posed for $p(n/4 + 1/4 - s) \leq n/4 + 5/4 - s$ (Lorentz).

On the positive side, local well-posedness has been almost fully proved in the complementary region of indices, with the exception of a tiny spot near the endpoint $s=0$, $p=(n+5)/(n+1)$ where the problem is still open (and the conjecture is that the equation is ill posed for indices in that region). These results are due to several authors, among the others we cite C Kenig, G Ponce, L Vega, H Lindblad, C Sogge, L Kapitanski, and T Tao.

When the nonlinearity depends also on the first-order derivatives of $u$, the situation becomes more complex. In the general case, the best result available is still the local existence theorem (Theorem 1); the only possible refinement is the use of fractional Sobolev spaces $H^s$, but in general local solvability only holds for $s > n/2+1$. If we assume that $F = F(u')$ is a quadratic form in the first-order derivatives, a clever use of Strichartz estimates allows us to prove local solvability down to $s > n/2 + 1/2$ for $n \geq 3$ and $s > 7/4$ for $n=2$ (Ponce and Sideris).

However, exactly as in the case of the small nonlinear waves examined in the previous section, if the nonlinear term has a null structure the result can be improved. Indeed, when $F(u')$ is a combination of the forms [37]–[39], then local solvability and uniqueness can be proved for all $s > n/2$, as in the case of a nonlinear term of the type $F(u)$. This result is due to Klainerman, Machedon, and Selberg. Again, the proof is based on a variation of the contraction method; the additional ingredient here is the use of suitable function spaces, which are the counterpart for the wave equation of the spaces used by Bourgain in the study of the nonlinear Schrödinger equation. The norm of these spaces is defined as follows:

$$\|u\|_{H^{s,\theta}} \equiv \|\langle\xi\rangle^s \langle|\tau| - |\xi|\rangle^\theta \widetilde{u}(\tau,\xi)\|_{L^2(\mathbb{R}^{n+1})}$$

where $\langle\xi\rangle = (1+|\xi|^2)^{1/2}$ and $\widetilde{u}$ is the spacetime Fourier transform of $u(t,x)$. The wave operator can be regarded as a spacetime Fourier multiplier of the form $\tau^2 - |\xi|^2 = (|\tau| - |\xi|)(|\tau| + |\xi|)$, and we see that "inverting" the operator $\Box$ has a regularizing effect in the scale of $H^{s,\theta}$ spaces, since it decreases both

$s$ and $\theta$ by one unit. Substantiating this formal argument and complementing it with suitable estimates for the nonlinear term requires some hard work, which is contained in the theory of bilinear estimates developed by Klainerman and his school.

# Separation of Variables for Differential Equations

**S Rauch-Wojciechowski**, Linköping University, Linköping, Sweden

**K Marciniak**, Linköping University, Norrköping, Sweden

## Introduction

The method of separation of variables (SoV) is a way of finding particular and general solutions of certain types of partial differential equations (PDEs). Its main idea is to consider the additive ansatz $u(x)=\sum_{\mathrm{i}} w_i(x^i,\alpha)$ or the multiplicative ansatz $u(x)=\prod_{\mathrm{i}} u_i(x^i,\alpha)$ for a solution of a PDE that allows for reducing this PDE to a set of (uncoupled) ordinary differential equations (ODEs) for the unknown functions $w_i(x^i,\alpha)$ or $u_i(x^i,\alpha)$ of one variable $x^i$, where $x=(x^1,\ldots,x^n)$. Locally, the additive ansatz is, through the change of variables $u(x)=\exp(\sum_{\mathrm{i}} w_i(x^i,\alpha))$, equivalent to the multiplicative ansatz.

Many well-known equations of mathematical physics such as the heat equation, the wave equation, the Schrödinger equation, and the Hamilton–Jacobi equation are solved by separating variables in suitably chosen systems of coordinates.

## Fourier Method

The SoV method can be attributed to Fourier (1945), who solved the heat equation

$$\partial_t u = \partial_{xx} u \qquad [1]$$

for distribution of temperature $u(x,t)$ in a one-dimensional metal rod (of length $L$) by looking first for special solutions of the product type $u(x,t)=X(x)T(t)$. This ansatz, substituted to [1], reduces it to two ODEs: $\partial_t T=-k^2 T$ and $\partial_{xx}X=-k^2X$ that can be solved by quadratures:

$$T_k(t)=A\mathrm{e}^{-k^2 t}, \qquad X_k(x)=B\cos(kx)+C\sin(kx)$$

Due to linearity of [1], any formal linear combination $u(x,t)=\sum_k c_k X_k(x)T_k(t)$ is again a solution of the heat equation and can be used for solving an initial boundary-value problem (IBVP). For instance,

in the case of the IBVP on the interval $0 \le x \le L$ and with zero boundary conditions

$$\begin{aligned} &\partial_t u = \partial_{xx} u, && 0 < t, 0 < x < L \\ &u(0,t) = u(L,t) = 0, && 0 < t \\ &u(x,0) = f(x), && 0 < x < L \end{aligned}$$

only a countable set of values for the separation constant $k$ is admissible: $k_n = (n\pi/L)$, $n = 1, 2, \ldots$. Then the general solution has the form of the Fourier series

$$u(x,t) = \sum_{n=1}^{\infty} c_n \exp\left(-k_n^2 t\right) \sin(k_n x)$$

where the coefficients $c_n$ are given by the integrals

$$c_n = \frac{2}{L} \int_0^L f(x) \sin(k_n x)\, \mathrm{d}x$$

The sequence of functions $\sin(k_n x)$ is complete on the interval $[0, L]$. That means that any regular (continuous and differentiable) initial data function $f(x)$ such that $f(0) = f(L) = 0$ can be uniquely expressed as an infinite convergent sum of the orthogonal set of functions $\sin(k_n x)$. The study of mathematical properties of the Fourier expansion gave rise to the classical theory of Fourier series and Fourier integrals.

## Separability of PDEs in General Setting

A general setting for an additive separability of a single, usually nonlinear, PDE has been developed by Levi-Civita (1904) and by Kalnins and Miller (1980) (see also Miller (1983)). Let

$$\begin{aligned} &H(x^1, \ldots, x^n; u, u_i, u_{ij}, u_{ijk}, \ldots) = E \\ &\quad 1 \le i, j, k \le n \end{aligned} \qquad [2]$$

be a finite-order PDE for an unknown function $u(x)$, where $u_i(x) = \partial_{x^i} u$, $u_{ij} = \partial_{x^j} \partial_{x^i} u$, etc., and $E$ is a constant. A separable solution $u(x) = \sum_i W_i(x^i)$ satisfies the simpler equation

$$E = H(x; u, u_i, u_{ii}, \ldots) \equiv H[x, u] \qquad [3]$$

where all mixed derivatives $u_{ij}$, etc., disappear. If a separable solution is admissible by eqn [2], then the function $H(x; u, u_i, u_{ii}, \ldots)$ has to satisfy a set of integrability conditions following from the total derivatives of [3]. Let

$$\begin{aligned} D_i &= \partial_{x^i} + u_{i,1} \partial_u + u_{i,2} \partial_{u_{i,1}} + \cdots + u_{i,m_i+1} \partial_{u_{i,m_i}} \\ &\equiv \widetilde{D}_i + u_{i,m_i+1} \partial_{u_{i,m_i}} \end{aligned}$$

(where $u_{i,1} = u_i, u_{i,j+1} = \partial_{x^i} u_{i,j}$, etc., and $m_i$ is the largest number $l$ such that $\partial_{u_{i,l}} H \ne 0$) denote the operator of total derivative with respect to (w.r.t.) $x^i$; then, $D_i H[x, u] = 0$ or

$$u_{i,m_i+1} = -\frac{\widetilde{D}_i H}{H_{u_i,m_i}}$$

where $H_{u_i,m_i} = \partial_{u_i,m_i} H$. The integrability conditions $D_j u_{i,m_i+1} = 0$, $j \ne i$, give rise to a large set of differential conditions to be satisfied by $H[x, u]$:

$$\begin{aligned} &H_{u_i,m_i} H_{u_j,m_j} \left(\widetilde{D}_i \widetilde{D}_j H\right) + H_{u_i,m_i u_j,m_j} \left(\widetilde{D}_i H\right)\left(\widetilde{D}_j H\right) \\ &\quad = H_{u_j,m_j} \left(\widetilde{D}_i H\right)\left(\widetilde{D}_j H_{u_i,m_i}\right) \\ &\qquad + H_{u_i,m_i} \left(\widetilde{D}_j H\right)\left(\widetilde{D}_i H_{u_j,m_j}\right) \end{aligned} \qquad [4]$$

In general, the conditions [4] are restrictions for both $H$ and the form of a particular separable solution $u(x)$. If [4] is satisfied identically w.r.t. all $u$, $u_{k,l}$, we say that the corresponding coordinate system $x^i$ is a regular separable coordinate system; then the PDE [3] admits a $(\sum_i m_i + 1)$-parameter family of separable solutions. Most cases considered in literature are regular; since then the separable solution is usually sufficiently general for solving various IBVPs.

A given PDE, however, usually does not satisfy [4]; since these equations are not of tensorial type, the natural question arises if there exists a suitable change of coordinates $y(x)$ such that the transformed PDE satisfies [4]. Such separation coordinates may or may not exist; it is usually very difficult to decide.

Here and in what follows, we speak about separability of a single (scalar) PDE. The theory of separability of systems of PDEs is still not developed fully, although it is of relevance in the theory of Maxwell equations and of the Dirac equation.

We present here the most classical part of SoV theory: orthogonal separability of the Hamilton–Jacobi equation for geodesic motions on Riemannian manifolds.

## Configurational Separation of Hamilton–Jacobi Equation on Riemannian Manifolds

Around 1842, C G J Jacobi invented the method of generating function for solving the canonical Hamilton equations

$$\begin{aligned} &\dot{x} = \frac{\partial H(x,y)}{\partial y}, && \dot{y} = -\frac{\partial H(x,y)}{\partial x} \\ &x = (x^1, \ldots, x^n) && y = (y^1, \ldots, y^n) \end{aligned} \qquad [5]$$

where $H(x, y)$ is a Hamiltonian and dot denotes the time derivative (Landau and Lifshitz 1976). In this

method, one looks for a generating function $W(x, \alpha)$ of a canonical transformation

$$y = \frac{\partial W(x, \alpha)}{\partial x}, \qquad \beta = \frac{\partial W(x, \alpha)}{\partial \alpha}$$

that transforms Hamiltonian equations [5] into simple equations for the new variables $\beta \in R^n$, $\alpha \in R^n$. Since the transformation is canonical, the transformed equations are again Hamiltonian with the new Hamiltonian $\widetilde{H}(\beta, \alpha) = H(x(\beta, \alpha), y(\beta, \alpha))$. If we choose this transformation so that $\widetilde{H}(\beta, \alpha) = \alpha_1$, then the transformed Hamilton equations become

$$\dot{\beta} = \frac{\partial \widetilde{H}(\beta, \alpha)}{\partial \alpha} = (1, 0, \ldots, 0)$$
$$\dot{\alpha} = -\frac{\partial \widetilde{H}(\beta, \alpha)}{\partial \beta} = 0$$

so that $\beta(t) = (t + \beta_{10}, \beta_{20}, \ldots, \beta_{n0})$, $\alpha(t) = (\alpha_{10}, \ldots, \alpha_{n0}) = \text{const.}$ and the solution $x(t), y(t)$ of the Hamilton equations [5] is then given implicitly by the equations

$$\beta(t) = \frac{\partial W(x(t), \alpha)}{\partial \alpha}, \qquad y(t) = \frac{\partial W(x(t), \alpha)}{\partial x}$$

Since

$$y = \frac{\partial W(x, \alpha)}{\partial x}$$

the generating function $W(x, \alpha)$ has to satisfy (identically w.r.t. $(x, \alpha)$) the first-order nonlinear PDE

$$H\left(x, \frac{\partial W(x, \alpha)}{\partial x}\right) = \alpha_1 \qquad [6]$$

This equation is called the Hamilton–Jacobi equation for the generating function $W(x, \alpha)$. It is solved when its complete integral $W(x, \alpha)$, complete means that

$$\det\left(\frac{\partial^2 W(x, \alpha)}{\partial x^i \partial \alpha_j}\right) \neq 0$$

depending on $n$ independent constants $\alpha$ is known. In general, it is very difficult to find solutions of [6]. The most important method is the method of separation of variables when one looks for a solution in the form $W(x, \alpha) = \sum_{k=1}^{n} W_k(x^k, \alpha)$ which is a sum of $n$ functions $W_k(x^k, \alpha)$, each depending on a single variable $x^k$ and, possibly, all constants $a$. If the Hamilton–Jacobi equation [6] admits such a solution, then integrating this equation is reduced to integrating $n$ (uncoupled) first-order ODEs for functions $W_k(x^k, \alpha)$. The constants $\alpha_k$ acquire then the meaning of integration constants.

A separable solution $W(x, \alpha)$ of [6] exists whenever the Hamiltonian $H(x, y)$ satisfies (identically) the integrability conditions [4] which in this case acquire the (nonlinear) form

$$\begin{aligned} L_{ij}(H) &\equiv \partial_i H \partial_j H \partial^i \partial^j H + \partial^i H \partial^j H \partial_i \partial_j H \\ &\quad - \partial_i H \partial^j H \partial^i \partial_j H - \partial^i H \partial_j H \partial_i \partial^j H \\ &= 0 \quad \text{for all } i, j = 1, \ldots, n \end{aligned} \qquad [7]$$

($\partial_i = \partial/\partial x^i, \partial^i = \partial/\partial y_i$) found by Levi-Civita (1904).

In classical mechanics the most important Hamiltonians are natural ones:

$$H(x, y) = \frac{1}{2}\sum_{i,j} g^{ij}(x) y_i y_j + V(x) \equiv G + V \qquad [8]$$

They are defined on the cotangent bundle $T^*Q$ of a configurational Riemannian manifold $Q$ with the metric tensor $g$. The function $G$ is the geodesic Hamiltonian associated with the metric tensor $g$. For such natural Hamiltonians, the Levi-Civita condition $L_{ij}(G + V) = 0$ splits into the condition $L_{ij}(G) = 0$ and a condition for the potential $V(x)$. The condition $L_{ij}(G) = 0$, depending solely on the kinetic energy term, is thus a necessary condition for coordinates $x^i$ on $Q$ to be separation coordinates for [8].

In the fundamental case of orthogonal separation (i.e., when $g^{ij} = 0$ for $i \neq j$), the Levi-Civita conditions $L_{ij}(G + V) = 0$ read

$$\begin{aligned} &\partial_i \partial_j g^{kk} - \left(\partial_i \ln g^{jj}\right)\partial_j g^{kk} \\ &\quad - \left(\partial_j \ln g^{ii}\right)\partial_i g^{kk} = 0, \quad i \neq j \end{aligned} \qquad [9]$$

$$\begin{aligned} &\partial_i \partial_j V - \left(\partial_i \ln g^{jj}\right)\partial_j V \\ &\quad - \left(\partial_j \ln g^{ii}\right)\partial_i V = 0, \quad i \neq j \end{aligned} \qquad [10]$$

The main questions arising here are

1. What is the algebraic form of orthogonally separable Riemannian metrics?
2. What is the form of separable coordinates on Riemannian manifolds?

The first question is answered by the Stäckel theorem (Stäckel 1891) that provides an algebraic characterization of orthogonal separability of a natural Hamiltonian $H = G + V$.

**Theorem 1** *The Hamilton–Jacobi equation for the natural Hamiltonian*

$$H = G + V = \frac{1}{2}\sum_i g^{ii}(x) y_i^2 + V(x)$$

*is separable in the (orthogonal) coordinates x if and only if*

(i) *There exists a matrix* $\Phi = [\varphi_{ij}(x^i)]$, $\det(\Phi) \neq 0$ *(so that the row i depends only on* $x^i$*) such that* $[g^{11}, \ldots, g^{nn}]$ *is the first row of the inverse matrix* $\Psi = \Phi^{-1}$.

(ii) *The potential V has the form* $V(x) = \sum_i g^{ii} f_i(x^i)$, *where each* $f_i(x^i)$ *is a function of one variable* $x^i$ *only.*

Such matrix $\Phi$ is called a Stäckel matrix.

**Proof** If

$$[g^{11}, \ldots, g^{nn}] \begin{bmatrix} \varphi_{11}(x^1) & \cdots & \varphi_{1n}(x^1) \\ \vdots & \ddots & \vdots \\ \varphi_{n1}(x^n) & \cdots & \varphi_{nn}(x^n) \end{bmatrix} = [1, 0, \ldots, 0] \qquad [11]$$

then the Hamilton–Jacobi equation for $H$ can be written as

$$\begin{aligned} \frac{1}{2}\sum_i g^{ii}\left(\frac{\partial W}{\partial x^i}\right)^2 + \sum_i g^{ii} f_i(x^i) = \alpha_1 \\ = \alpha_1 \sum_i g^{ii}\varphi_{i1}(x^i) + \alpha_2 \sum_i g^{ii}\varphi_{i2}(x^i) \\ + \cdots + \alpha_n \sum_i g^{ii}\varphi_{in}(x^i) \end{aligned} \qquad [12]$$

This equation admits an additively separable solution $W = \sum_i W_i(x^i)$, where the functions $W_i$ satisfy $n$ ODEs (separation equations):

$$\begin{aligned} \frac{1}{2}\left(\frac{\partial W_i}{\partial x^i}\right)^2 + f_i(x^i) \\ = \alpha_1\varphi_{i1}(x^i) + \alpha_2\varphi_{i2}(x^i) + \cdots + \alpha_n\varphi_{in}(x^i) \\ i = 1, \ldots, n \end{aligned} \qquad [13]$$

By differentiating [13] w.r.t. $\alpha_j$, we get

$$\varphi_{ij}(x^i) = \frac{\partial W_i}{\partial x^i}\frac{\partial^2 W_i}{\partial x^i \partial \alpha_j}$$

and thus

$$\det[\varphi_{ij}(x^i)] = \frac{\partial W_1}{\partial x^1} \cdots \frac{\partial W_n}{\partial x^n} \det\left(\frac{\partial^2 W}{\partial x^i \partial \alpha_j}\right) \neq 0$$

so that $W = \sum_i W_i(x^i)$ is indeed a complete integral of the Hamilton–Jacobi equation [12]. Conversely, if $W = \sum_i W_i(x^i)$ is a complete integral of the Hamilton–Jacobi equation [12], then by differentiating it w.r.t. $\alpha_j$ we get for $j = 1$

$$\sum_i g^{ii}\frac{\partial W_i}{\partial x^i}\frac{\partial^2 W_i}{\partial x^i \partial \alpha_j} = 1$$

and

$$\sum_i g^{ii}\frac{\partial W_i}{\partial x^i}\frac{\partial^2 W_i}{\partial x^i \partial \alpha_j} = 0$$

(for $j = 2, \ldots, n$), that is, the condition [11] for the Stäckel matrix

$$\Phi = \left[\frac{\partial W_i}{\partial x^i}\frac{\partial^2 W_i}{\partial x^i \partial \alpha_j}\right]$$

Further, we see that

$$\begin{aligned} V &= \alpha_1 - \frac{1}{2}\sum_i g^{ii}(\partial_{x^i} W_i)^2 \\ &= \frac{1}{2}\sum_i g^{ii}\left[\alpha_1\varphi_{i1}(x^i) - \frac{1}{2}(\partial_{x^i} W_i)^2\right] \\ &= \sum_i g^{ii} f_i(x^i) \end{aligned} \qquad \square$$

**Remark 2** The Stäckel characterization of orthogonal separability is equivalent to Levi-Civita conditions [9] and [10]. It is in fact a solution of these conditions.

**Remark 3** With every Stäckel matrix, one can relate a family of $n$ quadratic in momenta Hamiltonians defined by $n$ rows of the inverse Stäckel matrix $\Psi = \Phi^{-1} = [\psi_{kr}]$:

$$H_k = \frac{1}{2}\sum_{r=1}^{n} \psi_{kr} y_r^2, \quad k = 1, \ldots, n \qquad [14]$$

(so that $H_1 = G$). These Hamiltonians are linearly and functionally independent; they Poisson-commute (so that they form a Liouville integrable system) and are all diagonal so that they have common eigenvectors.

These properties are the main ingredients of an intrinsic (coordinate-independent) characterization of separable geodesic Hamiltonians $G$ in terms of involutive Killing tensors that is due to works of Eisenhart (1934), Kalnins and Miller (1980), and Benenti (1997).

**Theorem 4** *A necessary and sufficient condition for the existence of an orthogonal additive separable coordinate system x for the Hamilton–Jacobi equation of the geodesic Hamiltonian* $H_1 = G$ *on an n-dimensional (pseudo)-Riemannian manifold is that there exist n quadratic forms* $H_r = \sum_{i,j}^{n} h_r^{ij}(x) y_i y_j$ *such that*

(i) *They all Poisson-commute:* $\{H_r, H_s\} = 0, 1 \leq r, s \leq n$.

(ii) *The set* $\{H_r\}_{r=1}^{n}$ *is linearly independent.*

(iii) *There is a basis* $\{\omega_{(j)}\}_{j=1}^{n}$ *of n simultaneous eigenforms for all* $H_r$.

*If conditions(i)–(iii) are satisfied then there exist functions $g_j(x)$ such that $\omega_{(j)} = g_j \mathrm{d}x^j$, $j = 1, \ldots, n$.*

This theorem has been further simplified by Benenti (1997), who has shown that for separability it is sufficient that $g^{ij}$ admits a single Killing 2-tensor with simple eigenvalues and normal eigenvectors. He has also explained the role of ignorable coordinates.

These results are key ingredients of an answer to the question (2). Eisenhart (1934), starting from the fact that every separable geodesic Hamiltonian $H = G$ admits $n$ quadratic (w.r.t. momenta $y_i$) integrals of motion, derived a set of nonlinear PDEs characterizing separable Riemannian metrics. He has solved these equations for spaces of constant curvature. This solution is the basis of the Kalnins and Miller's (1986) diagrammatic classification of all orthogonal separation coordinates on $\boldsymbol{R}^n$ and the sphere $\boldsymbol{S}^n$. Separable coordinates on the Minkowski space $\boldsymbol{M}^n$ have not been classified yet.

Since the work of Robertson (1927) and Eisenhart (1934), it is known that in $\boldsymbol{R}^n, \boldsymbol{S}^n$ and, in general, in the space with diagonal Ricci tensor, the (additive) separability of Hamilton–Jacobi equation for the natural Hamiltonian $H = G + V$ is equivalent to multiplicative separability of the stationary Schrödinger equation with the same potential $V$:

$$(\Delta + V(x))\Theta(x) = E\Theta(x) \qquad [15]$$

where

$$\Delta = \sum_{i,j=1}^{n} \frac{1}{\sqrt{\det(g)}} \partial_i \left( \sqrt{\det(g)} g^{ij} \partial_j \right)$$

is the Laplace–Beltrami operator. Usually, multiplicative separated solutions $\Theta(x) = \prod_{i=1}^{n} \Theta_i(x)$ is considered but the change of the dependent variable $u = \ln \Theta$ transforms it into an additive separable solution. If we restrict our considerations to orthogonal separation coordinates ($g^{ij} = 0$ for $i \neq j$), eqn [15] becomes

$$\sum_{i=1}^{n} \left( g^{ii} (u_{ii} + u_i^2) + \frac{1}{\sqrt{\det(g)}} \partial_i \times \left( \sqrt{\det(g)} g^{ii} \right) u_i \right) + V(x) = E$$

where $u_i = \partial_i u$, $u_{ii} = \partial_i \partial_i u$. The integrability conditions [4] for regular separation lead to the Levi-Civita condition [9] on the components $g^{ii}$ of the metric tensor, upon comparison of the coefficients at $u_i^2$. The coefficients at $u_{ii}$ yield the Robertson condition

$$\partial_i \partial_j \ln \left( \sqrt{\det(g)} g^{ii} \right) = 0, \quad i \neq j$$

and the constant terms in [4] give the Levi-Civita equation [10] meaning that $V(x) = \sum_{i=1}^{n} g^{ii} f_i(x^i)$. Eisenhart has shown that the Robertson condition is equivalent to the requirement that the Ricci tensor is diagonal: $R_{ij} = 0$, $i \neq j$ in variables $x$ so that the Robertson condition is satisfied automatically in the Euclidean space, in spaces of constant curvature and in Einstein spaces. Thus every orthogonal coordinate system permitting multiplicative separation of the Schrödinger equation corresponds to the Stäckel form.

### Jacobi Problem of Separability

In order to apply the separability theory to physical Hamiltonians $H = (1/2)p^2 + V(q)$, $p = (p_1, \ldots, p_n)$, $q = (q^1, \ldots, q^n)$, it is essential to solve the following problem: "given a potential $V(q)$, decide if there exists a point transformation $x(q)$ to some curvilinear coordinates $x$ such that the Hamilton–Jacobi equation associated with $H$ is separable in coordinates $x$, and if such transformation exists, determine it and solve the obtained Hamilton–Jacobi equation."

This problem has been raised by Jacobi (1884) in connection with the problem of finding geodesic motions on a 3-axial ellipsoid. For solving this problem Jacobi introduced his "remarkable change of coordinates" to the generalized elliptic coordinates $x(q)$ defined through zeros of the rational function

$$1 + \sum_{i=1}^{n} \frac{(q^i)^2}{(z - \lambda_i)} \equiv \frac{\prod_j (z - x^j)}{\prod_i (z - \lambda_i)} \qquad [16]$$

where the constants $\lambda_i > 0$ are all different. From the graph of the left-hand side of [16], it is easy to see that there are exactly $n$ simple, real zeros. For given values of elliptic coordinates $x^j$, the values of $(q^i)^2$ are uniquely determined as residues at $\lambda_i$ while Cartesian coordinates $q^i$ are determined uniquely only in each $n$-tant of $\boldsymbol{R}^n$.

The Jacobi elliptic coordinates play a pivotal role in orthogonal separability on $\boldsymbol{R}^n$ and $\boldsymbol{S}^n$ since they are the mother of all other separation coordinates that can be obtained through proper and improper degenerations of $\lambda_i$'s. By using these coordinates Jacobi solved not only the geodesic motions on the ellipsoid but also the motion on the ellipsoid under the action of harmonic potential $V(q) = (1/2)q^2$. He has also found separation coordinates for a system of three interacting particles on the line known today as the Calogero system. In general, however, Jacobi considered the problem of finding separation coordinates for a given potential $V(q)$ to be very difficult. In *Vörlesungen über Dynamik*, ch. 26, he writes: "The main difficulty in integrating a given

differential equation lies in introducing convenient variables, which there is no rule for finding. Therefore, we must travel the reverse path and after finding some notable substitution, look for problems to which it can be successfully applied". This statement had a profound influence on further development of SoV theory that concentrated on characterizing separable Hamiltonians (as expressed in terms of separation coordinates) and on describing and classifying separation coordinates.

The original problem of Jacobi of finding separation variables for a given natural Hamiltonian has been taken up by Rauch-Wojciechowski (1986), who found a characterization of separable potentials $V(q)$ in terms of Cartesian coordinates $q_i$. Its invariant geometric form has been given by Benenti. A complete criterion of separability that allows for an effective testing and calculation of separation coordinates (if they exist) for $V(q)$ has been solved by Waksjö and Rauch-Wojciechowski (2003). This criterion is directly applicable to the problem of finding SoV for the Schrödinger equation.

### Criterion of Separability for $n=2$

The criterion of separability for $n=2$ can be read from the Bertrand–Darboux theorem.

**Theorem 5** (Bertrand–Darboux). *For the Hamiltonian*:

$$H=\tfrac{1}{2}(p_1^2+p_2^2)+V(q_1,\,q_2)$$

*the following statements are equivalent*:

(i) *H has a functionally independent integral of motion $\{H,K\}=0$ of the form*

$$\begin{aligned}K=&\left(aq_2^2+bq_2+c\right)p_1^2+\left(aq_1^2+\widetilde{b}q_1+\widetilde{c}\right)p_2^2\\&+\left(-2aq_1q_2-bq_1-\widetilde{b}q_2+d\right)p_1p_2\\&+k(q_1,q_2)\end{aligned}$$

(ii) *The potential $V(q_1,q_2)$ satisfies the following linear second-order PDE with quadratic coefficients*

$$\begin{aligned}0=&\,2\left(aq_2^2-aq_1^2+bq_2-\widetilde{b}q_1+c-\widetilde{c}\right)\partial_1\partial_2V\\&+(-2aq_1q_2-bq_1-\widetilde{b}q_2+d)\left(\partial_2^2V-\partial_1^2V\right)\\&+(6aq_2+3b)\partial_1V-(6aq_1+3\widetilde{b})\partial_2V\end{aligned}\qquad[17]$$

*where $a,b,\widetilde{b},c,\widetilde{c},d$ are some constants, $\partial_1=\partial_{q_1},\partial_2=\partial_{q_2}$.*

(iii) *The Hamilton–Jacobi equation for H is separable in one of the four orthogonal coordinate systems in the plane: elliptic, parabolic, polar, or Cartesian.*

**Remark 6** If the potential $V(q_1,q_2)$ is separable, then it admits an integral of motion $K$ that is quadratic w.r.t. momenta and $V$ satisfies (identically w.r.t. $q_1,q_2$) eqn [17] for certain values of the undetermined constants $a,b,\widetilde{b},c,\widetilde{c},d$. Since coefficients at linearly independent expressions of $q_1,q_2$ have to be equal to zero, the parameters $a,b,\widetilde{b},c,\widetilde{c},d$ have to satisfy a set of linear, algebraic, homogeneous equations. If there is a nonzero solution for $a,b,\widetilde{b},c,\widetilde{c},d$, then there exists an integral of motion $K$ and separation coordinates can be determined as characteristic variables for equation [17].

**Example 7** Separable cases of the Henon–Heiles potential

$$V=\tfrac{1}{2}\left(\omega_1q_1^2+\omega_2q_2^2\right)+\alpha q_1^2q_2-\tfrac{1}{3}\beta q_2^3$$

By substituting this form of $V$ into [17], we get two sets of admissible solutions for parameters $\alpha$, $\beta$, $\omega_1$, $\omega_2$: (i) $\beta=-\alpha$, $\omega_1=\omega_2$ with $V$ separable in rotated (by $\pi/4$) Cartesian coordinates; (ii) $\beta=-6\alpha$, $\omega_1$, $\omega_2$-arbitrary with $V$ separable in the shifted parabolic coordinates. In case (ii) eqn [17] becomes

$$\begin{aligned}2&\left(q_2-\frac{1}{4\alpha}(4\omega_1-\omega_2)\right)\partial_1\partial_2V\\&+q_1\left(\partial_2^2V-\partial_1^2V\right)+3\partial_1V=0\end{aligned}$$

and in its characteristic coordinates defined as $q_1=\sqrt{\xi\eta}$, $q_2=(1/2)(\xi-\eta)+(1/4\alpha)(4\omega_1-\omega_2)$ it takes the form $(\xi-\eta)\partial_\xi\partial_\eta V+\partial_\xi V+\partial_\eta V=0$ solved by $V(\xi,\eta)=(\xi+\eta)^2[f(\xi)+g(\eta)]$ which is separable in the parabolic coordinates.

### Effective Criterion of Separability for Arbitrary Dimension

For $n>2$, a similar theorem characterizing separability in generalized elliptic coordinates has been formulated by Rauch-Wojciechowski (1986).

**Theorem 8** (Elliptic Bertrand–Darboux). *For a natural Hamiltonian $H=(1/2)p^2+V(q)$, the following statements are equivalent*:

(i) *H has n global, functionally independent and involutive integrals of motion $\{H,K_i\}=0$, $\{K_i,K_j\}=0$, $i,j=1,\ldots,n$, having the form*

$$\begin{aligned}K_i&=\sum_{r=1,r\neq i}^{n}(\lambda_i-\lambda_r)^{-1}l_{ir}^2+p_i^2+k_i(q)\\l_{ir}&=q_ip_r-q_rp_i\end{aligned}\qquad[18]$$

(ii) *The potential V satisfies the following system of linear second-order PDEs*

$$(\lambda_i - \lambda_j)\partial_i\partial_j V - \Im_{ij}(2 + \Re)V = 0 \quad i,j = 1,\ldots,n,\ i \neq j \qquad [19]$$

$$\lambda_i\partial_i\Im_{jk}V + \lambda_j\partial_j\Im_{ki}V + \lambda_k\partial_k\Im_{ij}V = 0 \quad \text{all } i,j,k \text{ different} \qquad [20]$$

*where* $\Im_{ij} = q_i\partial_j - q_j\partial_i$, $\Re = \sum_{r=1}^{n} q_r\partial_r$.

(iii) *The Hamilton–Jacobi equation for H is separable in the generalized elliptic coordinates [16] with parameters* $\lambda_i$.

**Remark 9** Equations [19]–[20] follow from the compatibility conditions that mixed derivatives of $k_i(q)$ calculated from the conditions $\{H, K_r\} = 0$, are equal. This leads to an overdetermined system [19]–[20] of PDEs for $V(q)$. Equations [19]–[20] are not linearly independent but we keep both sets [19]–[20] in the formulation of this theorem because eqns [19] give rise to the basic Bertrand–Darboux equations [21] used in the criterion of separability while eqns [20] give rise to cyclic Bertrand–Darboux equations [22] used for testing the level of spherical symmetry in the potential.

For testing elliptic separability of any given potential $V(q)$, it is necessary to introduce into eqns [19] and [20] the freedom of choice of the Euclidean reference frame (as described by the Euclidean transformation $\widetilde{q} = A^t(q - b)$, $A \in \mathrm{SO}(n)$, $b \in \boldsymbol{R}^n$). By substituting it into [19]–[20], omitting tildes and summing over one of the indices, we obtain new equations

$$\begin{aligned} 0 = \sum_{k=1}^{n}\big(&(\alpha q_i q_k + \beta_i q_k + \beta_k q_i + \gamma_{ik})\partial_k\partial_j V \\ &- (\alpha q_j q_k + \beta_j q_k + \beta_k q_j + \gamma_{jk})\partial_k\partial_i V \\ &+ 3\big((\alpha q_i + \beta_i)\partial_j V - (\alpha q_j + \beta_j)\partial_i V\big)\big) \\ &i,j = 1,\ldots,n,\ i \neq j \end{aligned} \qquad [21]$$

$$\begin{aligned} 0 = \sum_{l=1}^{n}\big(&(\gamma_{il}q_j - \gamma_{jl}q_i)\partial_k\partial_l V + (\gamma_{jl}q_k - \gamma_{kl}q_j)\partial_i\partial_l V \\ &+ (\gamma_{kl}q_i - \gamma_{il}q_k)\partial_j\partial_l V\big) \end{aligned} \qquad [22]$$

with the new coefficients $\alpha$, $\beta_i$, $\gamma_{ij}$ that are unconstrained despite that the orthogonal matrix $A$ satisfies the quadratic algebraic constraint $AA^t = I$.

Theorem 8 provides the following test of elliptic separability for a potential $V(q)$ given in Cartesian coordinates.

1. Insert $V(q)$ into the Bertrand–Darboux equations [21]. This gives a system of linear, homogeneous, algebraic equations for the unknown parameters $\alpha$, $\beta_i$, $\gamma_{ij}$. If $\alpha = 0$, then $V(q)$ is not separable in elliptic coordinates.
2. If $\alpha \neq 0$, set $b = -\alpha^{-1}\beta$, $S = bb^t - \alpha^{-1}\gamma$ and diagonalize $S$: $S = A\,\mathrm{diag}(\lambda_1,\ldots,\lambda_n)A^t$. If some eigenvalues $\lambda_i$ coincide, then $V(q)$ is not separable in elliptic coordinates. Otherwise $V(q)$ is separable in the elliptic coordinates $x = (x^1,\ldots,x^n)$ given by

$$1 + \sum_{i=1}^{n}\frac{(\widetilde{q}^i)^2}{(z - \lambda_i)} \equiv \frac{\prod_j (z - x^j)}{\prod_i (z - \lambda_i)}$$

(compare with [16]), where $q = A\widetilde{q} + b$, with $b$ and $A$ found as above.

If $\alpha = 0$, $\beta \neq 0$, then there exists a similar algorithm for separability in generalized parabolic coordinates and for $\alpha = 0$, $\beta = 0$, $\gamma \neq tI$, we have separability in Cartesian coordinates if all $\lambda_i$ are different. For giving an idea of what happens when degenerations occur, consider the case $\alpha = 0$, $\beta = 0$. Then the Bertrand–Darboux equations [21] are Euclidean equivalent to the canonical form $(\lambda_i - \lambda_j)\ \partial_i\partial_j V = 0$ and if all $\lambda_i$ are different, then equations $\partial_i\partial_j V = 0$ imply that $V(q)$ is a sum of functions of one variable only: $V(q) = \sum_{i=1}^{n} V_i(q^i)$.

The main problem is to handle all possible degenerations when certain $\lambda$'s coincide. Let $\lambda_1 = \cdots = \lambda_j < \lambda_{j+1} < \cdots < \lambda_n$, where $1 < j < n$. Then $V(q) = V_j(q^1,\ldots,q^j) + V_{j+1}(q^{j+1}) + \cdots + V_n(q^n)$ which means that variables $q^{j+1},\ldots,q^n$ separate off while the potential $V_j(q^1,\ldots,q^j)$ has to be tested again on $\boldsymbol{R}^j$ with the use of eqns [21]. Degenerations for $\alpha \neq 0$ or $\beta \neq 0$ are more complicated and the cyclic Bertrand–Darboux equations [22] have to be used. They unfold the level of spherical degeneracy of spheres and embedded subspheres. A complete analysis of all possible degenerations is technical. It requires considering of all possible degenerations of the sequences $\lambda_1 < \cdots < \lambda_n$ and of the related equations [21]–[22] for the potential $V(q)$. It has been proved by Waksjö and Rauch-Wojciechowski (2003) that there is a one-to-one correspondence between all possible sets of PDEs [21]–[22] characterizing separable potentials and all possible types of Riemannian metrics (in the Kalnins and Miller (1986) classification of all separable coordinates on $\boldsymbol{R}^n$ and $\boldsymbol{S}^n$) so that no completely separable case is missed. The most important is that after maximally $n$ steps separation coordinates are always determined (if they exist) by a sequential use of the Bertrand–Darboux and cyclic Bertrand–Darboux equations [21]–[22].

## Separation of Eigenvalues Problems

Eigenvalues problems (in a given domain $D$) of the form

$$\Delta w(q) + \lambda\rho(q)w(q) = 0, \quad \rho > 0 \qquad [23]$$

(where $\Delta$ is the Laplace operator) arise when separating the wave equation $\rho(q)u_{tt} = \Delta u$ and the diffusion equation $\rho(q)u_t = \Delta u$ (Courant and Hilbert 1989). The multiplicative ansatz $u(q,t) = w(q)g(t)$ yields eqn [23] together with $\ddot{g} = \lambda g$ or $\dot{g} = \lambda g$. The problem [23] is also used for solving the inhomogeneous equation $\Delta u = f$ with the zero boundary condition $u|_{\partial D} = 0$. In general, the properties of the eigenvalues $\lambda_i$ and of the corresponding eigenfunctions $w_i$ of the problem [23] depend on the regularity requirements for $w_i$ and on the boundary conditions at $\partial D$.

For the zero boundary conditions $w(q)|_{\partial D} = 0$, one seeks a nontrivial ($w \neq 0$) solution having in the region $D$ continuous first- and second-order derivatives. General theorems (Courant and Hilbert 1989) state that for such problems there exists a growing sequence $\{\lambda_i\}_{i=1}^n$ of positive eigenvalues $\lambda_i$ such that $\lambda_i \to \infty$ as $i$ increases, and that there is a related sequence of normalized eigenfunctions $\sqrt{\rho}w_1$, $\sqrt{\rho}w_2, \ldots$ that form a complete weighted-orthogonal (in the sense that $\int_D \rho w_i w_j = \delta_{ij}$, $i, j = 1, 2, \ldots$) system of functions so that every regular initial function $\nu(q)$ with $\nu(q)|_{\partial D} = 0$ may be expanded in terms of the eigenfunctions $w_m$ in an absolutely and uniformly convergent series $\nu(q) = \sum_{m=1}^{\infty} c_m w_m(q)$ with $c_m = \int_D \rho\nu w_m$. This makes it possible to express a solution of the IBVP for the wave or for the diffusion equation with zero boundary conditions:

$$\begin{aligned} \rho(q)u_{tt} = \Delta u \text{ respectively } \rho(q)u_t = \Delta u \\ u(q,t)|_{\partial D} = 0, \quad u(q, t = 0) = \nu(q) \end{aligned} \qquad [24]$$

as a convergent infinite series $u(q,t) = \sum_{m=1}^{\infty} c_m w_m(q) g_m(t)$, where $g_m(t)$ satisfy $\ddot{g} = \lambda g$ respectively $\dot{g} = \lambda g$. Further determination of properties of the eigenfunctions $w_n$ is possible only in special domains $D$ when the problem [23] can be reduced to one-dimensional eigenvalue problems by separating variables in some suitable coordinates.

**Example 10** Consider the spherical domain $r^2 = x^2 + y^2 + z^2 \leq 1$. Equation [23] with $\rho = 1$ attains in the spherical coordinates $(r, \varphi, \theta)$ the form

$$\Delta w + \lambda w \equiv \frac{1}{r^2 \sin\theta}\left(\partial_r(r^2 \sin\theta\, \partial_r w) + \partial_\varphi\left(\frac{1}{\sin\theta}\partial_\varphi w\right) + \partial_\theta(\sin\theta\, \partial_\theta w)\right) + \lambda w = 0$$

The ansatz $w = f(r)Y(\theta, \varphi)$ gives the separated equation

$$\frac{(r^2 f')' + \lambda r^2 f}{f} = -\frac{1}{Y\sin\theta}\left(\partial_\varphi\left(\frac{1}{\sin\theta}\partial_\varphi Y\right) + \partial_\theta(\sin\theta\, \partial_\theta Y)\right)$$

so that its both sides must be equal to a constant $\kappa$. Continuity of $Y$ implies that it has to be periodic in $\varphi$ (with period $2\pi$) and regular at $\theta = 0$, $\theta = \pi$. It can only be satisfied for $\kappa = n(n+1)$. The left-hand side of the above equation yields then $(r^2 f')' - n(n+1)f + \lambda r^2 f = 0$. Solutions that are regular at $r = 0$ are the Bessel functions $(1/\sqrt{r})J_{n+(1/2)}(\sqrt{\lambda}r)$. The equation for spherical harmonics

$$\frac{1}{Y\sin\theta}\left(\partial_\varphi\left(\frac{1}{\sin\theta}\partial_\varphi Y\right) + \partial_\theta(\sin\theta\, \partial_\theta Y)\right) + n(n+1)Y = 0$$

can be further multiplicatively separated by assuming $Y = \Theta(\theta)\Phi(\varphi)$. The function $P(z = \cos\theta) = \Theta(\theta)$ satisfies then the Legendre equation

$$\left((1 - z^2)P'(z)\right)' + \left(n(n+1) - \frac{\sigma}{1 - z^2}\right)P(z) = 0$$

$P(z)$ is regular at $z = \pm 1$ only when $\sigma = k^2$, $k = 0, 1, 2, \ldots$. The function $\Phi(\varphi)$ satisfies then $\Phi'' = -k^2\Phi$ with solutions $\Phi_k(\varphi) = a_k \cos(k\varphi) + b_k \sin(k\varphi)$. The full solution of the eigenvalue problem $\Delta w + \lambda w = 0$ has the form of an infinite series

$$w_m(r, \varphi, \theta) = \sum_{n=0}^{\infty} \frac{1}{\sqrt{r}} J_{n+(1/2)}\left(\sqrt{\lambda_{m,n}}r\right)\Big[a_{n,0}P(\cos\theta) + \sum_{k=1}^{n}\left(a_{n,k}\cos(k\theta) + b_{n,k}\sin(k\theta)\right) \times P_{n,k}(\cos\theta)\Big]$$

where the constants $\lambda_{m,n}$, $m = 1, 2, \ldots$, are determined by the transcendental equation $J_{n+(1/2)}(\sqrt{\lambda}) = 0$ that follows from the boundary condition $u(q,t)|_{\partial D} = 0$.

Almost all BVPs that can be reduced to one-dimensional eigenvalue problems may be considered as a special or limiting case of the Lame problem where the boundary $\partial D$ is given by pieces of confocal quadrics corresponding to some separation coordinates. If $D = \{q(x) \in \boldsymbol{R}^3 : x_i^0 \leq x_i \leq x_i^1,\ i = 1, 2, 3\}$ is a domain defined by parametrizing $q$ with the elliptic coordinates $x_i$ given by [16], then the eigenvalue problem $\Delta w + \lambda w = 0$ splits into three one-dimensional equations of the form

$$\varphi(s)Y''(s) + \tfrac{1}{2}\varphi'(s)Y'(s) + (\lambda s + \mu)Y(s) = 0$$

where $\varphi(s) = 4(s - e_1)(s - e_2)(s - e_3)$ and $e_i$ are parameters of the elliptic coordinates. This is the Lame equation; its solutions define new transcendental functions that depend on the choice of the constants $\lambda, \mu$.

The approach presented here extends to diverse modifications such as vibrations with forcing term $\Delta w(q) + \lambda w(q) = f(q)$, vibrations of a nonhomogeneousmedium $\Delta w(q) + \lambda \rho(q) w(q) = 0$, the stationary Schrödinger equation $\Delta w(q) + V(q) w(q) = \lambda w(q)$ whenever the functions $\rho(q)$, $f(q)$, $V(q)$ are compatible with the separation coordinates.

Separation equations for the second-order BVP are the source of one-dimensional eigenvalue problems of the Sturm–Liouville type

$$(p(s)u')' - q(s)u + \lambda \rho(s) u = 0$$

with singularities that may occur at the endpoints of the fundamental domain. Majority of orthogonal polynomials and special functions appearing in mathematical physics are solutions of Sturm–Liouville problems.

In the complex domain the study of singularities of Laurent series solutions of the same equations led to development of theory of linear ODEs with singular points of the Fuchs class and the Böcher class.

## Constructive Approach to Separability of Liouville Integrable Systems

In the constructive approach to separability, one considers simultaneously all Hamilton–Jacobi equations following from a set of $n$, functionally independent, commuting integrals $H_1(x, y), \ldots, H_n(x, y)$, $\{H_i, H_j\} = 0$, that define a Liouville integrable system (Sklyanin 1995).

One starts with the separation equations, a set of $n$ decoupled ODEs for the functions $W_i(x_i, \alpha)$ depending on one variable $x_i$ and parametric $\alpha \in \boldsymbol{R}^n$:

$$f_i\left(x_i, y_i = \frac{\partial W_i(x_i, \alpha)}{\partial x_i}; \alpha\right) = 0 \qquad [25]$$

Assume that the dependence on $\alpha_i$ is essential (i.e., that $\det(\partial f_i / \partial \alpha_j) \neq 0$) so that we can resolve eqns [25] w.r.t. $\alpha_i$ so that $\alpha_i = H_i(x, y)$ for some functions $H_i$. If the functions $W_i(x_i, \alpha)$ solve [25] identically w.r.t. $x$ and $\alpha$, then the function $W(x, \alpha) = \sum_{i=1}^{n} W_i(x_i, \alpha)$ is simultaneously an additively separable solution of eqns [25] and of the equations

$$\alpha_i \overset{x,\alpha}{\equiv} H_i\left(x, y = \frac{\partial W(x, \alpha)}{\partial x}\right), \quad i = 1, \ldots, n \qquad [26]$$

since solving [25] w.r.t. $\alpha$ is a purely algebraic operation. We can treat eqns [26] as a set of simultaneously separable (in the canonical variables $(x, y)$) Hamilton–Jacobi equations related to the Hamiltonians $H_i$. Assume now that

$$\det\left(\frac{\partial^2 W}{\partial x_i \, \partial \alpha_j}\right) = \det\left(\frac{\partial^2 W_i}{\partial x_i \, \partial \alpha_j}\right) \neq 0$$

i.e. that $W$ is a complete integral for [26]. Then the Hamiltonians $H_i(x, y) = \alpha_i$ Poisson-commute since $\alpha_i$ can be treated as new canonical variables obtained by the canonical transformation $(x, y) \rightarrow (\beta, \alpha)$ given by

$$y = \frac{\partial W(x, \alpha)}{\partial x}, \qquad \beta = \frac{\partial W(x, \alpha)}{\partial \alpha}$$

Thus, any solvable w.r.t. $\alpha$ set of separation relations [25] defines a Liouville integrable system.

If we perform a canonical transformation from $(x, y)$ to new variables $(q, p)$, then the new set of commuting Hamiltonians $\widetilde{H}_i(q, p) = H_i(x(q, p), y(q, p))$ is also called separable.

The main problem for any given set of commuting Hamiltonians $\widetilde{H}_i(q, p)$ is to decide if there exists a canonical transformation $(q, p) \rightarrow (x, y)$ to the separation variables $(x, y)$ so that the related Hamilton–Jacobi equations [26] are simultaneously separable. An answer to this problem is known for integrable Hamiltonians solvable through the spectral curve method (Sklyanin 1995) and for the whole class of natural Hamiltonians discussed earlier.

This approach brings new, wider perspective to the classical separability mechanism stated in the Stäckel theorem. It contains majority of all known separable Hamiltonian systems. For example, if we specify the separation relations [25] to be affine in $\alpha_i$,

$$\sum_{k=1}^{n} f_{ik}(x_i, y_i) \alpha_k = g_i(x_i, y_i), \quad i = 1, \ldots, n \qquad [27]$$

then [27] are called generalized Stäckel separability conditions. To recover the explicit form of Hamiltonians $H_k = \alpha_k$, it is enough to solve relations [27] w.r.t. $\alpha_k$. It has been proved that the Stäckel Hamiltonians in [27] constitute a quasi-bi-Hamiltonian chain. If we specify further relations [27] by assuming that functions $f_{ik}$ do not depend on $y_i$ and functions $g_i$ are quadratic in $y_i$, then we obtain the classical Stäckel separability conditions (see Theorem 1)

$$\sum_{k=1}^{n} f_{ik}(x_i) \alpha_k = \frac{1}{2} g_i(x_i) y_i^2 + h_i(x_i) \qquad [28]$$

that can be solved for $\alpha_k$ yielding

$$\alpha_k(x,y) = \frac{1}{2}\sum_{i=1}^{n}(\Phi^{-1})_{ik}\left(y_i^2 + \frac{h_i(x_i)}{g_i(x_i)}\right)$$

that is, the Stäckel Hamiltonians [14] with the Stäckel matrix $\Phi = [\varphi_{ik}]$, where $\varphi_{ik} = f_{ik}(x_i)/g_i(x_i)$. By specifying [28] further, we obtain separation relations

$$x_i^{n-1}\alpha_1 + x_i^{n-2}\alpha_2 + \cdots + \alpha_n = \tfrac{1}{2}g(x_i)y_i^2 + h(x_i)$$

which give the so-called Benenti systems associated with conformal Killing tensors and cofactor pair systems.

Relations [27], with $g_i(x_i, y_i)$ depending exponentially on momenta $y$, contain several well-known systems such as periodic Toda lattice, the KdV dressing chain, and the Ruijsenaar–Schneider system. Relations with $g_i$ cubic in momenta $y$ yield stationary flows of Boussinesq hierarchy and integrable systems on the loop algebra sl(3).

# Separatrix Splitting

**D Treschev**, Moscow State University, Moscow, Russia

Separatrices are asymptotic manifolds in dynamical systems. However, this term is applied usually in the case of a small dimension of the phase space, where these manifolds are hypersurfaces. In the context of separatrix splitting manifolds asymptotic to hyperbolic tori are usually considered, where tori of dimension 0 and 1 are called equilibrium positions and periodic trajectories, respectively. A separatrix can be stable (asymptotic as $t \to +\infty$) and unstable (asymptotic as $t \to -\infty$).

In this article we consider the case of systems with finite-dimensional phase space. Basically we deal with nonautonomous Hamiltonian systems $2\pi$-periodic in time. However, it is useful to keep in mind the fact that the cases of autonomous Hamiltonian systems and symplectic maps are dynamically the same. Some results for non-Hamiltonian perturbations will also be presented. Hamiltonian systems with one-and-a-half or two degrees of freedom as well as area-preserving two-dimensional maps are especially important for us because the results on the separatrix splitting in this case are more clear and complete. Dynamics in such systems is essentially the same. Below we call these systems two dimensional.

We assume that all systems are at least $C^\infty$-smooth.

## Poincaré Integral

Consider a Liouville integrable Hamiltonian system. Then any separatrix either goes to infinity or joins two hyperbolic tori. From a dynamical point of view, the latter case is more interesting. If these tori are different, the situation is called heteroclinic, otherwise homoclinic. Poincaré was the first to notice that after a generic perturbation stable and unstable separatrices become different submanifolds of the phase space. This phenomenon is called the separatrix splitting.

Poincaré (1987) considered perturbations of separatrices homoclinic to a periodic solution in a Hamiltonian system with one-and-a-half degrees of freedom. In this case the system has the form

$$\dot{x} = \frac{\partial H}{\partial y}, \qquad \dot{y} = -\frac{\partial H}{\partial x}, \qquad (x, y) \in D \subset \boldsymbol{R}^2 \qquad [1]$$

where $D$ is an open domain and

$$H(x, y, t, \varepsilon) = H_0(x, y) + \varepsilon H_1(x, y, t) + O(\varepsilon^2) \qquad [2]$$

We assume that $H$ is $2\pi$-periodic in $t$ and $\varepsilon$ is a small parameter. Let $(x_0, y_0) \in D$ be an equilibrium position for the unperturbed $(\varepsilon = 0)$ system: $\operatorname{grad} H_0(x_0, y_0) = 0$. Without loss of generality, $(x_0, y_0) = 0$. In the extended phase space $D \times \boldsymbol{T}$ ($\boldsymbol{T} = \{t \bmod 2\pi\}$ is a one-dimensional torus) instead of the equilibrium we have a $2\pi$-periodic solution $0 \times \boldsymbol{T}$. Suppose that the equilibrium (and therefore, the periodic solution) is hyperbolic and the corresponding stable and unstable separatrices $\Lambda^{s,u}$ are doubled: $\Lambda^s = \Lambda^u = \Lambda$. Let $\gamma(t)$ be a natural parametrization of $\Lambda$, that is, $(x(t), y(t)) = \gamma(t)$ is a solution of eqns [1]. In the extended phase space, we have the asymptotic surface

$$(\gamma(t + \tau), t), \quad t \in \boldsymbol{T}, \ \tau \in \boldsymbol{R}$$

For small values of $\varepsilon$, the perturbed system has a hyperbolic periodic solution $(\sigma_\varepsilon(t), t), \sigma_\varepsilon(t) = O(\varepsilon) \in D$ and the separatrices

$$(\gamma_\varepsilon^{s,u}(t, \tau), t), \quad \gamma_0^{s,u}(t, \tau) = \gamma(t + \tau)$$

Since the addition to the Hamiltonian of a function, depending only on $t$ and $\varepsilon$, does not change the dynamics, without loss of generality we can assume that $H_1(0, 0, t) \equiv 0$. Hence the Poincaré integral

$$\mathcal{P}(\tau) = \int_{-\infty}^{+\infty} H_1(\gamma(t + \tau), t)\, \mathrm{d}t$$

converges. The function $\mathcal{P}$ carries all information on the separatrix splitting in the first approximation in $\varepsilon$.

Periodicity of $H_1$ in $t$ implies $2\pi$-periodicity of $\mathcal{P}(\tau)$. There is also the following obvious identity:

$$\frac{\mathrm{d}\mathcal{P}(\tau)}{\mathrm{d}\tau} = \int_{-\infty}^{+\infty} \{H_0, H_1\}(\gamma(t + \tau), t)\, \mathrm{d}t$$

where $\{,\}$ is the Poisson bracket.

## Melnikov Integral

Melnikov (1963) considered general (not necessarily Hamiltonian) $2\pi$-periodic in $t$ perturbations:

$$\dot{x} = \frac{\partial H_0}{\partial y} + \varepsilon v_1(x, y, t) + O(\varepsilon^2)$$
$$\dot{y} = -\frac{\partial H_0}{\partial x} + \varepsilon v_2(x, y, t) + O(\varepsilon^2)$$

In this case, information on the separatrix splitting in the first approximation is contained in the Melnikov integral

$$\mathcal{M}(\tau) = \int_{-\infty}^{+\infty} vH_0(\gamma(t + \tau), t)\, \mathrm{d}t$$

where $vH_0 = v_1 \partial H_0/\partial x + v_2 \partial H_0/\partial y$.

Note that if the vector field $v$ is Hamiltonian and $H_1$ is the corresponding Hamiltonian function, we have: $vH_0 = -\{H_0, H_1\}$. Hence in Hamiltonian systems we have: $\mathcal{M}(\tau) = -\mathrm{d}\mathcal{P}(\tau)/\mathrm{d}\tau$.

A multidimensional version of the Melnikov integral is presented in Wiggins (1988).

## Geometric Meaning of $\mathcal{M}(\tau)$

Let $\Gamma_T$ be a compact piece of the unperturbed separatrix

$$\Gamma_T = \{(x, y) \in D\colon (x, y) = \gamma(t),\ |t| \le T\}$$

Then for any $T > 0$ there exists a neighborhood $U$ of $\Gamma_T$ and symplectic coordinates (time–energy coordinates) $\tau$, $h$ on $U$ such that the section of the perturbed separatrices $\Lambda_\varepsilon^{s,u}$ by the plane $\{t = 0\}$ is as follows:

$$\Lambda_\varepsilon^{s,u}|_{t=0} = \{(\tau, h) : h = h_\varepsilon^{s,u}(\tau)\}$$

where

1. $h_\varepsilon^u(\tau) = O(\varepsilon^2)$,
2. $h_\varepsilon^s(\tau) = -\varepsilon\mathcal{M}(\tau) + O(\varepsilon^2)$.

   Moreover, let $g_\varepsilon^t : D \to D$ be the phase flow of the perturbed system. The map $g_\varepsilon^{2\pi}$ is called the Poincaré map. The following statement holds.
3. For any two points $z_0, z_1 \in U$ such that $z_1 = g_\varepsilon^{2\pi}(z_0)$, let $(\tau_0, h_0)$ and $(\tau_1, h_1)$ be their time–energy coordinates. Then

$$\tau_1 = \tau_0 + 2\pi + O(\varepsilon), \qquad h_1 = h_0 + O(\varepsilon)$$

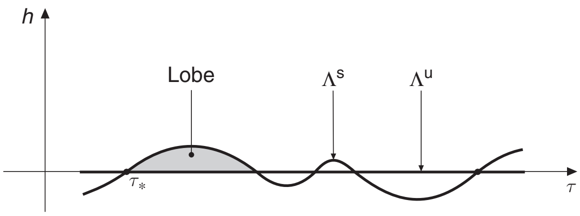

**Figure 1** Perturbed separatrices in time–energy coordinates.

Existence of such coordinates has several corollaries.

- If $\mathcal{P}$ is not identically constant, the separatrices split and this splitting is of the first order in $\varepsilon$.
- Let $\tau_*$ be a simple zero of $\mathcal{M}$. Then the perturbed separatrices intersect transversally at a point $z_*(\varepsilon)$ with time–energy coordinates $(\tau_* + O(\varepsilon), O(\varepsilon^2), t = 0)$. Such a point $z_*(\varepsilon)$ is called a transversal homoclinic point. It generates a doubly asymptotic solution in the perturbed system.
- Consider a lobe domain $\mathcal{L}(\tau_*, \varepsilon)$ bounded by two segments of separatrices on the section $\{t = 0\}$ (see Figure 1). Let another "corner point" of the lobe $\mathcal{L}(\tau_*, \varepsilon)$ correspond to the simple zero $\tau_*'$ of $\mathcal{M}$. Then the symplectic area of $\mathcal{L}(\tau_*, \varepsilon)$ equals

$$\mathcal{A}_{\mathcal{L}}(\tau_*, \varepsilon) = -\varepsilon \int_{\tau_*}^{\tau_*'} \mathcal{M}(\tau)\, d\tau + O(\varepsilon^2)$$

## A Standard Example

Consider as an example a pendulum with periodically oscillating suspension point. The Hamiltonian of the system can be presented in the form

$$H(x, y, t, \varepsilon) = \tfrac{1}{2}y^2 + \Omega^2 \cos x + \varepsilon\theta(t)\cos x \qquad [3]$$

where $\Omega$ is the "internal" frequency of the pendulum. The function $\theta$ is $2\pi$-periodic in time. Hence the frequency of the suspension point oscillation equals 1. In this case, the unperturbed homoclinic solution $\gamma(t)$ can be computed explicitly. In particular,

$$\cos(x(t)) = 1 - 2\cosh^{-2}(\Omega t)$$

Therefore, $\mathcal{P}(\tau) = \int_{-\infty}^{+\infty} \theta(t)(\cos(x(t+\tau)) - 1)\, dt$. For example, if $\theta(t) = \cos t$, we have

$$\mathcal{P}(\tau) = -\frac{2\pi \cos\tau}{\Omega^2 \sinh(\pi/2\Omega)}$$

In this case, different lobes have the same area

$$\mathcal{A}_{\mathcal{L}} = \frac{4\varepsilon\pi}{\Omega^2 \sinh(\pi/2\Omega)} + O(\varepsilon^2)$$

## Multidimensional Case

Multidimensional generalization of the Poincaré–Melnikov construction is strongly connected to the concept of a (partially) hyperbolic torus. Let $(M, \omega, H)$ be a Hamiltonian system on the $2m$-dimensional symplectic manifold $(M, \omega)$.

An invariant $n$-torus $N \subset M\, (0 \le n < m)$ is called hyperbolic if there exist coordinates $x, y, z$ on $M$ in a neighborhood of $N$ such that

1. $y = (y_1, \ldots, y_n)$, $x = (x_1, \ldots, x_n) \bmod 2\pi$, $z = (z^s, z^u)$, $z^{s,u} = (z_1^{s,u}, \ldots, z_l^{s,u})$, $l + n = m$;
2. $\omega = dy \wedge dx + dz^u \wedge dz^s$;
3. $N = \{(x, y, z) : y = 0,\ z = 0\}$; and
4. $H = \langle \nu, y\rangle + (1/2)\langle Ay, y\rangle + \langle z^u, \Omega(x) z^s\rangle + O_3(y, z)$,

where $\nu \in \boldsymbol{R}^n$ is a constant vector, $A$ is a constant $n \times n$ matrix, $\Omega$ is an $l \times l$ matrix such that $\Omega(x) + \Omega^T(x)$ is positive definite for any $x \bmod 2\pi$, the symbol $O_3$ denotes terms of order not less than 3, and $\langle a, b\rangle = \sum a_j b_j$.

If $\det A \ne 0$, the torus is called nondegenerate. If $\nu$ is Diophantine, that is, for some $\alpha, \beta > 0$ and any $0 \ne k \in \boldsymbol{Z}^n$

$$|\langle \nu, k\rangle| \ge \alpha |k|^{-\beta}$$

the torus $N$ is called Diophantine. The coordinates $(x, y, z)$ are called canonical for $N$.

Now suppose that the Hamiltonian $H$ depends smoothly on the parameter $\varepsilon$:

$$H = H_0 + \varepsilon H_1 + O(\varepsilon^2)$$

and for $\varepsilon = 0$ the system is Liouville integrable with the commuting first integrals $F_1, \ldots, F_m$:

$$\{F_j, F_k\} = 0, \quad 1 \le j, k \le m$$

Let $M_0 = \{F_1 = \cdots = F_m = 0\} \subset M$ be their zero common level and let $N \subset M$ be an $n$-dimensional nondegenerate Diophantine hyperbolic torus. The torus $N$ generates the invariant Lagrangian asymptotic manifolds $\Lambda^{s,u} \subset M$. Suppose that the separatrices are doubled, that is, there is a Lagrangian manifold $\Lambda \subset \Lambda^s \cap \Lambda^u$.

Consider the perturbed Hamiltonian $H = H_0 + \varepsilon H_1 + O(\varepsilon^2)$. The torus $N$ as well as the asymptotic manifolds $\Lambda^{s,u}$ survive the perturbation. Let $N_\varepsilon$ be the corresponding hyperbolic torus in the perturbed system and $\Lambda_\varepsilon^{s,u}$ its asymptotic manifolds: $N_\varepsilon$ and $\Lambda_\varepsilon^{s,u}$ depend smoothly on $\varepsilon$ and $N_0 = N$, $\Lambda_0^{s,u} = \Lambda^{s,u}$.

Let the function $\chi(x)$ satisfy the equation

$$\langle \nu, \partial\chi(x)/\partial x\rangle + H_1(x, 0, 0) = \frac{1}{(2\pi)^n}\int_{T^n} H_1(x, 0, 0)\, dx$$

This equation has a smooth solution unique up to an additive constant.

Consider a solution of the unperturbed Hamiltonian equations $\gamma(t) \subset \Lambda$. Let $I_j^\gamma, I_{j,l}^\gamma, 1 \le j, l \le m$ be the following quantities (Treschev 1994):

$$I_j^\gamma = \lim_{T \to +\infty} \Big( - \int_{-T}^{T} \{F_j, H_1\}(\gamma(t))\, dt + \{F_j, \chi\}(\gamma(-T)) - \{F_j, \chi\}(\gamma(T)) \Big)$$

$$I_{j,l}^\gamma = \lim_{T \to +\infty} \Big( - \int_{-T}^{T} \{F_j, \{F_l, H_1\}\}(\gamma(t))\, dt + \{F_j\{F_l, \chi\}\}(\gamma(-T)) - \{F_j\{F_l, \chi\}\}(\gamma(T)) \Big)$$

The numbers $I_j^\gamma, I_{j,l}^\gamma$ play the role of the first and second derivatives of the Poincaré integral at some point.

If any of the quantities $I_j^\gamma, I_{j,l}^\gamma$ does not vanish, the asymptotic manifolds $\Lambda^{s,u}$ split. Moreover, suppose that $I_1^\gamma = \cdots = I_m^\gamma = 0$ and the rank of the matrix $(I_{j,l}^\gamma)$ equals $m-1$. Then for small values of $\varepsilon$, the manifolds $\Lambda^s$ and $\Lambda^u$ intersect transversally on the energy level at points of the solution $\gamma_\varepsilon(t)$, where $\gamma_\varepsilon \to \gamma$ as $\varepsilon \to 0$.

## Poincaré Integral in Multidimensional Case

Suppose that the Hamiltonian from the previous section equals

$$H(x, y, u, v, t, \varepsilon) = H_0(y, u, v) + \varepsilon H_1(x, y, u, v, t) + O(\varepsilon^2)$$

Here $x = (x_1, \ldots, x_n) \bmod 2\pi$, $y = (y_1, \ldots, y_n) \in \boldsymbol{R}^n$, and $(u, v) \in \boldsymbol{R}^2$. The symplectic structure $\omega = dy \wedge dx + dv \wedge du$.

We assume that in the unperturbed integrable system the variables separate:

$$H_0(y, u, v) = F(y) + f(u, v)$$

and the system with one degree of freedom and Hamiltonian $f$ has a hyperbolic equilibrium $(u, v) = 0$ with a homoclinic solution $\gamma(t)$. Any torus

$$N(y^0) = \{(x, y, u, v, t) \colon y = y^0,\ u = v = 0\}$$

is a hyperbolic torus of the unperturbed system with frequency vector

$$\begin{pmatrix} \nu(y^0) \\ 1 \end{pmatrix}, \quad \nu(y) = \partial F / \partial y$$

Suppose that $N = N(0)$ is Diophantine and nondegenerate. Then in the perturbed system there is smooth in $\varepsilon$ hyperbolic torus $N_\varepsilon$, $N_0 = N$. Consider the Poincaré function

$$\mathcal{P}(\xi, \tau) = \int_{-\infty}^{+\infty} \Big( H_1(\xi + \nu(t+\tau), 0, \gamma(t+\tau), t) - H_1(\xi + \nu(t+\tau), 0, 0, 0, t) \Big) dt$$

Obviously, $\mathcal{P}(\xi, \tau)$ is $2\pi$-periodic in $\xi$ and $\tau$.

If $\mathcal{P}$ is not identically constant, asymptotic surfaces of $N_\varepsilon$ split in the first approximation in $\varepsilon$. Nondegenerate critical points of $\mathcal{P}$ correspond to transversal homoclinic solutions of the perturbed system.

Other results on the splitting of multidimensional asymptotic manifolds are presented in Arnol'd *et al.* (1988) and Lochak *et al.* (2003).

## Exponentially Small Separatrix Splitting

If in the unperturbed (integrable) system there are no asymptotic manifolds, they can appear after a perturbation. Consider, for example, perturbation of a real-analytic Liouville integrable system near a simple resonance:

$$\dot{x} = \frac{\partial H}{\partial y}, \quad \dot{y} = \frac{\partial H}{\partial x}, \quad x \in \boldsymbol{T}^m, \quad y \in D \subset \boldsymbol{R}^m$$

$$H(x, y, t, \varepsilon) = H_0(y) + \varepsilon H_1(x, y, t, \varepsilon)$$

As usual, we assume $2\pi$-periodicity in $t$. A simple resonance corresponds to a value of the action variable $y = y^0$ such that the frequency vector

$$\hat{\nu} = \begin{pmatrix} \nu^0 \\ 1 \end{pmatrix}, \quad \nu^0 = \frac{\partial H_0}{\partial y}(y^0) \in \boldsymbol{R}^m$$

(here 1 is the frequency, corresponding to the time variable) admits only one resonance. More precisely, there exists a nonzero $\hat{k} \in \boldsymbol{Z}^{m+1}$, satisfying $\langle \hat{k}, \hat{\nu} \rangle = 0$ and any $k \in \boldsymbol{Z}^{m+1}$ such that $\langle k, \hat{\nu} \rangle = 0$ is collinear with $\hat{k}$.

Without loss of generality, we can assume that $y^0 = 0$ and $\nu^0 = \binom{0}{\tilde{\nu}}$, $\tilde{\nu} \in \boldsymbol{R}^{m-1}$. Then the vector $\bar{\nu} = \binom{\tilde{\nu}}{1} \in \boldsymbol{R}^m$ is nonresonant.

In a $\sqrt{\varepsilon}$-neighborhood of the resonance we have a system with fast variables $X = (x_2, \ldots, x_m, t) \bmod 2\pi$ and slow variables $Y = (x_1, \varepsilon^{-1/2} y_1, \ldots, \varepsilon^{-1/2} y_m)$ variables:

$$\dot{Y} = O(\sqrt{\varepsilon}), \qquad \dot{X} = \bar{\nu} + O(\sqrt{\varepsilon}) \qquad [4]$$

If the frequency vector $\bar{\nu}$ is Diophantine, by using the Neishtadt averaging procedure, we can reduce the dependence of the right-hand sides of eqns [4] on

the fast variables to exponentially small in $\varepsilon$ terms. This means that there exist new symplectic variables

$$P = Y + O(\sqrt{\varepsilon}), \quad Q = X + O(\sqrt{\varepsilon})$$

(new time coincides with the old one) such that system [4] takes the form

$$\dot{P} = \sqrt{\varepsilon} F(P, \sqrt{\varepsilon}) + O\big(\exp(-a\varepsilon^{-b})\big)$$
$$\dot{Q} = \overline{\nu} + \sqrt{\varepsilon} G(P, \sqrt{\varepsilon}) + O\big(\exp(-a\varepsilon^{-b})\big)$$

with positive constants $a, b$.

If we neglect the exponentially small reminders, the system turns out to be integrable. Generically, it has a family of hyperbolic $m$-tori of the form $\{(P, Q)\colon P = \text{const.}\}$ with doubled asymptotic manifolds. However, the terms $O(\exp(-a\varepsilon^{-b}))$ generically cannot be removed completely. They produce an exponentially small splitting of the asymptotic manifolds. This splitting implies nonintegrability, chaotic behavior, Arnol'd diffusion, and other dynamical effects.

It is important to note that exponentially small splitting appears only in the analytic case. In smooth systems the splitting is much stronger.

Unfortunately, at present there are no quantitative methods for studying such splittings except obvious upper estimates and the case of two-dimensional systems.

## Exponentially Small Splitting in Two-Dimensional Systems

The main results on exponentially small separatrix splitting were obtained by Lasutkin and his students (Gelfreich and others). Another effective approach was proposed by Treschev. There are no general theorems in this situation; however, many examples were studied. We discuss the splitting in the pendulum with rapidly oscillating suspension point. The Hamiltonian of the system has the form

$$H = \tfrac{1}{2} y^2 + (1 + 2b\cos(t/\varepsilon))\cos x$$

(cf. [3]). For any value of $\varepsilon$ the circle $\{(x, y, t)\colon x = y = 0\}$ is a periodic trajectory. For small $\varepsilon > 0$ the trajectory is hyperbolic.

Poincaré integral can be formally written in this system. It predicts the area of lobes $16\pi b\varepsilon^{-1} \mathrm{e}^{-\pi(2\varepsilon)^{-1}}$. However, there is no reason to expect that this asymptotics of the splitting is correct. Indeed, its value is exponentially small in $\varepsilon$, while the error of the Poincaré–Melnikov method is in general quadratic in the perturbation. To obtain correct asymptotics of the separatrix splitting, one has to study singularities of the solutions with respect to complex time. Area of lobes in this system equals (Treschev 1997)

$$\mathcal{A}_{\mathcal{L}} = 4bf(b, \varepsilon)\varepsilon^{-1} \mathrm{e}^{-\pi(2\varepsilon)^{-1}}$$

Here $f(b, \varepsilon), \varepsilon \geq 0$ is a smooth function. The function $f(b, 0)$ is even and entire. It can be computed numerically as a solution of a problem which does not contain $\varepsilon$. The value $f(0, 0) = 4\pi$ corresponds to the Poincaré integral, but the function $f(b, 0)$ is not constant. It is possible to prove that $f$ can be expanded in a power series in $\varepsilon$. Apparently, this series diverges for any $b \neq 0$.

## Separatrix Splitting and Dynamics

1. Separatrix splitting can be regarded as an obstacle to the integrability of the perturbed system. However, this statement needs some comments. Doubled asymptotic surfaces in an integrable Hamiltonian system can have self-intersections. In the case of equilibrium, such intersections can even be transversal. In the literature, there is no general result saying that separatrix splitting implies nonintegrability. Some particular cases (studied by Kozlov, Ziglin, Bolotin, and others) are presented in Arnol'd *et al.* (1989). For example, in the two-dimensional case, this is seen to be true.
2. Conceptual reason for the nonintegrability, discussed in the previous item, is a complicated dynamics near the splitted separatrices. In many situations, it is possible to find in this domain a Smale horseshoe. This implies positive topological entropy, existence of nontrivial hyperbolic sets, symbolic dynamics, etc.
3. Consider a near-integrable area-preserving two-dimensional map. In the perturbed system in the vicinity of the splitted separatrices of a hyperbolic fixed point $z_\varepsilon$ the so-called stochastic layer is formed. Here we mean the domain bounded by invariant curves, closest to the separatrices. An important quantity, describing the rate of chaos, is the area of the stochastic layer $\mathcal{A}_{\mathrm{SL}}(\varepsilon)$. It turns out (Treschev 1998b) that $\mathcal{A}_{\mathrm{SL}}(\varepsilon)$ is connected with the area of the largest lobe $\mathcal{A}_{\mathcal{L}}(\varepsilon)$ by the simple formula

$$c_1 \mathcal{A}_{\mathrm{SL}}(\varepsilon) < \frac{\mathcal{A}_{\mathcal{L}}(\varepsilon)\log(\mathcal{A}_{\mathcal{L}}(\varepsilon))}{\log^2 \mu} < c_2 \mathcal{A}_{\mathrm{SL}}(\varepsilon)$$

   with some constants $c_1, c_2 > 0$, where $\mu$ is the largest multiplier (Lyapunov exponent) of the fixed point $z_0$.
4. Let $\hat{z}$ be a hyperbolic fixed point of an area-preserving two-dimensional map. The point $\hat{z}$

divides the corresponding separatrices $\Lambda^{s,u}$ in 4 branches $\Lambda^s_{1,2}$ and $\Lambda^u_{1,2}$. Suppose that the pair of branches $\Lambda^s_j$ and $\Lambda^u_l$ satisfies the following conditions:

- $\Lambda^s_j$ and $\Lambda^u_l$ lie in a compact invariant domain;
- $\Lambda^s_j$ and $\Lambda^u_l$ do not coincide and intersect at a homoclinic point.

Then the closures $\overline{\Lambda}^s_j, \overline{\Lambda}^u_l$ are compact invariant sets. Very little is known about these sets. For example, it is not known if their measure is positive. However, by using the Poincaré recurrence theorem, it is possible to prove (Treschev 1998a) that $\overline{\Lambda}^s_j = \overline{\Lambda}^u_l$.

# Several Complex Variables: Basic Geometric Theory

**A Huckleberry**, Ruhr-Universität Bochum, Bochum, Germany
**T Peternell**, Universität Bayreuth, Bayreuth, Germany

## Introduction

The rubric "several complex variables" is attached to a wide area of mathematics which involves the study of holomorphic phenomena in dimensions higher than one. In this area there are viewpoints, methods and results which range from those on the analytic side, where analytic techniques of partial differential equations (PDEs) are involved, to those of algebraic geometry which pertain to varieties defined over finite fields. Here we outline selected basic methods which are aimed at understanding global geometric phenomena. Detailed presentations of most results discussed here can be found in the basic texts (Demailly, Grauert and Fritzsche 2001, Griffiths and Harris 1978, Grauert *et al.* 1994, Grauert and Remmert 1979, 1984).

## Domains in $\mathbb{C}^n$

Complex analysis begins with the study of holomorphic functions on domains $D$ in $\mathbb{C}^n$. These are smooth complex-valued functions $f$ which satisfy

$$\bar{\partial} f := \sum \frac{\partial f}{\partial \bar{z}_i} \mathrm{d}\bar{z}_i = 0$$

Some results from the one-dimensional theory extend to the case where $n > 1$. However, even at the early stages of development, one sees that there are many new phenomena in the higher-dimensional setting.

### Extending Results from the One-Dimensional Theory

For local results one may restrict considerations to functions $f$ which are holomorphic in a neighborhood of $0 \in \mathbb{C}^n$. The restriction of $f$ to, for example, any complex line through 0 is holomorphic, and therefore the maximum principle can be immediately transferred to the higher-dimensional setting.

The zero-set $V(f)$ of a nonconstant holomorphic function is one-codimensional over the complex numbers (two-codimensional over the reals). Thus the identity principle must be formulated in a different way from its one-dimensional version. For example, under the usual connectivity assumptions, if $f$ vanishes on a set $E$ with Hausdorff dimension bigger than $2n-2$, then it vanishes identically. Here

is another useful version: if $M$ is a real submanifold such that the real tangent space $T_zM$ generates the full complex tangent space at one of its points, that is, $T_zM + iT_zM = T_z\mathbb{C}^n$, and $f|M \equiv 0$, then $f \equiv 0$.

In the one-dimensional theory, after choosing appropriate holomorphic coordinates, $f(z) = z^k$ for some $k$. This local normal form implies that nonconstant holomorphic functions are open mappings. Positive results in the mapping theory of several complex variables are discussed below. The simple example $F: \mathbb{C}^2 \to \mathbb{C}^2, (z, w) \to (z, zw)$, shows that the open mapping theorem cannot be transferred without further assumptions.

The local normal-form theorem in several complex variables is called the "Weierstraß preparation theorem." It states that after appropriate normalization of the coordinates, $f$ is locally the product of a nonvanishing holomorphic function with a "polynomial"

$$P(z, z') = z^k + a_{k-1}(z')z^{k-1} + \cdots + a_0(z')$$

where $z$ is a single complex variable, $z'$ denotes the remaining $n-1$ variables, and the coefficients are holomorphic in $z'$. This is a strong inductive device for the local theory.

If $D$ is a product $D = D_1 \times \cdots \times D_n$ of relatively compact domains in the complex plane $\mathbb{C}$, then repeated integration transfers the one-variable Cauchy integral formula from the $D_i$ to $D$. The resulting integral is over the product $\mathrm{bd}(D_1) \times \cdots \times \mathrm{bd}(D_n)$ of the boundaries which is topologically a small set in $\mathrm{bd}(D)$. Complex analytically it is, however, large in the sense of the above identity principle.

It follows from, for example, the $n$-variable Cauchy integral formula that holomorphic functions agree with their convergent power series developments. As in the one-variable theory, the appropriate topology on the space $\mathcal{O}(D)$ of holomorphic functions on $D$ is that of uniform convergence on compact subsets. In this way $\mathcal{O}(D)$ is equipped with the topology of a Fréchet space.

### First Theorems on Analytic Continuation

Analytic continuation is a fundamental phenomenon in complex geometry. One type of continuation theorem which is known in the one-variable theory is of the following type: If $E$ is a small closed set in $D$ and $f \in \mathcal{O}(D\backslash E)$ is a holomorphic function which satisfies some growth condition near $E$, then it extends holomorphically to $D$. The notion "small" can be discussed in terms of measure, but it is more appropriate to discuss it in complex analytic terms.

An analytic subset $A$ of $D$ is locally the common zero set $\{a \in D; f_1(a) = \cdots = f_m(a) = 0\}$ of finitely many holomorphic functions. A function $g$ on $A$ is said to be holomorphic if at each $a \in A$ it is the restriction of a holomorphic function on some neighborhood of $a$ in $D$. There is an appropriate notion of an irreducible component of $A$. If $A$ is irreducible, it contains a dense open set $A_{\mathrm{reg}}$, which is a connected $k$-dimensional complex manifold, that is, at each of its points $a$ there are functions $f_1, \ldots, f_k$ which define a map $F := (f_1, \ldots, f_k)$, which is a holomorphic diffeomorphism of $A_{reg}$ onto an open set in $\mathbb{C}^k$. The boundary $A_{\mathrm{sing}}$ is the set of singular points of $A$, which is a lower-dimensional analytic set. The dimension of an analytic set is the maximum of the dimensions of its irreducible components.

Here are typical examples of theorems on continuing holomorphic functions across small analytic sets $E$. If codim $E \geq 2$, then every function which is holomorphic on $D\backslash E$ extends to a holomorphic function on $D$. The same is true of meromorphic functions, that is, functions which are locally defined as quotients $m = f/g$ of holomorphic functions. If $f$ is holomorphic on $D$, then $g := 1/f$ is holomorphic outside the analytic set $E := V(f)$. Thus $g$ cannot be holomorphically continued across this one-codimensional set. However, Riemann's Hebbarkeitssatz is valid in several complex variables: if $f$ is locally bounded outside an analytic subset $E$ of any positive codimension, then it extends holomorphically to $D$.

With a bit of care, continuation results of this type can be proved for (reduced) complex spaces. These are defined as paracompact Hausdorff spaces which possess charts $(U_\alpha, \varphi_\alpha)$, where the local homeomorphism $\varphi_\alpha$ identifies the open set $U_\alpha$ with a closed analytic subset $A_\alpha$ of a domain $D_\alpha$ in some $\mathbb{C}^{n_\alpha}$. As indicated above, a continuous function on $A_\alpha$ is holomorphic if at each point it can be holomorphically extended to some neighborhood of that point in $D_\alpha$. Finally, just as in the case of manifolds, the compatibility between charts is guaranteed by requiring that coordinate change $\varphi_{\alpha\beta}: U_{\alpha\beta} \to U_{\beta\alpha}$ is biholomorphic, that is, it is a homeomorphism so that it and its inverse are given by holomorphic functions as $F = (f_1, \ldots, f_m)$. The discussion of irreducible components, sets of singularities, and dimension for complex spaces goes exactly in the same way as that above for analytic sets.

If $E$ is everywhere at least two-codimensional, then the above result on continuation of meromorphic functions holds in complete generality. The Hebbarkeitssatz requires the additional condition that the complex space is normal. In many situations this causes no problem at all, because, in general, there is a canonically defined associated normal

complex space $\tilde{X}$ and a proper, surjective, finite-fibered holomorphic map $\tilde{X} \to X$ which is biholomorphic outside a nowhere-dense proper analytic subset. Difficulties can be overcome by simply lifting functions to this normalization and applying the Hebbarkeitssatz.

Continuation theorems of Hartogs-type reflect the fact that complex analysis in dimensions larger than one is really quite different from the one-variable version. The following is such a theorem. Let $(z, w)$ be the standard coordinates in $\mathbb{C}^2$ and think of the $z$-axis as a parameter space for geometric figures in the $w$-plane. For example, let $D_z := \{(z, w) : |w| < 1\}$ be a disk and $A_z := \{(z, w) : 1 - \varepsilon < |w| < 1\}$ be an annulus. An example of a Hartogs figure $H$ in $\mathbb{C}^2$ is the union of the family of disks $D_z$ for $|z| < 1 - \delta$ with the family $A_z$ of annuli for $1 - \delta \leq |z| < 1$. One should visualize the moving disks which suddenly change to moving annuli. One speaks of filling in the Hartogs figure to obtain the polydisk $\hat{H} := \{(z, w); |z|, |w| < 1\}$. Hartogs' continuation theorem states that a function which is holomorphic on $H$ extends holomorphically to $\hat{H}$.

### Cartan–Thullen Theorem

One of the major developments in complex analysis in several variables was the realization that certain convexity concepts lie behind the strong continuation properties. At the analytic level one such is defined as follows by the full algebra of holomorphic functions $\mathcal{O}(D)$. If $K$ is a compact subset of $D$, then its holomorphic convex hull $\hat{K}$ is defined as the intersection of the sets $P(f) := \{p \in D : |f(p)| \leq |f|_K\}$ as $f$ runs through $\mathcal{O}(D)$. One says that $D$ is holomorphically convex if $\hat{K}$ is compact for every compact subset $K$ of $D$.

The theorem of H. Cartan and Thullen relates this concept to analytic continuation phenomena as follows. A domain $D$ is said to be a domain of holomorphy if, given a divergent sequence $\{z_n\} \subset D$, there exists $f \in \mathcal{O}(D)$ which is unbounded along it. In other words, the phenomenon of being able to extend all holomorphic functions on $D$ to a truly larger domain $\hat{D}$ does not occur. The Cartan–Thullen theorem states that $D$ is a domain of holomorphy if and only if it is holomorphically convex. In the next paragraph the relation between this type of convexity and a certain complex geometric convexity of the boundary bd$(D)$ will be indicated.

### Levi Theorem and the Levi Problem

Consider a smooth (local) real hypersurface $\Sigma$ containing $0 \in \mathbb{C}^n$ with $n > 1$. It is the zero-set $\{\rho = 0\}$ in some neighborhood $U$ of 0 of a smooth function with $\mathrm{d}\rho \neq 0$ on $U$. This is viewed as a piece of a boundary of a domain $D$, where $U \cap D = \{\rho < 0\}$. The real tangent space $T_0\Sigma = \mathrm{Ker}(\mathrm{d}\rho(0))$ contains a unique maximal (one-codimensional) complex subspace $T_0^{\mathbb{C}}\Sigma = \mathrm{Ker}(\partial\rho(0)) = H$. The signature of the restriction of the complex Hessian (or Levi form) $\mathrm{i}\partial\bar{\partial}\rho$ to $H$ is a biholomorphic invariant of $\Sigma$. In this notation the Hessian is a real alternating 2-form which is compatible with the complex structure, and its signature is defined to be the signature of the associated symmetric form.

If the restriction of this Levi form to the complex tangent space has a negative eigenvalue, that is, if the boundary bd$(D)$ has a certain degree of concavity, then there is a map $F : \Delta \to U$ of the unit disk $\Delta$ which is biholomorphic onto its image with $F(0) = 0$ and otherwise $F(\mathrm{cl}(\Delta)) \subset D$. The reader can imagine pushing the image of this map into the domain to obtain a family of disks which are in the domain, and pushing it in the outward pointing direction to obtain annuli which are also in the domain. Making this precise, one builds a (higher-dimensional) Hartogs figure $H$ at the base point 0 so that $\hat{H}$ is an open neighborhood of 0. In particular this proves the theorem of E. E. Levi: *every function holomorphic on $U \cap D$ extends to a neighborhood of* 0. This can be globally formulated as follows:

**Theorem** *If $D$ is a domain of holomorphy with smooth boundary in $\mathbb{C}^n$, then* bd$(D)$ *is Levi-pseudoconvex.*

Here the terminology Levi-pseudoconvex is used to denote the condition that the restriction of the Levi form to the complex tangent space of every boundary point is positive semidefinite.

One of the guiding problems of complex analysis in higher dimensions is the Levi problem. This is the converse statement to that of the Levi's theorem:

**Levi Problem** *Is a domain $D$ with smooth Levi-pseudoconvex boundary in a complex manifold necessarily a domain of holomorphy?*

Stated in this form it is not true, but for domains in $\mathbb{C}^n$ it is true. As will be sketched below, under stronger assumptions on the Levi form it is almost true. However, there are still interesting open problems in complex analysis which are related to the Levi problem.

### Bounded Domains and Their Automorphisms

The unit disk in the complex plane is particularly important, because, with the exceptions of projective

space $\mathbb{P}_1(\mathbb{C})$, the complex plane $\mathbb{C}$, the punctured plane $\mathbb{C}\backslash\{0\}$, and compact complex tori, it is the universal cover of every (connected) one-dimensional complex manifold.

In higher dimensions it should first be underlined that, without some further condition, there is no best bounded domain in $\mathbb{C}^n$. For example, two randomly chosen small perturbations of the unit ball $\mathbb{B}_2 := \{(z, w); |z|^2 + |w|^2 < 1\}$, with, for example, real analytic boundary, are not biholomorphically equivalent.

On the other hand, the following theorem of H. Cartan shows that bounded domains $D$ are good candidates for covering spaces:

**Theorem** *Equipped with the compact open topology, the group* Aut($D$) *of holomorphic automorphisms of $D$ is a Lie group acting properly on $D$.*

The notion of a proper group action of a topological group on a topological space is fundamental and should be underlined. It means that if $\{x_n\}$ is a convergent sequence in the space where the group is acting, then a sequence of group elements $\{g_n\}$, with the property that $\{g_n(x_n)\}$ is convergent, itself possesses a convergent subsequence. As a consequence, isotropy groups are compact and orbits are closed.

In the context of bounded domains $D$ this implies that if $\Gamma$ is a discrete subgroup of Aut($D$), then $X = D/\Gamma$ carries a natural structure of a complex space. If in addition $\Gamma$ is acting freely, something that, with minor modifications, can be arranged, then $X$ is a complex manifold.

Many nontrivial compact complex manifolds arise as quotients $D/\Gamma$ of bounded domains. Even very concrete quotients, for example, where $D = \mathbb{B}_2$, are extremely interesting. Conversely, if Aut($D$) contains a discrete subgroup $\Gamma$ so that $D/\Gamma$ is compact, then $D$ is probably very special. For example, it is known to be holomorphically convex!

Any compact quotient $X = D/\Gamma$ of a bounded domain is projective algebraic in the sense that it can be realized as a complex (algebraic) submanifold of some complex projective space. In fact the embedding can be given by quite special $\Gamma$-invariant holomorphic tensors on $D$, and this in turn implies that $X$ is of general type (see below). For further details, in particular on Cartan's theorem on the automorphism group of a bounded domain, the reader is referred to Narasimhan (1971).

## Stein Manifolds

The founding fathers of the first phase of "modern complex analysis" (Cartan, Oka, and Thullen) realized that domains of holomorphy form the basic class of spaces where it would be possible to solve the important problems of the subject concerning the existence of holomorphic or meromorphic functions with reasonably prescribed properties. In fact, Oka formulated a principle which more or less states that if a complex analytic problem which is well formulated on a domain of holomorphy has a continuous solution, then it should have a holomorphic solution. Given the flexibility of continuous functions and the rigidity of holomorphic functions, this would seem impossible but in fact is true!

Beginning in the late 1930s, Stein worked on problems related to this Oka principle, in particular on those related to what we would now call the algebraic topological aspects of the subject, and he was led to formulate conditions on a general complex manifold $X$ which should hold if problems of the above type are to be solved. First, his axiom of holomorphic convexity was simply that, given a divergent sequence $\{x_n\}$ in $X$, there should be a function $f \in \mathcal{O}(X)$ such that $\{f(x_n)\}$ is unbounded. Secondly, holomorphic functions should separate points in the sense that, given distinct points $x_1, x_2 \in X$, there exists $f \in \mathcal{O}(X)$ with $f(x_1) \neq f(x_2)$. Finally, globally defined holomorphic functions should give local coordinates. Assuming that $X$ is $n$-dimensional, this means that, given a point $x \in X$, there exist $f_1, \ldots, f_n \in \mathcal{O}(X)$ such that $\mathrm{d}f_1(x) \wedge \cdots \wedge \mathrm{d}f_n(x) \neq 0$.

Assuming Stein's axioms, Cartan and Serre then produced a powerful theory in the context of sheaf cohomology which proved certain vanishing theorems that led to the desired existence theorems. This theory and typical applications are sketched below. Before going into this, we would like to mention that Grauert's version of the Cartan–Serre theory requires only very weak versions of Stein's axioms: (1) The connected component containing $K$ of the holomorphic convex hull $\hat{K}$ of every compact set should be compact. (2) Given $x \in X$, there are functions $f_1, \ldots, f_m \in \mathcal{O}(X)$ so that $x$ is an isolated point in the fiber of the map $F := (f_1, \ldots, f_m) : X \to \mathbb{C}^m$. Of course the results also hold for complex spaces.

Holomorphically convex domains in $\mathbb{C}^n$ are Stein manifolds, and since closed complex manifolds of Stein manifolds are Stein, it follows that any complex submanifold of $\mathbb{C}^n$ is Stein. In particular, affine varieties are Stein spaces. Remmert's theorem states the converse: an $n$-dimensional Stein manifold can be embedded as a closed complex submanifold of $\mathbb{C}^{2n+1}$. A nontrivial result of Behnke and Stein implies that every noncompact Riemann surface is also Stein.

### Basic Formalism

The following first Cousin problem is typical of those which can be solved by Stein theory. Let $X$ be a complex manifold which is covered by open sets $U_i$. Suppose that on each such set a meromorphic function $m_i$ is given so that on the overlap $U_{ij} := U_i \cap U_j$ the difference $m_{ij} = m_j - m_i =: f_{ij}$ is holomorphic. This means that the distribution of polar parts of these functions is well defined. The question is whether or not there exists a globally defined meromorphic function $m \in \mathcal{M}(X)$ with these prescribed polar parts, that is, with $m - m_i =: f_i \in \mathcal{O}(U_i)$.

If one applies the Oka principle, this problem can be easily solved. For this one can assume that the covering is locally finite and take $\gamma_i$ to be a partition of unity subordinate to the cover. Using standard shrinking and cut-off arguments, one extends the $f_{ij}$ to the full space $X$ as smooth functions so that the alternating cocycle relations $f_{ij} + f_{jk} + f_{ki} = 0$ and $f_{ij} = -f_{ji}$ still hold. Then $f_j := \sum \gamma_k f_{jk}$ is a smooth function on $U_j$ which satisfies $f_j - f_i = f_{ij}$ on the overlap $U_{ij}$. It follows that $f := m_i + f_i = m_j + f_j$ is a globally well-defined "smooth" function with the prescribed polar parts. The Oka principle would then imply that there is a globally defined meromorphic function with the same property.

The basic sheaf cohomological formalism for Stein theory can be seen in the above argument. Suppose that instead of applying extension and cut-off techniques from the smooth category, we could answer positively the question "given the holomorphic functions $\{f_{ij}\}$ on the $U_{ij}$, do there exist holomorphic functions $\{f_i\}$ on the $U_i$ such that $f_j - f_i = f_{ij}$ on the $U_{ij}$?" Then we would immediately have the desired globally defined meromorphic function $m := m_i + f_i$. This question is exactly the question of whether or not the Cech cohomology class of the alternating cocycle $\{f_{ij}\}$ vanishes.

Let us quickly summarize the language of Cech cohomology. A presheaf of abelian groups is a mapping $U \to S(U)$ which associates to every open subset of $X$ an abelian group. Typical examples are $U \to \mathcal{O}(U)$, $U \to C^\infty(U)$, $U \to H^*(U, \mathbb{Z}), \ldots$ . The last example which associates to $U$ its topological cohomology does not localize well in terms of following the basic axioms for a sheaf: (1) Given a covering $\{U_i\}$ of an open subset $U$ of $X$ and elements $s_i \in S(U_i)$ with $s_j - s_i = 0$ on $U_{ij}$, there exists $s \in S(U)$ with $s|U_i = s_i$. (2) If $s, t \in S(U)$ are such that $s|U_i = t|U_i$ for all $i$, then $s = t$. For this we have assumed that the restriction mappings have been built into the definition of a presheaf.

Associated to a sheaf $S$ on $X$ and a covering $\mathcal{U} = \{U_i\}$ is the space of alternating $q$-cocycles $\mathcal{C}^q(U, S)$, which is the set of alternating maps $\xi$ from the set of $(q+1)$-fold indices of the form $(i_0, \ldots, i_q) \mapsto s_{i_0,\ldots,i_q} \in S(U_{i_0,\ldots,i_q})$. Here $U_{i_0,\ldots,i_q} := U_{i_0} \cap \cdots \cap U_{i_q}$. The boundary mapping $\delta : \mathcal{C}^q \to \mathcal{C}^{q+1}$ is defined by $\delta(\xi)_{i_0,\ldots i_{q+1}} = \sum_k (-1)^k s_{i_0,\ldots,i_{k-1},i_{k+1},\ldots,i_{q+1}}$. It follows that $\delta^2 = 0$, and $H^*(\mathcal{U}, S)$ is defined to be the cohomology of the associated complex.

In any consideration it is necessary to refine coverings, shrink, etc., and therefore one goes to the limit $H^*(X, \mathcal{S})$ over all refinements of the coverings. The script notation $\mathcal{S}$ is used to denote that we have then localized the sheaf to the germ level. Due to a theorem of Leray one can, however, always take a suitable covering so that $H^q(\mathcal{U}, \mathcal{S}) = H^q(X, \mathcal{S})$ for all $q$, where now $\mathcal{S}(U)$ satisfies the above axioms.

One of the important facts in this cohomology theory is that a short exact sequence of sheaves $0 \to \mathcal{S}' \to \mathcal{S} \to \mathcal{S}'' \to 0$ yields a long exact sequence

$$\begin{aligned} 0 &\to H^0(X, \mathcal{S}') \to H^0(X, \mathcal{S}) \to H^0(X, \mathcal{S}'') \\ &\to H^1(X, \mathcal{S}') \to H^1(X, \mathcal{S}) \to H^1(X, \mathcal{S}'') \to \cdots \end{aligned}$$

in cohomology.

A fundamental theorem of Stein theory, Theorem B, states that for the basic analytic sheaves $\mathcal{S}$ of complex analysis, the so-called coherent sheaves, all cohomology spaces $H^q(X, \mathcal{S})$ vanish for all $q \geq 1$. In the above example of the first Cousin problem the desired vanishing is that of $H^1(\mathcal{U}, \mathcal{O})$.

### Coherent Sheaves

Numerous important sheaves in complex analysis are associated to vector bundles on complex manifolds. A holomorphic vector bundle $\pi : E \to X$ over a complex manifold is a holomorphic surjective maximal rank fibration. Every fiber $E_x := \pi^{-1}(x)$ is a complex vector space, and the vector space structure is defined holomorphically over $X$. For example, addition is a holomorphic map $E \times_X E \to E$. Such bundles are locally trivial, that is, there is a covering $\{U_i\}$ of the base such that $\pi^{-1}(U_i)$ is isomorphic to $U_i \times \mathbb{C}^r$ and on the overlap the gluing maps in the fibers are holomorphic maps $\varphi_{ij} : U_{ij} \to \mathrm{GL}_n(\mathbb{C})$. The number $r$ is called the rank of the bundle. Holomorphic bundles of rank 1 are referred to as holomorphic line bundles. Of course all of these definitions make sense in other categories, for example, topological, smooth, real analytic, etc.

A holomorphic section of $E$ over an open set $U$ is a holomorphic map $s : U \to E$ with $\pi \circ s = \mathrm{Id}_U$. The space of these sections is denoted by $\mathcal{E}(U)$, and the map $U \to \mathcal{E}(U)$ defines a sheaf which is locally just $\mathcal{O}_X^r$. It is therefore called a locally free sheaf of

$\mathcal{O}$-modules. Conversely, by taking bases of a locally free sheaf $\mathcal{S}$ on the open sets where it is isomorphic to a direct sum $\mathcal{O}^r$, one builds an associated holomorphic vector bundle $E$ so that $\mathcal{E} = \mathcal{S}$.

It is not possible to restrict our attention to these locally free sheaves or equivalently to holomorphic vector bundles. One important reason is that images of holomorphic vector bundle maps are not necessarily vector bundles. A related reason is that the sheaf of ideals of holomorphic functions which vanish on a given analytic set $A$ is not always a vector bundle. This is caused by the presence of singularities in $A$. There are many other reasons, but these should suffice for this sketch.

The sheaves $\mathcal{S}$ that arise naturally in complex analysis are almost vector bundles. If $X$ is the base complex manifold or complex space under consideration, then $\mathcal{S}$ will come from a vector bundle on some big open subset $X_0$ whose boundary is an analytic set $X_1$, and then on the irreducible components of $X_1$ it will come from vector bundles on such big open sets, etc. These sheaves are called coherent analytic sheaves of $\mathcal{O}_X$-modules. The correct algebraic definition is that locally there exists an exact sequence

$$0 \to \mathcal{O}^{p_d} \to \cdots \to \mathcal{O}^{p_1} \to \mathcal{O}^{p_0} \to \mathcal{S} \to 0 \qquad [1]$$

of sheaves of $\mathcal{O}$-modules. This implies in particular that, although $\mathcal{S}$ might not be locally free, it is locally finitely generated, and the relations among the generators are also finitely generated.

## Selected Theorems

The following efficiently formulated fundamental theorem contains a great deal of information about Stein manifolds.

**Theorem B** *A complex space $X$ is Stein if and only if for every coherent sheaf $\mathcal{S}$ of $\mathcal{O}_X$-modules $H^q(X, \mathcal{S}) = 0$ for all $q \geq 1$.*

Since $\mathcal{S}$ is a sheaf, it follows that $H^0(X, \mathcal{S}) = \mathcal{S}(X)$. This is referred to as the space of sections of $\mathcal{S}$ over $X$. As a result of Theorem B, we are able to construct sections with prescribed properties. Let us give two concrete applications (there are many more!).

**Example** Let $A$ be a closed analytic subset of a Stein space $X$, and let $\mathcal{I}$ denote the subsheaf of $\mathcal{O}_X$ which consists of those functions which vanish on $A$. Note that this must be defined for every open subset $U$ of $X$. Then we have the short exact sequence $0 \to \mathcal{I} \to \mathcal{O}_X \to \mathcal{O}_X/\mathcal{I} \to 0$. The restriction of $\mathcal{O}_X/\mathcal{I}$ to $A$ is called the (reduced) structure sheaf $\mathcal{O}_A$ of $A$. In other words, for $U$ open in $A$ the space $\mathcal{O}_A(U)$ should be regarded as the space of holomorphic functions on $U$.

Now, $\mathcal{I}$ is a coherent sheaf on $X$ and therefore by Theorem B the cohomology group $H^1(X, \mathcal{I})$ vanishes. Consequently, the associated long exact sequence in cohomology implies that the restriction mapping $\mathcal{O}_X(X) \to \mathcal{O}_A(A)$ is surjective. This special case of Theorem A means that every (global!) holomorphic function on $A$ is the restriction of a holomorphic function on $X$. ◇

**Example** Let us consider the multiplicative (second) Cousin problem. In this case meromorphic functions $m_i$ are given on the open subsets $U_i$ of a covering $\mathcal{U}$ with the property that $m_i = f_{ij} m_j$, where $f_{ij}$ is holomorphic and nowhere vanishing on the overlap $U_{ij}$. This is a distribution $D$ of the zero and polar parts of meromorphic functions, which in complex geometry is called a divisor, and the interesting question is whether or not there exists a globally defined meromorphic function which has $D$ as its divisor.

Now we note that $\mathrm{GL}_1(\mathbb{C}) = \mathbb{C}^*$ and thus $f_{ij} : U_{ij} \to \mathbb{C}^*$ defines a line bundle $L$ on $X$ and we regard it as an element of the space $H^1(X, \mathcal{O}^*)$ of equivalence classes of line bundles on $X$. Here $\mathcal{O}^*$ is the sheaf of nowhere-vanishing holomorphic functions on $X$. It is not even a sheaf of $\mathcal{O}$-modules; therefore coherence is not discussed in this case.

The long exact sequence in cohomology associated to the short exact sequence $0 \to \mathbb{Z} \longrightarrow \mathcal{O} \xrightarrow{\exp} \mathcal{O}^* \to 1$ yields an element $c_1(L) \in H^2(X, \mathbb{Z})$, which is a purely topological invariant. It is called the Chern class of $L$, and one knows that $L$ is topologically trivial if and only if $c_1(L) = 0$.

Coming back to the Cousin II problem, using the same argument as in the Cousin I problem, we can solve it if and only if we can find nowhere-vanishing functions $f_i \in \mathcal{O}^*(U_i)$ with $f_i = f_{ij} f_j$. This is equivalent to finding a nowhere-vanishing section of $L$. But a line bundle has a nowhere-vanishing section if and only if it is isomorphic to the trivial bundle. In other words, the Cousin II problem can be solved for a given divisor $D$ if and only if the associated line bundle $L(D)$ is trivial in $H^1(X, \mathcal{O}^*)$. For this, a necessary condition is that the Chern class $c_1(L(D))$ vanishes. But if $X$ is Stein, this is also sufficient, because the vanishing of $H^1(X, \mathcal{O})$ together with the long exact sequence in cohomology shows that $H^1(X, \mathcal{O}^*) \xrightarrow{c_1} H^2(X, \mathbb{Z})$ is injective.

Hence, in this case we have the following precise formulation of the Oka principle: "A given divisor $D$ on a Stein manifold is the divisor of a globally defined meromorphic function if and only if the associated line bundle is topologically trivial." ◇

A slightly refined statement from that above is the fact that on a Stein manifold the space of topological line bundles is the same as the space of holomorphic line bundles. In the case of (higher rank) vector bundles this is a deep and important theorem of Grauert. It can be formulated as follows.

**Grauert's Oka principle** On a Stein space the map $F:\mathrm{Vect}_{\mathrm{holo}}(X) \to \mathrm{Vect}_{\mathrm{top}}(X)$ from the space of holomorphic vector bundles to the space of topological vector bundles which forgets the complex structure is bijective.

In closing this section, a few words concerning the proofs of the major theorems, for example, Theorem B, should be mentioned. In all cases one must solve something like an additive Cousin problem and one first does this on special relatively compact subsets. For this step there are at least two different ways to proceed. One is to delicately piece together solutions which are known to exist on very special polyhedral-type domains or build up from lower-dimensional pieces of such.

Another method is to solve certain systems of PDEs on relatively compact domains where control at the boundary is given by the positivity of the Levi-form. An example of how such PDEs occur can already be seen at the level of the above Cousin I problem. At the point where we have solved it topologically, that is, the holomorphic cocycle $\{f_{ij}\}$ is a coboundary $f_{ij} = f_j - f_i$ of smooth functions, we observe that since $\bar{\partial} f_{ij} = 0$, it follows that $\alpha = \bar{\partial} f_i$ is a globally defined $(0,1)$-form. It is $\bar{\partial}$-closed, that is, the compatibility condition for solving the system $\bar{\partial} u = \alpha$ is fulfilled. If this system can be solved, then we use the solution $u$ to adjust the topological solutions of the Cousin problem by replacing $f_i$ by $f_i - u$. We still have $f_{ij} = f_j - f_i$, but now the $f_i$ are holomorphic on $U_i$.

To obtain the global solution to a Cousin-type problem, one exhausts the Stein space by the special relatively compact subsets $U_n$ where, by one method or another, we have solved the problem with solutions $s_n$. One would like to say that the $s_n$ converge to a global solution $s$. However, there is no way to *a priori* guarantee this without making some sort of estimates. One main way of handling this problem is to adjust the solutions as $n \to \infty$ by an approximation procedure. For this one needs to know that holomorphic objects, for example, functions on $U_n$, can be approximated on $U_n$ by objects of the same type which are defined on the bigger set $U_{n+1}$. This Runge-type theorem, which is a nontrivial ingredient in the whole theory, requires the introduction of an appropriate Fréchet structure on the spaces of sections of a coherent sheaf. This is in itself a point that needs some attention.

## Montel's Theorem and Fredholm Mappings

If $U$ is an open subset of a complex space $X$, then $\mathcal{O}(U)$ has the Fréchet topology of convergence on compact subsets $K$ defined by the seminorms $|\cdot|_K$. Using resolutions of type (1) above, one shows that the space of sections $\mathcal{S}(U)$ of every coherent sheaf $\mathcal{S}$ also possesses a canonical Fréchet topology. This is then extended to the spaces $\mathcal{C}^q(\mathcal{U}, \mathcal{S})$, and consequently one is able to equip the cohomology spaces $H^q(X, \mathcal{S})$ with (often non-Hausdorff) quotient topology.

Elements of such cohomology groups can be regarded as obstructions to solving complex analytic problems. One often expects such obstructions, and is satisfied whenever it can be shown if there are only finitely many, that is, a finiteness theorem of the type $\dim H^q(X, \mathcal{S}) < \infty$ is desirable. Here we sketch two finiteness theorems which hold in seemingly different contexts, but their proofs are based on one principle: use the compactness guaranteed by Montel's theorem as the necessary input for the Fredholm theorem in the context of Fréchet spaces.

Recall that a continuous linear map $T: E \to F$ between topological vector spaces is said to be compact if there is an open neighborhood $U$ of $0 \in E$ such that $T(U)$ is relatively compact in $F$. If $Y$ is a relatively compact open subset of a complex space $X$, then Montel's theorem states that the restriction map $r^X_Y: \mathcal{O}(X) \to \mathcal{O}(Y)$ is compact. This can be extended to coherent sheaves, and using the Fredholm theorem for certain natural restriction and boundary maps, one proves the following fundamental fact.

**Lemma 1** *If the restriction map* $r^X_Y: H^q(X, \mathcal{S}) \to H^q(Y, \mathcal{S})$ *is surjective, then* $H^q(Y, \mathcal{S})$ *is finite dimensional.*

Since the methods for the proof are basic in complex analysis, we outline it here. Take a covering $\tilde{\mathcal{U}}$ of $X$ such that $H^q(\mathcal{U}, \mathcal{S}) = H^q(X, \mathcal{S})$. Then intersect its elements with $Y$ to obtain a covering $\tilde{\mathcal{U}}$ of $Y$. Finally, refine that covering with refinement mapping $\tau$ to a covering $\mathcal{V}$ of $Y$ such that $H^q(\mathcal{V}, \mathcal{S}) = H^q(X, \mathcal{S})$ and so that $U_i$ contains $V_{\tau(i)}$ as a relatively compact subset for all $i$. Let $Z^q(\mathcal{U}, \mathcal{S})$ denote the kernel of the boundary map $\delta$ for the covering $\mathcal{U}$, and consider the map $Z^q(\mathcal{U}, \mathcal{S}) \oplus \mathcal{C}^{q-1}(\mathcal{V}, \mathcal{S}) \to \mathcal{C}^q(\mathcal{V}, \mathcal{S})$ which is the direct sum $\tau \oplus \delta$ of the restriction and boundary maps. By assumption it is surjective. Since $\delta$ is the difference of this map and the compact map $\tau$, L Schwartz's version of the Fredholm theorem for Fréchet spaces implies that its image is of finite

codimension, that is, $H^q(Y, \mathcal{S}) = H^q(\mathcal{V}, \mathcal{S})$ is finite dimensional.

Applying this Lemma in the case of compact spaces where $X = Y$, one has the following theorem of Cartan and Serre:

**Theorem** *If $X$ is a compact complex space and $\mathcal{S}$ is a coherent sheaf on $X$, then* $\dim H^q(X, \mathcal{S}) < \infty$ *for all $q$.*

Grauert made use of this technique in solving the Levi problem for a strongly pseudoconvex relatively compact domain $D$ with smooth boundary in a complex manifold $X$. Here strongly pseudoconvex means that the restriction of the Levi form to the complex tangent space of every boundary point is positive definite. To do this he sequentially made "bumps" at boundary points to obtain a finite sequence of domains $D = D_0 \subset D_1 \subset \cdots \subset D_m$ in such a way that the restriction mappings at the level of $q$th cohomology, $q \geq 1$, are all surjective and such that at the last step $D$ is relatively compact in $D_m$. Applying the above Lemma, $\dim H^q(D, \mathcal{S}) < \infty$. Using another bumping procedure, it then follows that $D$ is holomorphically convex and, in fact, that $D$ is almost Stein.

This last statement means that one can guarantee that $\mathcal{O}(D)$ separates points outside of some compact subset which could contain compact subvarietes on which the global holomorphic functions are constant. In this situation one can apply Remmert's reduction theorem which implies that there is a canonically defined proper surjective holomorphic map $\pi : D \to Z$ to a Stein space which is biholomorphic outside of finitely many fibers. One says that, in order to obtain the Stein space $Z$, finitely many compact analytic subsets must be blown down to points.

The above mentioned reduction theorem is a general result which applies to any holomorphically convex complex space $X$. For this one observes that if $X$ is holomorphically convex, then for $x \in X$ the level set $L(x) := \{y \in X; f(y) = f(x) \text{ for all } f \in \mathcal{O}(X)\}$ is a compact analytic subset of $X$. One then defines an equivalence relation: $x \sim y$ if and only if the connected component of $L(x)$ containing $x$ and that of $L(y)$ which contains $y$ are the same. One then equips $X/\sim$ with the quotient topology and proves that the canonical quotient $\pi : X \to X/\sim =: Z$ is proper. Finally, for $U$ open in $Z$ one defines $\mathcal{O}_Z(U) = \mathcal{O}_X(\pi^{-1}(U))$ and proves that, equipped with this structure, $Z$ is a Stein space. This Remmert reduction is universal with respect to holomorphic maps to holomorphically separable complex spaces, that is, if $\varphi : X \to Y$ and $\mathcal{O}_Y(Y)$ separates the points of $Y$, then there exists a uniquely defined holomorphic map $\tau_\varphi : Z \to Y$ so that $\tau_\varphi \circ \pi = \varphi$. It should be noted that, even if the original space $X$ is a complex manifold, the associated Stein space $Z$ may be singular. This reflects the fact that it is difficult to avoid singularities in complex geometry.

## Mapping Theory

Above we have attempted to make it clear that holomorphic maps play a central role in complex geometry. It is even important to regard a holomorphic function as a map. Here we outline the basic background necessary for dealing with maps and then state three basic theorems which involve proper holomorphic mappings.

### Basic Facts

A holomorphic map $F : X \to Y$ between (reduced) complex spaces is a continuous map which can be represented locally as a holomorphic map between analytic subsets of the spaces in which $X$ and $Y$ are locally embedded. In other words, $F$ is the restriction of a map $F = (f_1, \ldots, f_m)$ which is defined by holomorphic functions.

If $X$ is irreducible and $X$ and $Y$ are one-dimensional, then a nonconstant holomorphic map $F : X \to Y$ is an open mapping. This statement is far from being true in the higher-dimensional setting. The reader need only consider the example $F : \mathbb{C}^2 \to \mathbb{C}^2, (z, w) \to (zw, z)$.

Despite the fact that holomorphic maps can be quite complicated, they have properties that in certain respects render them tenable. Let us sketch these in the case where $X$ is irreducible. First, one notes that every fiber $F^{-1}(y)$ is a closed analytic subset of $X$. One defines $\text{rank}_x F$ to be the codimension at $x$ of the fiber $F^{-1}(F(x))$ at $x$. Then $\text{rank}\, F := \max\{\text{rank}_x F; x \in X\}$. It then can be shown that $\{x \in X; \text{rank}_x F \leq k\}$ is a closed analytic subset of $X$ for every $k$. Applying this for $k = \text{rank}\, F - 1$ we see that, outside a proper closed analytic subset, $F$ has constant maximal rank.

If $F : X \to Y$ has constant rank $k$ in a neighborhood of some point $x \in X$, then one can choose neighborhoods $U$ of $x$ in $X$ and $V$ of $F(x)$ in $Y$ so that $F|U$ maps $U$ onto a closed analytic subset of $Y$. By restricting $F$ to the sets where it has lower rank and applying this local-image theorem, it follows that the local images of the set where $F$ has lower rank are at least two dimensions smaller than those of top rank. Conversely, the fiber dimension $d_F(x) := \dim_x F^{-1}(F(x))$ is semicontinuous in the sense that $d_F(x) \geq d_F(z)$ for all $z$ near $x$. Finally, we note that if $Y$ is $m$-dimensional, then $F : X \to Y$ is an open map if and only if it is of constant rank $m$.

### Proper Mappings

By definition a mapping $F: X \to Y$ between topological spaces is proper if and only if the inverse image $F^{-1}(K)$ of an arbitrary compact subset in $Y$ is compact in $X$. This is a more delicate condition than meets the eye. For example, if $F: X \to Y$ is a proper map and one removes one point from some fiber, then it is normally no longer proper! On the other hand, the restriction of a proper map to a closed subset is still proper.

Remmert's "Proper mapping theorem" is the first basic theorem on proper holomorphic maps:

**Theorem** *The image of a proper holomorphic map $F: X \to Y$ is a closed analytic subset of $Y$.*

Given another basic theorem of complex analysis, the reader can imagine how this might be proved. This is the continuation theorem for analytic sets due to Remmert and Stein:

> *If $X$ is a complex space and $Y$ is a closed analytic subset with $\dim_y Y \leq k$ for all $y \in Y$ and $Z$ is a closed analytic subset of the complement $X \backslash Y$ with $\dim_z Z \geq k+1$ at all $z \in Z$, then the topological closure $\mathrm{cl}(Z)$ of $Z$ in $X$ is a closed analytic subset of $X$ with $E = \mathrm{cl}(Z) \backslash Z = \mathrm{cl}(Z) \cap Y$ a proper analytic subset of $\mathrm{cl}(Z)$.*

Similar results hold for more general complex analytic objects. For example, closed positive currents with (locally) finite volume can be continued across any proper analytic subset (Skoda 1982). A sketch of the proof of the proper mapping theorem (for $X$ irreducible) goes as follows. From the assumption that $F$ is proper, the image $F(X)$ is closed. If $F$ has constant rank $k$, then, by the local result stated above, its image is everywhere locally a $k$-dimensional analytic set. Since the image is closed, the desired result follows. If rank $F = k$ and $E := \{x \in X;\ \mathrm{rank}_x F < k\} \neq \emptyset$, then by induction $F(E)$ is a closed analytic subset of dimension at most $k-2$. Let $A := F^{-1}(E)$ and apply the previous discussion for constant rank maps to $F|(X \backslash A): \ X \backslash A \to Y \backslash E$. The image is a closed $k$-dimensional analytic subset of $Y \backslash E$ and its Remmert–Stein extension is the full image $F(X)$.

In this framework the Stein factorization theorem is an important tool. Here $F: X \to Y$ is again a proper holomorphic map which we may now assume to be surjective. Analogous to the construction of the reduction of a holomorphically convex space, one says that two points in $X$ are equivalent if they are in the same connected component of an $F$-fiber. This is indeed an equivalence relation, and the quotient $Z := X/\sim$ is a complex space equipped with the direct image sheaf. Thus one decomposes $F$ into two maps $X \to Z \to Y$, where $X \to Z$ is a canonically associated surjective map with connected fiber, and $Z \to Y$ is a finite map.

This geometric proper mapping theorem is a preview of one of the deepest results in complex analysis: Grauert's direct image theorem. This concerns the images of sheaves, not just the images of points. For this, given a sheaf $\mathcal{S}$ on $X$ one defines the $q$th direct image sheaf on $Y$ as the sheaf associated to the presheaf which attaches to an open set $U$ in $Y$ the cohomology space $H^q(F^{-1}(U), \mathcal{S})$. Grauert's "Bildgarbensatz" states the following: "If $F: X \to Y$ is a proper holomorphic map, then all direct image sheaves of any coherent sheaf on $X$ are coherent on $Y$."

## Complex Analysis and Algebraic Geometry

The interplay between these subjects has motivated research and produced deep results on both sides. Here we indicate just a few results of the type which show that objects which are *a priori* of an analytic nature are in fact algebraic geometric.

### Projective Varieties

Let us begin with the algebraic geometric side of the picture where we consider algebraic subvarieties $X$ of projective space $\mathbb{P}_n(\mathbb{C})$. If $[z_0 : z_1 : \cdots : z_n]$ are homogeneous coordinates of $\mathbb{P}_n$, such a variety is the simultaneous zero-set, $X := V(P_1, \ldots, P_m)$, of finitely many (holomorphic) homogeneous polynomials $P_i = P_i(z_0, \ldots, z_m)$. Chow's theorem states that in this context there are no further analytic phenomena:

**Theorem** *Closed complex analytic subsets of projective space $\mathbb{P}_n(\mathbb{C})$ are algebraic subvarieties.*

This observation has numerous consequences. For example, if $F: X \to Y$ is a holomorphic map between algebraic varieties, then, by applying Chow's theorem to its graph, it follows that $F$ is algebraic.

Chow's theorem can be proved via an application of the Remmert–Stein theorem in a very simple situation. For this, let $\pi: \mathbb{C}^{n+1} \backslash \{0\} \to \mathbb{P}_n(\mathbb{C})$ be the standard projection, and let $Z := \pi^{-1}(X)$. Since $Z$ is positive dimensional, by the Remmert–Stein theorem it can be extended to an analytic subset of $\mathbb{C}^{n+1}$. The resulting subvariety $K(X)$ (the cone over $X$) is invariant by the $\mathbb{C}^*$-action which is defined by $v \to \lambda v$ for $\lambda \in \mathbb{C}^*$. If $f$ is a holomorphic function on $\mathbb{C}^{n+1}$ which vanishes on $K(X)$, then we develop it in homogeneous polynomials $f = \sum P_d$ and note that $\lambda(f)(z) = f(\lambda z) = \sum \lambda^d P_d$ also vanishes for all $\lambda$. Hence, all $P_d$ vanish identically and therefore the ideal of holomorphic functions which vanish on $K(X)$

is generated by the homogeneous polynomials which vanish on $K(X)$ and consequently finitely many of these define $X$ as a subvariety of $\mathbb{P}_n(\mathbb{C})$.

Complements of subvarieties in projective varieties occur in numerous applications and are important objects in complex geometry. Even complements $\mathbb{P}_n \backslash Y$ of subvarieties $Y$ in the full projective space are not well understood. If $Y$ is the intersection of a compact projective variety $X$ with a projective hyperplane, that is, $Y$ is a hyperplane section, then $X \backslash Y$ is affine. If $Y$ is $q$-codimensional in $X$, then $X \backslash Y$ possesses a certain degree of Levi convexity and general theorems of Andreotti and Grauert (1962) on the finiteness and vanishing of cohomology indeed apply. However, not nearly as much is understood in this case as in the case of a hyperplane section.

### Kodaira Embedding Theorem

Given that analytic subvarieties of projective space are algebraic, one would like to understand whether a given compact complex manifold or complex space can be realized as such a subvariety. Kodaira's theorem is a prototype of such an embedding theorem. Most often one formulates projective embedding theorems in the language of bundles.

For this, observe that if $L \to X$ is a holomorphic line bundle over a compact complex manifold, then its space $\Gamma(X, L)$ of holomorphic sections is a finite-dimensional vector space $V$. The zero-set of a section $s \in V$ is a one-codimensional subvariety of $X$. Let us restrict our attention to bundles which are generated by their sections which for line bundles simply means that for every $x \in X$ there is some section $s \in V$ with $s(x) \neq 0$. It then follows that for every $x \in X$ the space $H_x := \{x \in X; s(x) = 0\}$ is a one-codimensional vector subspace of $V$. Thus $L$ defines a holomorphic map $\varphi_L : X \to \mathbb{P}(V^*), x \mapsto H_x$. Note that we must go to the projective space $\mathbb{P}(V^*)$, because a linear function defining such an $H_x$ is only unique up to a complex multiple.

Projective embedding theorems state that under certain conditions on $L$ the map $\varphi_L$ is a holomorphic embedding, that is, it is injective and is everywhere of maximal rank in the analytic sense that its differential has maximal rank. Here we outline a complex analytic approach of Grauert for proving embedding theorems. It makes strong use of the complex geometry of bundle spaces.

Let $L \to X$ be a holomorphic line bundle over a compact complex manifold. A Hermitian bundle metric is a smoothly varying metric $h$ in the fibers of $L$. This defines a norm function $v \mapsto |v|^2 := h(v, v)$ on the bundle space $L$. One says that $L$ is positive if the tubular neighborhood $T := \{v \in L; |v|^3 < 1\}$ is strongly pseudoconcave, that is, when regarded from outside $T$, its boundary is strongly pseudoconvex.

To prove an embedding theorem, one must produce sections with prescribed properties. Sections of powers $L^k$ are closely related to holomorphic functions on the dual bundle space $L^*$. This is due to the fact that if $\pi : L \to X$ is the bundle projection, $\pi^{-1}(U_\alpha) \cong U_\alpha \times \mathbb{C}$ is a local trivialization, and $z_\alpha$ is a fiber coordinate, then a holomorphic function $f$ on $L^*$ has a Taylor series development

$$f(v) = \sum s_\alpha(n)(\pi(v)) z_\alpha^n(v)$$

The function $f$ is well defined on $L$. Hence, the transformation law for the $z_\alpha^n$ must be canceled out by a transformation law for the coefficient functions $s_\alpha(n)$. This implies that the $s_\alpha(n)$ are sections of $L^n$. Hence, proving the existence of sections in the powers of $L$ with prescribed properties amounts to the same thing as proving the existence of holomorphic funtions on $L^*$ with analogous properties.

The positivity assumption on $L$ is equivalent to assuming that the tubular neighborhoods of the zero-section in $L^*$ defined by the norm function associated to the dual metric are strongly pseudoconvex. The solution to the Levi problem, which was sketched above, then shows that $L^*$ is holomorphically convex, and its Remmert reduction is achieved by simply blowing down its zero-section. In other words, $L^*$ is essentially a Stein manifold, and using Stein theory, it is possible to produce enough holomorphic functions on $L$ to show that some power $L^k$ defines a holomorphic embedding $\varphi_{L^k} : X \to \mathbb{P}(\Gamma(X, L^k)^*)$. Bundles with this property are said to be ample, and thus we have outlined the following fact: "a line bundle which is Grauert-positive is ample."

It should be underlined that we defined the Chern class of $L$ as the image in $H^2(X, \mathbb{Z})$ of its equivalence class in $H^1(X, \mathcal{O}^*)$, that is, in this formulation the Chern class is a Cech cohomology class. It is, however, often more useful to consider it as a deRham class where it lies in the (1, 1)-part of $H^2_{deR}(X, \mathbb{C})$. If $h$ is a bundle metric as above, then the Levi form of the norm function is a representative $-c_1(L, h)$ of the Chern class of $L^*$. Thus $c_1(L, h)$ is an integral (1, 1)-form which represents $c_1(L)$. It is called the Chern form of $L$ associated to the metric $h$. The following is Kodaira's formulation of his embedding theorem:

**Theorem** *A line bundle $L$ is ample if and only if it possesses a metric $h$ so that $c_1(L, h)$ is positive definite.*

Kodaira's proof of this fact follows from his vanishing theorem (*see* Several Complex Variables: Compact Manifolds) in the same way the example of Theorem A was derived from Theorem B in the

first example in the subsection "Selected theorems." That an ample bundle is positive follows immediately from the fact that if $\varphi_{L^k}$ is an embedding, then its pullback of the (positive) hyperplane bundle on projective space agrees with $L^k$.

Finally, one asks the question "under what natural conditions can one construct a bundle $L$ which is positive?" The following is an example of an answer which is related to geometric quantization.

Suppose that $X$ is a compact complex manifold equipped with a symplectic structure $\omega$, that is, $\omega$ is a $d$-closed, nondegenerate 2-form. One says that $\omega$ is Kählerian if it is compatible with the complex structure $J$ in the sense that $\omega(Jv, Jw) = \omega(v, w)$ and $\omega(Jv, v) > 0$ for every $v$ and $w$ in every tangent space of $X$. Note that if $L$ is a positive line bundle, then it possesses a Hermitian metric $h$ such that $\omega = c_1(L, h)$ is a Kählerian structure on $X$.

It should be underlined that there are Kähler manifolds without positive bundles, for example, every compact complex torus $T = \mathbb{C}^n/\Gamma$ possesses the Kählerian structure which comes from the standard linear structure on $\mathbb{C}^n$. However, for $n > 1$ most such tori are not projective algebraic and therefore do not have positive bundles.

If, on the other hand, the Kählerian structure is integral, a condition that is automatic for the Chern form $c_1(L, h)$ of a bundle, then there is indeed a line bundle $L \to X$ equipped with a Hermitian metric $h$ such that $c_1(L, h) = \omega$. The condition of integrality can be formulated in terms of the integrals of $\omega$ over homology classes being integral or that its deRham class is in the image of the deRham isomorphism from the Cech cohomology $H^2(X, \mathbb{Z}) \otimes \mathbb{C}$ to $H^2_{\text{de R}}(X, \mathbb{C})$. Coupling this with the embedding theorem for positive bundles, we have the following theorem of Kodaira:

**Theorem** *If $(X, \omega)$ is Kählerian and $\omega$ is integral, then $X$ is projective algebraic.*

This result has been refined in the following important way (a conjecture of Grauert and Riemenschneider proved with different methods by Siu (1984) and by Demailly (1985)): *the same result holds if $\omega$ is only assumed to be semipositive and positive in at least one point.*

For Grauert's proof of the Kodaira embedding theorem and a number of other important and beautiful results, we recommend the original paper (Grauert 1962).

### Quotients of Bounded Domains

Let $D$ be a bounded domain in $\mathbb{C}^n$ and $\Gamma$ be a discrete subgroup of $\text{Aut}(D)$ which is acting freely on $D$ with a compact quotient $X := D/\Gamma$. For $\gamma \in \Gamma$ let $J(\gamma, z)$ be the determinant of the Jacobian $d\gamma/dz$ and, given a holomorphic function $f$, consider (at least formally) the Poincaré series $\sum f(\gamma(z))J(\gamma, z)^k$ of weight $k$. If $f$ is bounded and $k \geq 2$, then this series converges to a holomorphic function $P(f)$ on $D$ which satisfies the transformation rule $P(f)\,(\gamma(z)) = J(\gamma, z)^{-k}P(f)(z)$.

Now the differential volume form $\Omega := dz_1 \wedge \cdots \wedge dz_n$ transforms in the opposite way (for $k = 1$). Therefore $s(f) = P(f)(\Omega)^k$ is a $\Gamma$-invariant section of the $k$th power of the determinant bundle $K := \Lambda^n T^*D$ of the holomorphic cotangent bundle of $D$. In other words, $s(f) \in \Gamma(X, K^k)$. Since the choice of $f$ may be varied to show that there are sufficiently many sections to separate points and to guarantee the maximal rank condition, it follows that the canonical bundle $K$ of $X$ is ample. Compact complex manifolds with ample canonical bundle are examples of manifolds which are said to be of general type (*see* Several Complex Variables: Compact Manifolds). Thus, this construction with Poincaré series proves the following: "Every compact quotient $D/\Gamma$ of a bounded domain is of general type and is in particular projective algebraic."

## Introduction

The aim of this article is to give an overview of the classification theory of compact complex manifolds. Very roughly, compact manifolds can be divided into three disjoint classes:

- Projective manifolds, that is, manifolds which can be embedded into some projective space, or manifolds birational to those, usually called Moishezon manifolds. These manifolds are treated by algebraic geometric methods, but very often transcendental methods are also indispensable.
- Compact (nonalgebraic) Kähler manifolds, that is, manifolds carrying a positive closed $(1,1)$-form, or manifolds bimeromorphic to those. This class is treated mainly by transcendental methods from complex analysis and complex differential geometry. However, some algebraic methods are also of use here.
- General compact manifolds which are not bimeromorphic to Kähler manifolds. For two reasons we will essentially ignore this class in our survey. First, because of the lack of methods, not much is known, for example, there is still no complete classification of compact complex surfaces, and it is still unknown whether or not the 6-sphere carries a complex structure. And second, for the purpose of this encyclopedia, this class seems to be less important.

The main problems of classification theory can be described as follows.

- Birational classification: describe all projective (Kähler) manifolds up to birational (bimeromorphic) equivalence; find good models in every equivalence class. This includes the study of invariants.
- Biholomorphic classification: classify all projective (Kähler) manifolds with some nice property, for example, curvature, many symmetries, etc.
- Topological classification and moduli: study all complex structures on a given topological manifold – including the study of topological invariants of complex manifolds; describe complex structures up to deformations and describe moduli spaces.
- Symmetries: describe group actions and invariants – this is deeply related with the moduli problem.

In this article we will assume familiarity with basic notions and methods from several complex variables and/or algebraic geometry. In particular we refer to Several Complex Variables: Basic Geometric Theory in this encyclopedia.

We first note some standard notation used in this article. If $X$ is a complex manifold of dimension $n$, then $T_X$ will denote its holomorphic tangent bundle and $\Omega_X^p$ the sheaf of holomorphic $p$-forms, that is, the sheaf of sections of the bundle $\bigwedge^p T_X^*$. The bundle $\bigwedge^n T_X^*$ is usually denoted by $K_X$, the canonical bundle of $X$ and its sheaf of sections is the dualizing sheaf $\omega_X$, but frequently we will not distinguish between vector bundles and their sheaves of sections. An effective (Cartier) divisor on a normal space $X$ is a finite linear combination $\sum n_i Y_i$, where $n_i > 0$ and $Y_i \subset X$ are irreducible reduced subvarieties of codimension, which are locally given by one equation. If $L$ is a line bundle, then instead of $L^{\otimes m}$ we often write $mL$. If $X$ is a compact variety and $E$ a vector bundle or coherent sheaf, then the dimension of the finite-dimensional vector space $H^q(X,E)$ will be denoted by $h^q(X,E)$.

## Birational Classification

Two compact manifolds $X$ and $Y$ are bimeromorphically equivalent, if there exist nowhere dense analytic subsets $A \subset X$ and $B \subset Y$ and a biholomorphic map $X \backslash A \to Y \backslash B$ such that the closure of the graph is an analytic set in $X \times Y$. In case $X$ and $Y$ are algebraic, one rather says that $X$ and $Y$ are birationally equivalent. This induces an isomorphism between the function fields of $X$ and $Y$. If $X$ and $Y$ are projective or Moishezon(see below), then conversely an isomorphism of their function fields induces a birational equivalence between $X$ and $Y$. Important examples are blow-ups of submanifolds; locally they can be described as follows. Suppose that locally $X$ is an open set $U \subset \mathbb{C}^n$ with coordinates $z_1, \ldots, z_n$ and that $A \subset X$ is given by $z_1 = \cdots = z_m = 0$. Then the blow-up $\hat{X} \to X$ is the submanifold $\hat{X} \subset U \times \mathbb{P}_{n-m-1}$ given by the equations

$$y_j t_i - y_i t_j = 0$$

where $t_j$ are homogeneous coordinates in $\mathbb{P}_{n-m-1}$.

The Chow lemma says that any birational – even rational – maps can be dominated by a sequence of blow-ups with smooth centers. Recently other factorizations ("weak factorization," using blow-ups and blow-downs) have been established.

A projective manifold is a compact manifold which is a submanifold of some projective space $\mathbb{P}_N$. Of course, a projective manifold can be embedded into projective spaces in many ways. According to Chow's theorem (*see* Several Complex Variables: Basic Geometric Theory), $X \subset \mathbb{P}_N$ is automatically given by polynomial equations and is therefore an algebraic variety. This is part of Serre's GAGA principle which roughly says that all global analytic objects on a projective manifold, for example, vector bundles or coherent sheaves and their cohomology are automatically algebraic. A compact manifold which is bimeromorphically equivalent to a projective manifold is called a Moishezon manifold. These arise naturally, for example, as quotient of group actions, compactifications, etc.

The most important birational invariant of compact manifolds is certainly the Kodaira dimension $\kappa(X)$. It is defined in three steps:

- $\kappa(X) = -\infty$ iff $h^0(mK_X) = 0$ for all $m \geq 1$.
- $\kappa(X) = 0$ iff $h^0(mK_X) \leq 1$ for all $m$, and $h^0(mK_X) = 1$ for some $m$.
- In all other cases we can consider the meromorphic map $f_m : X \to \mathbb{P}_{N(m)}$ associated to $H^0(mK_X)$ for all those $m$ for which $h^0(mK_X) \geq 2$. Let $V_m$ denote the (closure of the) image of $f_m$. Then $\kappa(X)$ is defined to be the maximal possible $\dim V_m$.

Recall that $f_m$ is defined by $[s_0 : \cdots : s_N]$ for a given base $s_i$ of $H^0(mK_X)$, cf. Several Complex Variables: Basic Geometric Theory.

In the same way one defines the Kodaira (or Iitaka) dimension $\kappa(L)$ of a holomorphic line bundle $L$ (instead of $L = K_X$).

We are now going to describe geometrically the different birational equivalence classes and how to single out nice models in each class. Using methods in characteristic $p$, Miyaoka and Mori proved the following theorem:

**Theorem 1** *Let X be a projective manifold and suppose that through a general point $x \in X$ there is a curve C such that $K_X \cdot C < 0$. Then X is uniruled, that is, there is a family of rational curves covering X.*

A rational curve is simply the image of nonconstant map $f : \mathbb{P}_1 \to X$. It is a simple matter to prove that uniruled manifolds have $\kappa(X) = -\infty$, but the converse is an important open problem. A step towards this conjecture has recently been made by Boucksom *et al.* (2004) if $K_X$ is not pseudoeffective, that is, $K_X$ "cannot be approximated by effective divisors," then $X$ is uniruled. Here one also finds a discussion of the case when $K_X$ is pseudoeffective.

Mori theory is central in birational geometry. To state the main results in this theory, we recall the notion of ampleness: a line bundle $L$ is ample if $L$ carries a metric of positive curvature. Alternatively some tensor power of $L$ has enough global section to separate points and tangents and there gives an embedding into some projective space; *see* Several Complex Variables: Basic Geometric Theory for more details. The notion of nefness, which is in a certain sense the degenerate version of ampleness, plays a central role in Mori theory: a line bundle or divisor $L$ is nef if

$$L \cdot C = \deg(L|C) \geq 0$$

for all curves $C \subset X$. Examples are those $L$ carrying a metric of semipositive curvature, but the converse is not true. However, if $L$ is nef, there exists for all positive $\epsilon > 0$ a metric $h_\epsilon$ with curvature $\Theta_\epsilon > -\epsilon\omega$, where $\omega$ is a fixed positive form. In this context singular metrics on $L$ are also important. Locally they are given by $e^{-\varphi}$ with a locally integrable weight function $\varphi$ and they still have a curvature current $\Theta$. If $L$ has a singular metric with $\Theta$ bounded from below as current by a Kähler form, then $L$ is big, that is, $\kappa(L) = \dim X$, the birational version of ampleness. If one simply has $\Theta \geq 0$ as current, then $L$ is pseudoeffective (and vice versa). All these positivity notions only depend on the Chern class $c_1(L)$ of $L$ and therefore one considers the ample cone

$$K_{\text{amp}} \subset (H^{1,1}(X) \cap H^2(X, \mathbb{Z})) \otimes \mathbb{R}$$

and the cone of curves

$$\overline{NE}(X) \subset (H^{n-1,n-1}(X) \cap H^{2n-2}(X, \mathbb{Z})) \otimes \mathbb{R}$$

The ample cone is by definition the closed cone of nef divisors, the interior being the ample classes, while the cone of curves is the closed cone generated by the fundamental classes of irreducible curves.

A basic result says that these cones are dual to each other. The structure of $\overline{NE}(X)$ in the part where $K_X$ is negative is very nice; one has the following cone theorem:

**Theorem 2** $\overline{NE}(X)$ *is locally finite polyhedral in the half-space $\{K_X < 0\}$; the (geometrically) extremal rays contain classes of rational curves.*

A ray $R = \mathbb{R}_+[a]$ is said to be extremal in a closed cone $K$ if the following holds: given $b, c \in K$ with $b + c \in R$, then $b, c \in R$. Given such an extremal ray $R \subset \overline{NE}(X)$, one can find an ample line bundle $H$ and a rational number $t$ such that $K_X + tH$ is nef and $K_X + tH \cdot R = 0$. Using the Kawamata–Viehweg vanishing theorem, a generalization of Kodaira's vanishing theorem, which is one of the technical corner stones of the theory, one proves the so-called

**Base point free theorem** *Some multiple of $K_X + tH$ is spanned by global sections and therefore defines a holomorphic map $f: X \to Y$ to some normal projective variety Y contracting exactly those curves whose classes belong to R.*

These maps are called "contractions of extremal rays" or "Mori contractions." In dimension 2 they are classical: either $X = \mathbb{P}_2$ and $f$ is the constant map, or $f$ is a $\mathbb{P}_1$-bundle or $f$ is birational and the contraction of a $\mathbb{P}_1$ with normal bundle $\mathcal{O}(-1)$, that is, $f$ contracts a $(-1)$-curve. In particular $Y$ is again smooth. In the first two cases $X$ has a very precise structure, but in the third birational case one proceeds by asking whether or not $K_Y$ is nef. If it is not nef, we start again by choosing the contraction of an extremal ray; if $K_Y$ is nef, then a fundamental result says that a multiple of $K_Y$ is spanned. The class of manifolds with this property will be discussed later.

The situation in higher dimensions is much more complicated. For example, $Y$ need no longer be smooth. However the singularities which appear are rather special.

**Definition 1** A normal variety $X$ is said to have only terminal singularities if first some multiple of the canonical (Weil) divisor $K_X$ is a Cartier divisor, that is, a line bundle (one says that $X$ is $\mathbb{Q}$-Gorenstein) and second if for some (hence for every) resolution of singularities $\pi: X \to X$ the following holds:

$$K_{\hat{X}} = \pi^*(K_X) + \sum a_i E_i$$

where the $E_i$ run over the irreducible $\pi$-exceptional divisors and the $a_i$ are strictly positive.

A brief remark concerning Weil divisors is in order: a Weil divisor is a finite linear combination $\sum a_i Y_i$ with $Y_i$ irreducible of codimension 1, but $Y_i$ is not necessarily locally defined by one equation. Recall that if each $Y_i$ is given locally by one equation, then the Weil divisor is Cartier. On a smooth variety these notions coincide.

One important consequence is that $\kappa(X) = \kappa(\hat{X})$ in case of terminal singularities, which is completely false for arbitrary singularities. Also notice that terminal singularities are rational: $R^q\pi_*(\mathcal{O}_{\hat{X}}) = 0$ for $q \geq 1$. Terminal singularities occur in codimension at least 3. Thus they are not present on surfaces. In dimension 3 terminal singularities are well understood. The main point in this context is that for a birational Mori contraction the image $Y$ often has terminal singularities.

Now the scheme of Mori theory is the following. Start with a projective manifold $X$. If $K_X$ is nef, we stop; this class is discussed later. If $K_X$ is not nef, then perform a Mori contraction $f: X \to Y$. There are two cases:

- If $\dim Y < \dim X$, then the general fiber $F$ is a manifold with ample $-K_F$, that is, a Fano manifold (discussed in the next section). Here we stop and observe that $\kappa(X) = -\infty$. Of course one can still investigate $Y$ and try to say more on the structure of the fibration $f$.
- If $\dim Y = \dim X$, then $Y$ has terminal singularities – unless $f$ is a small contraction which means that no divisors are contracted. Thus if $f$ is not small, we may attempt to proceed by substituting $X$ by $Y$.

As a result one must develop the entire theory for varieties with terminal singularities. The big problem arises from small contractions $f$. In that case $K_Y$ cannot be $\mathbb{Q}$-Cartier and the machinery stops. So new methods are required. At this stage, other aspects of the theory lead one to attempt a certain surgery procedure which should improve the situation and allow one to continue as above. The expected surgery $Y \rightharpoonup Y'$, which takes place in codimension at least 2, is a "flip." The idea is that we should substitute a small set, namely the exceptional set of a small contraction, by some other small set (on which the canonical bundle will be positive) to improve the situation. Of course $Y'$ should possess only terminal singularities. The existence of flips is very deep and has been proved by S Mori in dimension 3. Moreover, there cannot be an infinite sequence of flips, at least in dimension at most 4.

In summary, by performing contractions and flips one constructs from $X$ a birational model $X'$ with terminal singularities such that either

- $K_{X'}$ is nef in which case we call $X'$ a minimal model for $X$, or
- $X'$ admits a Fano fibration $f': X' \to Y'$ (discussed below), in which case $\kappa(X) = \kappa(X') = -\infty$.

Up to now, Mori theory (via the work of Kawamata, Kollár, Mori, Reid, Shokurov, and others) works well in dimension 3 (and possibly in the near future in dimension 4) but in higher dimensions there are big problems with the existence of flips. Of course there might be completely different and possibly less precise ways to construct a minimal model. One way is to consider the canonical ring $R$ of a manifold of general type:

$$R = \sum H^0(mK_X)$$

If $R$ is finitely generated as $\mathbb{C}$-algebra, then $\mathrm{Proj}(R)$ would be at least a canonical model which

has slightly more complicated singularities than a minimal model. However, it is known that this "finite generatedness problem" is equivalent to the existence of minimal models. On the other hand, if $X$ is of general type with $K_X$ nef (hence essentially ample) or more generally when some positive multiple $mK_X$ is generated by global sections, then $R$ is finitely generated.

We now must discuss the case of a nef canonical bundle. The behavior is predicted by the

**Abundance conjecture.** *If $X$ has only terminal singularities and $K_X$ is nef, then some multiple $mK_X$ is spanned.*

Up to now this conjecture is known only in dimension 3 (Kawamata, Kollár, Miyaoka). In higher dimensions it is even unknown if there is a single section in some multiple $mK_X$. If $mK_X$ is spanned, one considers the Stein factorization $f: X \to Y$ of the associated map, which is called the Iitaka fibration (if not birational) and we have $\dim Y = \kappa(X)$ by definition. The general fiber $F$ is a variety with $K_F \equiv 0$, a class discussed in the next section. If $f$ is birational, then $Y$ will be slightly singular (so-called canonical singularities) and $K_Y$ will be ample. Essentially we are in the case of negative Ricci curvature.

Everything that was outlined above holds for projective manifolds. In the Kähler case one would expect the same picture, but the methods completely fail, and new, analytic methods must be found. Only very few results are known in this context.

We come back to the case of a Fano fibration $f: X \to Y$. By definition the anticanoical bundle $-K_X$ is relatively ample so that the general fiber is a Fano variety. In this case there are no constraints on $Y$.

To see how much of the geometry of $X$ is dictated by the rational curves, one considers the so-called rational quotient of $X$. Here we identify two very general points on $X$ if they can be joined by a chain of rational curves. In that way we obtain the rational quotient

$$f: X \rightharpoonup Y$$

This map is merely meromorphic, but has the remarkable property of being "almost holomorphic," that is, the set of indeterminacies does not project onto $Y$. In other words, one has nice compact fibers not meeting the indeterminacy set. If $Y$ is just a point, then all points of $X$ can be joined by chains of rational curves and $X$ is called rationally connected. This notion is clearly birationally invariant.

A deep theorem of Graber–Harris–Starr states that, given a Fano fibration (or a fibration with rationally connected fibers) $f: X \to Y$, then $X$ is rationally connected if and only if $Y$ is.

Manifolds $X_n$ which are birational to $\mathbb{P}_n$ are called rational. If there merely exists a surjective ("dominant") rational map $\mathbb{P}_n \rightharpoonup X$, then $X$ is said to be unirational. Of course rational (resp. unirational) manifolds are rationally connected, but to decide whether a given manifold is rational/unirational is often a very deep problem. Therefore, rational connectedness is often viewed as a practical substitute for (uni)rationality.

Often it is very important to compute the Kodaira dimension of fiber spaces. Let us fix a holomorphic surjective map $f: X \to Y$ between projective manifolds and we suppose $f$ has connected fibers. Then the so-called conjecture $C_{nm}$ states that

$$\kappa(X) \geq \kappa(F) + \kappa(Y)$$

where $F$ is the general fiber of $f$. This conjecture is known in many cases, for example, when the general fiber is of general type, but it is wide open in general. It is deeply related to the existence of minimal models (Kawamata).

## Biholomorphic Classification

In this section we discuss manifolds $X$ with

- ample anticanonical bundles $-K_X$ (Fano manifolds),
- trivial canonical bundles, and
- ample canonical bundles $K_X$.

Due to the solution of the Calabi conjecture by Yau and Aubin, these classes are characterized by a Kähler metric of positive (resp. zero, resp. negative) Ricci curvature. In principle, in view of the results of Mori theory, one should rather consider varieties with terminal singularities, but we ignore this aspect completely. Philosophically, up to birational equivalence all manifolds are via fibrations somehow composed of those classes via fibrations, possibly also up to étale coverings.

Examples of Fano manifolds are hypersurfaces of degree at most $n+1$ in $\mathbb{P}_{n+1}$, Grassmannians, or more generally homogenenous varieties $G/P$ with $G$ semisimple and $P$ a parabolic subgroup. Fano manifolds are simply connected. This can be seen either by classical differential geometric methods using a Kähler metric of positive curvature or via the fundamental

**Theorem 3** *Fano manifolds are rationally connected.*

The only known proof of this fact uses, as in the uniruled criterion mentioned above, characteristic $p$ methods. By just using complex methods it is not

known how to construct a single rational curve (of course, in concrete examples the rational curves are seen immediately). One still has to observe that rationally connected manifolds are simply connected, which is not so surprising, since rational curves lift to the universal cover.

At least in principle, Fano manifolds can be classified:

**Theorem 4** *There are only finitely many families of Fano manifolds in every dimension.*

A family (of Fano manifolds) is a submersion $\pi: \mathcal{X} \to S$ (with $S$ irreducible) such that all fibers are Fano manifolds. The essential step is to bound $(-K_X)^n$. An actual classification has been carried out only in dimension up to 3; in dimension 2 one finds $\mathbb{P}_2, \mathbb{P}_1 \times \mathbb{P}_1$ and the so-called del Pezzo surfaces ($\mathbb{P}_2$ blown up in at most eight points in general position). In dimension 3 there are already 17 families of Fano 3-folds with $b_2 = 1$ and 88 families with $b_2 \geq 2$.

An extremely hard question is to decide whether a given Fano manifold is rational or unirational. Even in dimension 3 this is not completely decided.

The next class to be discussed are the manifolds with trivial canonical class $K_X$. This means that there is a holomorphic $n$-form without zeros ($n = \dim X$). Important examples are tori and hypersurface in $\mathbb{P}_{n+1}$ of degree $n+2$. Simply connected manifolds with trivial canonical bundles are further divided into irreducible Calabi–Yau manifolds and irreducible symplectic manifolds. The first class is defined by requiring that there are no holomorphic $p$-forms for $p < \dim X$ whereas the second is characterized by the existence of a holomorphic 2-form of everywhere maximal rank. A completely different characterization is by holonomy: an irreducible Calabi–Yau manifold has SU-holonomy whereas irreducible symplectic manifolds have Sp-holonomy (with respect to a suitable Kähler metric).

The splitting theorem of Beauville–Bogomolov–Kobayashi says

**Theorem 5** *Let $X$ be a projective (or compact Kähler) manifold with trivial canonical bundle. Then there exists a finite unbranched cover $\tilde{X} \to X$ such that*

$$X = A \times \Pi X_i \times \Pi Y_j$$

*with $A$ a torus, $X_i$ irreducible Calabi–Yau, and $Y_j$ irreducible symplectic.*

The key to the proof of this theorem is the existence of a Ricci-flat Kähler metric on $X$, a Kähler–Einstein metric with zero Ricci curvature. Actually one has a stronger result: instead of assuming $K_X$ to be trivial, just assume that $c_1(X) = 0$ in $H^2(X, \mathbb{R})$. Then there exists a finite unramified cover $X \to X$ such that $K_{\tilde{X}}$ is trivial. In view of Mori theory, normal projective varieties $X$ with at most terminal singularities and $K_X \equiv 0$ (i.e., $K_X \cdot C = 0$ for all curves) should also be investigated. It is expected that similar structure theorems hold; in particular $\pi_1(X)$ should be finite. The main difficulty is that there are no differential methods available; on the other hand an algebraic proof even for the splitting theorem in the smooth case is unknown.

Calabi–Yau manifolds play an important role in string theory and mirror symmetry (*see* Mirror Symmetry: A Geometric Survey). Here we mention two basic problems. The first is the problem of boundedness:

*Are there only finitely many families of Calabi–Yau manifolds in any dimension?*

This problem is wide open; in particular one might ask:

*Is the Hodge number $h^{1,2}$ bounded for Calabi–Yau 3-folds?*

The other problem asks for the existence of rational curves. In all known examples there are rational curves, but a general existence proof is not known. The case where $b_2(X) = 1$ seems to be particularly difficult. If $b_2(X) \geq 2$, then in may cases one can hope to find a fibration or a birational map, at least for 3-folds. Given such a map, the existence of rational curves is simple. For example, if $D \subset X$ is an irreducible hypersurface which is not nef, choose $H$ ample and consider the *a priori* positive real number $p$ such that $D + pH$ is on the boundary of the ample cone. Then actually $p$ is rational and a suitable multiple $m(D + pH)$ is spanned and defines a contraction on $X$. This comes from "logarithmic Mori theory."

The above splitting theorem exhibits a torus factor and all holomorphic 1-forms on $X$ come from this torus. This principle generalizes: given any projective or compact Kähler manifold $X$, there exists a "universal object," the Albanese torus

$$\mathrm{Alb}(X) = H^0(\Omega^1_X)^* / H_1(X, \mathbb{Z})$$

(which is algebraic if $X$ is) together with a holomorphic map

$$\alpha : X \to \mathrm{Alb}(X)$$

the Albanese map. This Albanese map is given by integrating 1-forms and is often far from being surjective. The important property is now that, given a holomorphic 1-form $\omega$ on $X$, there exists a holomorphic 1-form $\eta$ on the Albanese torus such that $\omega = \alpha^*(\eta)$. The universal property reads as

follows: every map $X \to T$ to a torus factors via an affine map $\mathrm{Alb}(X) \to T$.

There is a nonabelian analog, the so-called Shafarevich map, but at the moment this map is only known to be meromorphic. It is an important tool to study the fundamental group $\pi_1(X)$. We refer to Campana (1996) and Kollár (1995).

In the following, Chern classes of holomorphic vector bundles will be important. Let $X$ be a compact complex manifold and $E$ a holomorphic vector bundle on $X$. The $j$th Chern class of $E$ is an element

$$c_j(E) \in H^{2j}(X, \mathbb{Q}) \cap H^{j,j}(X)$$

It can be defined, for example, by putting a Hermitian metric on $E$, computing the curvature of the canonical connection compatible with both the metric and the holomorphic structure and then by applying certain linear operators coming from symmetric functions such as determinant and trace. Actually Chern classes can be attached to every complex topological vector bundle on a topological manifold; then $c_j(E)$ will simply live in $H^{2j}(X, \mathbb{R})$. There is also a purely algebraic construction by Grothendieck. We refer, for example, to Fulton (1984) as well as for a discussion of the elementary functorial properties of Chern classes. Here we just recall that for a rank-$r$ vector bundle $E$ the first Chern class

$$c_1(E) = c_1\left(\bigwedge E\right)$$

where the Chern class of the line bundle $\bigwedge^r E$ as given in Several Complex Variables: Basic Geometric Theory actually lives in $H^2(X, \mathbb{Z})$.

Finally we discuss manifolds with ample canonical class $K_X$. Here moduli question often plays a central role. Moduli spaces of surfaces with fixed $c_1^2$ and $c_2$ are very intensively studied (by Catanese, Ciliberto, and others). Here, without going into details, we will concentrate on the very interesting topic of Kähler–Einstein metrics.

A Kähler metric $\omega$ is said to be Kähler–Einstein, if its Ricci curvature $\mathrm{Ric}(\omega)$ is proportional to $\omega$. The proportionality factor $\lambda$ can be taken to be $-1, 0, 1$. In case $K_X$ is ample or trivial, Kähler–Einstein metrics always exist by Yau and Aubin (cases $\lambda = -1$, resp. $\lambda = 0$). However if $X$ is Fano, there are obstructions, and a Kähler–Einstein metric does not always exist. An important consequence of the existence of a Kähler–Einstein metric on a manifold $X_n$ with ample canonical class is the Miyaoka–Yau inequality:

$$c_1^2 \omega^{n-2} \leq \frac{2n+1}{n} \omega^{n-2}$$

In case of equality, $X$ is covered by the $n$-dimensional unit ball.

The same inequality holds in case $K_X = 0$, and as a consequence the Chern class $c_2(X)$ is in some sense semipositive. If $c_2(X) = 0$, then some finite unramified cover of $X$ is a torus.

There is an interesting relation to stability. Recall that a vector bundle $E$ on a compact Kähler manifold $X_n$ is semistable with respect to a given Kähler form $\omega$, if for all proper coherent subsheaves $\mathcal{F} \subset E$ of rank-$r$ the following inequality holds:

$$\frac{c_1(\mathcal{F}) \cdot \omega^{n-1}}{r} \leq \frac{c_1(E) \cdot \omega^{n-1}}{n}$$

In case of strict inequality, $E$ is said to be stable.

The basic observation is now that the tangent bundle of a manifold with a Kähler–Einstein metric is semistable (with respect to the Kähler–Einstein metric). It is expected that Fano manifolds with $b_2 = 1$ have (semi?-)stable tangent bundles, although in certain situations they do not admit a Kähler–Einstein metric.

Again the first two Chern classes of a semistable vector bundle fulfill an inequality:

$$c_1^2(E) \cdot \omega^{n-2} \leq \frac{2r}{r-1} c_2(E) \cdot \omega^{n-2}$$

Equally important, semistable bundles with fixed numerical data form moduli spaces, this being the origin of the stability notion (Mumford). In this context, the notion of an Hermite–Einstein bundle is also important. Given a holomorphic vector bundle $E$ with a Hermitian metric $h$, there is a unique connection $F_h$ on $E$ compatible both with $h$ and the complex structure. $F_h$ is a (1,1)-form with values in $\mathrm{End}(E)$. Now suppose $(X, \omega)$ is Kähler and let $\lambda F_h$ be the contraction of $F_h$ with $\omega$. Then $(E, h)$ is said to Hermite–Einstein on $(X, \omega)$, if

$$\lambda F_h = \gamma \mathrm{id}$$

with some constant $\gamma$ and id: $E \to E$ the identity. Notice that $(X, \omega)$ is Kähler–Einstein if $(T_X, h)$ is Hermite–Einstein over $(X, \omega)$ with $h$ the Kähler metric with Kähler form $\omega$. It is not so difficult to see that Hermite–Einstein bundles are semistable (with respect to the underlying Kähler form) and actually are directs sum of stable Hermite–Einstein bundles. Conversely, a very deep theorem of Uhlenbeck–Yau says that *every stable vector bundle on a compact Kähler manifold is Hermite–Einstein.* This is known as the Kobayashi–Hitchin correspondence; see Lübke and Teleman (1995).

## Topology, Invariants and Cohomology

Besides the Kodaira dimension there are other important invariants of compact complex manifolds. Of course there are topological invariants such as the Betti number $b_i(X) = \dim H^i(X, \mathbb{R})$ or the fundamental group $\pi_1(X)$. The fundamental group has been studied intensively in the last decade. A central question asks which groups can occur as fundamental groups of compact Kähler manifolds; another problem is the so-called Shafarevitch conjecture which says that the universal cover of a compact Kähler manifold should be holomorphically convex. We refer to Campana (1996) and Kollár (1995).

The plurigenera,

$$P_m(X) = \dim h^0(mK_X)$$

are also extremely important. Here, Siu recently proved that $P_m(X)$ is constant in families of projective manifolds. Other important invariants are $h^0(X, (\Omega^1_X)^{\otimes m})$. For example, it is conjectured that if

$$h^0(X, (\Omega^1_X)^{\otimes m}) = 0$$

for all positive $m$, then $X$ is rationally connected. Tensor powers of the cotangent bundle somehow capture more of the structure of $X$ than the Kodaria dimension but they are more difficult to treat. The relevance of the dimensions

$$h^0(X, \Omega^p_X)$$

of holomorphic forms is easier to understand. More generally one has the Hodge numbers

$$h^{p,q}(X) = \dim H^q(X, \Omega^p_X)$$

For compact Kähler manifolds, the Hodge decomposition states

$$H^r(X, \mathbb{C}) = \bigoplus_{p+q=r} H^{p,q}(X)$$

Furthermore, Hodge duality,

$$H^{p,q}(X) = H^{q,p}(X)$$

holds. These results form a cornerstone for the geometry of compact Kähler manifolds and the starting point of Hodge theory. Hodge theory is, for example, extremely important in the study of families of manifolds and moduli.

Concerning the topology of projective (Kähler) manifolds, the following two questions are very basic.

- Which invariants are topological (or diffeomorphic) invariants?
- What are the projective or Kähler structures on a given compact topological manifold?

Concerning the first, Hodge decomposition implies that the irregularity $h^0(\Omega^1_X)$ is actually a topological invariant. However it is unknown whether the number of holomorphic 2-forms is a topological invariant of Kähler 3-folds. Both questions have been intensively studied in dimension 2. However, in higher dimensions almost nothing is known. For example, it is not known whether there is projective manifold of general type of even dimension which is homeomorphic to a quadric, that is, a hypersurface of degree 2 in projective space.

Other important tools in the study of projective/Kähler manifolds are listed below.

- Cohomological methods: Riemann–Roch theorem and holomorphic Morse inequalities; vanishing theorems (Kodaira, Kawamata–Viehweg, etc.); Serre duality. References: Demailly (2000), Demailly and Lazarsfeld, Fulton (1984), Grauert *et al.* (1994), Lazarsfeld (2004).
- $L^2$ methods: extension theorems, singular metrics, multiplier ideals, etc. Reference: Demailly and Lazarsfeld (2001), Lazarsfeld (2004).
- Theory of currents. Reference: Demailly 2000.
- Cycle space and Douady space, resp. Chow scheme and Hilbert scheme. Reference: Fulton 1984, Grauert 1994, Kollár 1996.

We restrict our remarks on just one of these topics, vanishing theorems. The classical Kodaira–Nakano vanishing theorem says that if $X$ is a compact manifold of dimension $n$ with a positive (ample) line bundle $L$, then

$$H^q(X, L \otimes \Omega^p) = 0$$

for $p + q > n$. This is usually proved via harmonic theory, that is, by representing the cohomology space by harmonic $(p, q)$-forms with values in $L$ and by computing integrals of these forms. For many purposes, for example, for Mori theory, it is important to generalize this to a line bundle which have some positivity properties but which are not ample. This works only for $p = n$, however this is the most important part of the Kodaira–Nakano vanishing. The Kawamata–Viehweg vanishing theorem in its most basic version says that given a nef and big line bundle $L$, then Kodaira vanishing still holds:

$$H^q(X, L \otimes K_X) = 0$$

for $q \geq 1$. But actually it is not necessary to assume $L$ nef, in fact the following is true. Let

$$D = \sum a_i D_i$$

be an effective $\mathbb{Q}$-divisor, that is, all $a_i$ are positive rational numbers. Let $\langle a_i \rangle$ be the fractional part of $a_i$ and suppose that the $\mathbb{Q}$-divisor $\sum \langle a_i \rangle D_i$ has normal crossings. Let $\lceil a_i \rceil$ be the roundup of $a_i$ and put $L = \sum \lceil a_i \rceil D_i$. If $D$ is big and nef, then

$$H^q(X, L \otimes K_X) = 0$$

for $q \geq 1$. Of course $L$ itself need not be nef! This generalization is technically very important and yields substantial freedom for birational manipulations. We refer to Kawamata *et al.* (1987) and Lazarsfeld (2004). Even this is not the end of the story: the Kawamata–Viehweg theorem is embedded in the broader context of the Nadel vanishing theorem where multiplier ideal sheaves come into the play. See Demailly and Lazarsfeld and Lazarsfeld (2004).

## Homogeneous Manifolds

In this section we consider vector fields and holomorphic group actions on compact (Kähler) manifolds. Our main reference is Huckleberry (1990) with further literature given there.

We denote by $\mathrm{Aut}(X)$ the group of holomorphic automorphisms of the compact manifold $X$ (well known to be a complex Lie group), and by $G := \mathrm{Aut}^0(X)$ the connected component containing the identity. The tangent space at any point of $\mathrm{Aut}^0(X)$ can naturally be identified with $H^0(X, T_X)$, the (finite-dimensional) space of holomorphic vector fields on $X$. In fact, by integration, a vector field determines a one-parameter group of automorphisms.

One says that $X$ is homogeneous if $G$ acts transitively on $X$. Therefore, one can write

$$X = G/H$$

where $H$ is the isotropy subgroup of any point $x_0 \in X$, that is, the subgroup of automorphisms fixed $x_0$. Conversely one can take a complex Lie group $G$ and a closed subgroup $H$ and form the quotient $G/H$ which is again a complex manifold and in fact homogeneous (of course not necessarily compact).

Going back to a compact manifold $X$, the condition to be homogenenous can be rephrased by saying that the tangent bundle is generated by global sections, that is, if $x \in X$ and $e \in T_{X,x}$, then there exists $v \in H^0(X, T_X)$ such that $v(x) = e$. The easiest case is when $T_X$ is trivial. If $X$ is Kähler, this is exactly the case when $X$ is torus, $X = \mathbb{C}^n/\Gamma$ with $\Gamma \simeq \mathbb{Z}^{2n}$ a lattice, but without the Kähler assumption there are many more examples (the so-called parallelizable manifolds).

More generally, let us consider the case that the compact Kähler manifold $X$ admits a vector field $v$ without zeros, but $X$ is not required to be homogeneous. Then a theorem of Lieberman says that there is a finite unramified cover $f: X \to X$ and a splitting

$$\tilde{X} \simeq F \times T$$

with $T$ a torus, such that $f^*(v)$ is the pullback of a vector field on $T$. On the other hand, if $v$ has a zero, then a classical theorem of Rosenlicht says that $X$ is covered by rational curves, that is, $X$ is uniruled. In particular $\kappa(X) = -\infty$. Notice also that a manifold of general type can never carry a vector field, in other words, the automorphism group is discrete, even finite.

Coming back to compact homogeneous Kähler manifolds, the first thing to study is the Albanese map. The Borel–Remmert theorem says that

$$X \simeq T \times Q$$

where $T$ is the Albanese torus. This is proved using a maximal compact subgroup $K \subset G$ and by some averaging process over $K$. Moreover, $Q$ is a rational homogeneous manifold. The structure of $Q$ is more precisely the following. One can write $Q = S/P$ with $S$ a semisimple Lie group and $P \subset S$ parabolic, which means that $P$ contains a maximal connected solvable subgroup (the so-called Borel subgroup). The main ingredients of the proof are the Tits fibration, the Levi–Malcev decomposition of a Lie group into its radical and a semisimple group, and the Borel fixed point theorem:

**Theorem 6** *Let $G \subset \mathrm{GL}_n(\mathbb{C})$ be a connected solvable subgroup and $X \subset \mathbb{P}_{n-1}$ be a $G$-stable subvariety. Then $G$ has a fixed point on $X$.*

In the homogenenous Kähler case, the rationality of $Q$ is seen by exhibiting an open subset in $Q$ which is algebraically isomorphic to $\mathbb{C}^n$.

Now things come down to classify all rational homogenenous manifold $S/P$ which is of course classical. Notice that all rational homogeneous manifolds are Fano. One knows that a rational homogeneous manifold with Betti number $b_2 \geq 2$ can be fibered over another rational homogenenous manifold with fibers rational homogeneous – this is actually a fiber bundle. The case that $b_2 = 1$ can be rephrased by saying that $P$ is maximal parabolic. This fiber bundle might not be trivial as shown by the projectivized tangent bundle $\mathbb{P}(T_{\mathbb{P}_n})$.

Compact Hermitian symmetric spaces form a particularly interesting subclass of homogeneous Kähler manifolds. A manifold equipped with a

Hermitian metric is called Hermitian symmetric, if for every $x \in X$ there exists an involutive holomorphic isometry fixing $x$. Mok has shown the remarkable fact that the simply connected compact Hermitian symmetric spaces are exactly those simply connected compact manifolds carrying a Kähler metric with semipositive holomorphic bisectional curvature. The only manifold having a metric with positive holomorphic bisectional curvature is $\mathbb{P}_n$ (Siu-Yau, Mori).

# Shock Wave Refinement of the Friedman–Robertson–Walker Metric

**B Temple**, University of California at Davis, Davis, CA, USA

**J A Smoller**, University of Michigan, Ann Arbor, MI, USA

## Introduction

In the standard model of cosmology, the expanding universe of galaxies is described by a Friedman–Robertson–Walker (FRW) metric, which in spherical coordinates has a line element given by (Blau and Guth 1987, Weinberg 1972)

$$ds^2 = -dt^2 + R^2(t)\left\{\frac{dr^2}{1-kr^2} + r^2[d\theta^2 + \sin^2\theta\, d\phi^2]\right\} \quad [1]$$

In this model, which accounts for things on the largest length scale, the universe is approximated by a space of uniform density and pressure at each fixed time, and the expansion rate is determined by the cosmological scale factor $R(t)$ that evolves according to the Einstein equations. Astronomical observations show that the galaxies are uniform on a scale of about one billion light years, and the expansion is critical – that is, $k=0$ in [1] – and so, according to [1], on the largest scale, the universe is infinite flat Euclidian space $R^3$ at each fixed time. Matching the Hubble constant to its observed values, and invoking the Einstein equations, the FRW model implies that the entire infinite universe $R^3$ emerged all at once from a singularity ($R=0$), some 14 billion years ago, and this event is referred to as the big bang.

In this article, which summarizes the work of the authors in Smoller and Temple (1995, 2003), we describe a two-parameter family of exact solutions of the Einstein equations that refine the FRW metric by a spherical shock wave cutoff. In these exact solutions, the expanding FRW metric is reduced to a region of finite extent and finite total mass at each fixed time, and this FRW region is bounded by an entropy-satisfying shock wave that emerges from the origin (the center of the explosion), at the instant of the big bang, $t=0$. The shock wave, which marks the leading edge of the FRW expansion, propagates outward into a larger ambient spacetime from time $t=0$ onward. Thus, in this refinement of the FRW metric, the big bang that set the galaxies in motion is an explosion of finite mass that looks more like a classical shock wave explosion than does the big bang of the standard model. (The fact that the entire infinite space $R^3$ emerges at the instant of the big bang, is, loosely speaking, a consequence of the Copernican principle, the principle that the Earth is not in a special place in the universe on the largest scale of things. With a shock wave present, the Copernican principle is violated, in the sense that the Earth then has a special position relative to the shock wave. But, of course, in these shock wave refinements of the FRW metric, there is a spacetime on the other side of the shock wave, beyond the galaxies, and so the scale of uniformity of the FRW metric, the scale on which the density of the galaxies is uniform, is no longer the largest length scale.)

In order to construct a mathematically simple family of shock wave refinements of the FRW metric that meet the Einstein equations exactly, we assume $k=0$ (critical expansion), and we restrict to the case that the sound speed in the fluid on the FRW side of the shock wave is constant. That is, we assume an FRW equation of state $p=\sigma\rho$, where $\sigma$, the square of the sound speed $\sqrt{\partial p/\partial\rho}$, is constant, $0<\sigma\leq c^2$. At $\sigma=c^2/3$, this catches the important equation of state $p=(c^2/3)\rho$ which is correct at the earliest stage of big bang physics (Weinberg 1972). Also, as $\sigma$ ranges from 0 to $c^2$, we obtain qualitatively correct approximations to general equations of state. Taking $c=1$ (we use the convention that $c=1$, and Newton's constant $\mathcal{G}=1$ when convenient), the family of solutions is then determined by two parameters, $0<\sigma\leq 1$ and $r_*\geq 0$. The second parameter, $r_*$, is the FRW radial coordinate $r$ of the shock in the limit $t\to 0$, the instant of the big bang. (Since, when $k=0$, the FRW metric is invariant under the rescaling $r\to\alpha r$ and $R\to\alpha^{-1}R$, we fix the radial coordinate $r$ by fixing the scale factor $\alpha$ with the condition that $R(t_0)=1$ for some time $t_0$, say present time.) The FRW radial coordinate $r$ is singular with respect to radial arclength $\bar{r}=rR$ at the big bang $R=0$, so setting $r_*>0$ does not place the shock wave away from the origin at time $t=0$. The distance from the FRW center to the shock wave tends to zero in the limit $t\to 0$ even when $r_*>0$. In the limit $r_*\to\infty$, we recover from the family of solutions the usual (infinite) FRW metric with equation of state $p=\sigma\rho$ – that is, we recover the standard FRW metric in the limit that the shock wave is infinitely far out. In this sense our family of exact solutions of the Einstein equations considered here represents a two-parameter refinement of the standard FRW metric.

The exact solutions for the case $r_*=0$ were first constructed in Smoller and Temple (1995) (see also the notes by Smoller and Temple (1999)), and are qualitatively different from the solutions when $r_*>0$, which were constructed later in Smoller and Temple (2003). The difference is that, when $r_*=0$, the shock wave lies closer than one Hubble length from the center of the FRW spacetime throughout its motion (Smoller and Temple 2000), but when $r_*>0$, the shock wave emerges at the big bang at a distance beyond one Hubble length. (The Hubble length depends on time, and tends to zero as $t\to 0$.) We show in Smoller and Temple (2003) that one Hubble length, equal to $c/H$, where $H=\dot{R}/R$, is a critical length scale in a $k=0$ FRW metric because the total mass inside one Hubble length has a Schwarzschild radius equal exactly to one Hubble length. (Since $c/H$ is a good estimate for the age of the universe, it follows that the Hubble length $c/H$ is approximately the distance of light travel starting at the big bang up until the present time. In this sense, the Hubble length is a rough estimate for the distance to the further most objects visible in the universe.) That is, one Hubble length marks precisely the distance at which the Schwarzschild radius $\bar{r}_s\equiv 2M$ of the mass $M$ inside a radial shock wave at distance $\bar{r}$ from the FRW center, crosses from inside ($\bar{r}_s<\bar{r}$) to outside ($\bar{r}_s>\bar{r}$) the shock wave. If the shock wave is at a distance closer than one Hubble length from the FRW center, then $2M<\bar{r}$ and we say that the solution lies outside the black hole, but if the shock wave is at a distance greater than one Hubble length, then $2M>\bar{r}$ at the shock, and we say that the solution lies "inside" the black hole. Since $M$ increases like $\bar{r}^3$, it follows that $2M<\bar{r}$ for $\bar{r}$ sufficiently small, and $2M>\bar{r}$ for $\bar{r}$ sufficiently large, so there must be a critical radius at which $2M=\bar{r}$, and we show in what follows (see also Smoller and Temple (2003)) that when $k=0$, this critical radius is exactly the Hubble length. When the parameter $r_*=0$, the family of solutions for $0<\sigma\leq 1$ starts at the big bang, and evolves thereafter

"outside" the black hole, satisfying $2M/\bar{r} < 1$ everywhere from $t = 0$ onward. But, when $r_* > 0$, the shock wave is further out than one Hubble length at the instant of the big bang, and the solution begins with $2M/\bar{r} > 1$ at the shock wave. From this time onward, the spacetime expands until eventually the Hubble length catches up to the shock wave at $2M/\bar{r} = 1$, and then passes the shock wave, making $2M/\bar{r} < 1$ thereafter. Thus, when $r_* > 0$, the whole spacetime begins inside the black hole (with $2M/\bar{r} > 1$ for sufficiently large $\bar{r}$), but eventually evolves to a solution outside the black hole. The time when $\bar{r} = 2M$ actually marks the event horizon of a white hole (the time reversal of a black hole) in the ambient spacetime beyond the shock wave. We show that, when $r_* > 0$, the time when the Hubble length catches up to the shock wave comes after the time when the shock wave comes into view at the FRW center, and when $2M = \bar{r}$ (assuming $t$ is so large that we can neglect the pressure from this time onward), the whole solution emerges from the white hole as a finite ball of mass expanding into empty space, satisfying $2M/\bar{r} < 1$ everywhere thereafter. In fact, when $r_* > 0$, the zero pressure Oppenheimer–Snyder solution outside the black hole gives the large-time asymptotics of the solution (Oppenheimer and Snyder 1939, Smoller and Temple 1988, 2004 and the comments after Theorems 6–8 below).

The exact solutions in the case $r_* = 0$ give a general-relativistic version of an explosion into a static, singular, isothermal sphere of gas, qualitatively similar to the corresponding classical explosion outside the black hole (Smoller and Temple 1995). The main difference physically between the cases $r_* > 0$ and $r_* = 0$ is that, when $r_* > 0$ (the case when the shock wave emerges from the big bang at a distance beyond one Hubble length), a large region of uniform expansion is created behind the shock wave at the instant of the big bang. Thus, when $r_* > 0$, lightlike information about the shock wave propagates inward from the wave, rather than outward from the center, as is the case when $r_* = 0$ and the shock lies inside one Hubble length. (One can imagine that when $r_* > 0$, the shock wave can get out through a great deal of matter early on when everything is dense and compressed, and still not violate the speed of light bound. Thus, when $r_* > 0$, the shock wave "thermalizes," or more accurately "makes uniform," a large region at the center, early on in the explosion.) It follows that, when $r_* > 0$, an observer positioned in the FRW spacetime inside the shock wave will see exactly what the standard model of cosmology predicts, up until the time when the shock wave comes into view in the far field. In this sense, the case $r_* > 0$ gives a black hole cosmology that refines the standard FRW model of cosmology to the case of finite mass. One of the surprising differences between the case $r_* = 0$ and the case $r_* > 0$ is that, when $r_* > 0$, the important equation of state $p = \rho/3$ comes out of the analysis as special at the big bang. When $r_* > 0$, the shock wave emerges at the instant of the big bang at a finite nonzero speed (the speed of light) only for the special value $\sigma = 1/3$. In this case, the equation of state on both sides of the shock wave tends to the correct relation $p = \rho/3$ as $t \to 0$, and the shock wave decelerates to subluminous speed for all positive times thereafter (see Smoller and Temple (2003) and Theorem 8 below).

In all cases $0 < \sigma \leq 1$, $r_* \geq 0$, the spacetime metric that lies beyond the shock wave is taken to be a metric of Tolmann–Oppenheimer–Volkoff (TOV) form (Oppenheimar and Volkoff 1939):

$$ds^2 = -B(\bar{r})d\bar{t}^2 + A^{-1}(\bar{r})d\bar{r}^2 + \bar{r}^2[d\theta^2 + \sin^2\theta\, d\phi^2] \quad [2]$$

The metric [2] is in standard Schwarzschild coordinates (diagonal with radial coordinate equal to the area of the spheres of symmetry), and the metric components depend only on the radial coordinate $\bar{r}$. Barred coordinates are used to distinguish TOV coordinates from unbarred FRW coordinates for shock matching. The mass function $M(\bar{r})$ enters as a metric component through the relation

$$A = 1 - \frac{2M(\bar{r})}{\bar{r}} \quad [3]$$

The TOV metric [2] has a very different character depending on whether $A > 0$ or $A < 0$; that is, depending on whether the solution lies outside the black hole or inside the black hole. In the case $A > 0$, $\bar{r}$ is a spacelike coordinate, and the TOV metric describes a static fluid sphere in general relativity. (When $A > 0$, for example, the metric [2] is the starting point for the stability limits of Buchdahl and Chandresekhar for stars (Weinberg 1972, Smoller and Temple 1997, 1998).) When $A < 0$, $\bar{r}$ is the timelike coordinate, and [2] is a dynamical metric that evolves in time. The exact shock wave solutions are obtained by taking $\bar{r} = R(t)r$ to match the spheres of symmetry, and then matching the metrics [1] and [2] at an interface $\bar{r} = \bar{r}(t)$ across which the metrics are Lipschitz continuous. This can be done in general. In order for the interface to be a physically meaningful shock surface, we use the result in Theorem 4 below (see Smoller and Temple (1994)) that a single additional conservation constraint is sufficient to rule out $\delta$-function sources at the shock (the Einstein equations $G = \kappa T$ are second order in the metric, and

so $\delta$-function sources will in general be present at a Lipschitz continuous matching of metrics), and guarantee that the matched metric solves the Einstein equations in the weak sense. The Lipschitz matching of the metrics, together with the conservation constraint, leads to a system of ordinary differential equations (ODEs) that determine the shock position, together with the TOV density and pressure at the shock. Since the TOV metric depends only on $\bar{r}$, the equations thus determine the TOV spacetime beyond the shock wave. To obtain a physically meaningful outgoing shock wave, we impose the constriant $\bar{p} \leq \bar{\rho}$ to ensure that the equation of state on the TOV side of the shock is physically reasonable, and as the entropy condition we impose the condition that the shock be compressive. For an outgoing shock wave, this is the condition $\rho > \bar{\rho}$, $p > \bar{p}$, that the pressure and density be larger on the side of the shock that receives the mass flux – the FRW side when the shock wave is propagating away from the FRW center. This condition breaks the time-reversal symmetry of the equations, and is sufficient to rule out rarefaction shocks in classical gas dynamics (Smoller 1983, Smoller and Temple 2003). The ODEs, together with the equation-of-state bound and the conservation and entropy constraints, determine a unique solution of the ODEs for every $0 < \sigma \leq 1$ and $\bar{r}_* \geq 0$, and this provides the two-parameter family of solutions discussed here (Smoller and Temple 1995, 2003). The Lipschitz matching of the metrics implies that the total mass $M$ is continuous across the interface, and so when $r_* > 0$, the total mass of the entire solution, inside and outside the shock wave, is finite at each time $t > 0$, and both the FRW and TOV spacetimes emerge at the big bang. The total mass $M$ on the FRW side of the shock has the meaning of total mass inside the radius $\bar{r}$ at fixed time, but on the TOV side of the shock, $M$ does not evolve according to equations that give it the interpretation as a total mass because the metric is inside the black hole. Nevertheless, after the spacetime emerges from the black hole, the total mass takes on its usual meaning outside the black hole, and time asymptotically the big bang ends with an expansion of finite total mass in the usual sense. Thus, when $r_* > 0$, our shock wave refinement of the FRW metric leads to a big bang of finite total mass.

A final comment is in order regarding our overall philosophy. The family of exact shock wave solutions described here are rough models in the sense that the equation of state on the FRW side satisfies the condition $\sigma = \text{const.}$, and the equation of state on the TOV side is determined by the equations, and therefore cannot be imposed. Nevertheless, the bounds on the equations of state imply that the equations of state are qualitatively reasonable, and we expect that this family of solutions will capture the gross dynamics of solutions when more general equations of state are imposed. For more general equations of state, other waves, such as rarefaction waves and entropy waves, would need to be present to meet the conservation constraint, and thereby mediate the transition across the shock wave. Such transitional waves would be very difficult to model in an exact solution. But, the fact that we can find global solutions that meet our physical bounds, and that are qualitatively the same for all values of $\sigma \in (0,1]$ and all initial shock positions, strongly suggests that such a shock wave would be the dominant wave in a large class of problems.

In the next section, the FRW solution is derived for the case $\sigma = \text{const.}$, and the Hubble length is discussed as a critical length scale. Subsequently, the general theorems in Smoller and Temple (1994) for matching gravitational metrics across shock waves are employed. This is followed by a discussion of the construction of the family of solutions in the case $r_* = 0$. Finally, the case $r_* > 0$ is discussed. (Details can be found in Smoller and Temple (1995, 2003, 2004).)

## The FRW Metric

According to Einstein's theory of general relativity, all properties of the gravitational field are determined by a Lorentzian spacetime metric tensor $g$, whose line element in a given coordinate system $x = (x^0, \ldots, x^3)$ is given by

$$ds^2 = g_{ij} dx^i dx^j \tag{4}$$

(We use the Einstein summation convention, whereby repeated up–down indices are assumed summed from 0 to 3.) The components $g_{ij}$ of the gravitational metric $g$ satisfy the Einstein equations

$$G^{ij} = \kappa T^{ij}, \quad T^{ij} = (\rho c^2 + p) w^i w^j + p g^{ij} \tag{5}$$

where we assume that the stress-energy tensor $T$ corresponds to that of a perfect fluid. Here $G$ is the Einstein curvature tensor,

$$\kappa = \frac{8\pi\mathcal{G}}{c^4} \tag{6}$$

is the coupling constant, $\mathcal{G}$ is Newton's gravitational constant, $c$ is the speed of light, $\rho c^2$ is the energy density, $p$ is the pressure, and $\boldsymbol{w} = (w^0, \ldots, w^3)$ are the components of the 4-velocity of the fluid (cf. Weinberg 1972), and again we use the convention that $c = 1$ and $\mathcal{G} = 1$ when convenient.

Putting the metric ansatz [1] into the Einstein equations [5] gives the equations for the FRW metric (Weinberg 1972),

$$H^2 = \left(\frac{\dot{R}}{R}\right)^2 = \frac{\kappa}{3}\rho - \frac{k}{R^2} \qquad [7]$$

and

$$\dot{\rho} = -3(p+\rho)H \qquad [8]$$

The unknown quantities $R$, $\rho$, and $p$ are assumed to be functions of the FRW coordinate time $t$ alone, and the "dot" denotes differentiation with respect to $t$.

To verify that the Hubble length $\bar{r}_{\mathrm{crit}} = 1/H$ is the limit for FRW–TOV shock matching outside a black hole, write the FRW metric [1] in standard Schwarzschild coordinates $x = (\bar{r}, \bar{t})$, where the metric takes the form

$$\mathrm{d}s^2 = -B(\bar{r}, \bar{t})\mathrm{d}\bar{t}^2 + A(\bar{r}, \bar{t})^{-1}\mathrm{d}\bar{r}^2 + \bar{r}^2\mathrm{d}\Omega^2 \qquad [9]$$

and the mass function $M(\bar{r}, \bar{t})$ is defined through the relation

$$A = 1 - \frac{2M}{\bar{r}} \qquad [10]$$

It is well known that a general spherically symmetric metric can be transformed to the form [9] by coordinate transformation (see Weinberg (1972) and Groah and Temple (2004)). Substituting $\bar{r} = Rr$ into [1] and diagonalizing the resulting metric, we obtain (see Smoller and Temple (2004) for details)

$$\mathrm{d}s^2 = -\frac{1}{\psi^2}\left\{\frac{1-kr^2}{1-kr^2-H^2\bar{r}^2}\right\}\mathrm{d}\bar{t}^2 + \left\{\frac{1}{1-kr^2-H^2\bar{r}^2}\right\}\mathrm{d}\bar{r}^2 + \bar{r}^2\mathrm{d}\Omega^2 \qquad [11]$$

where $\psi$ is an integrating factor that solves the equation

$$\frac{\partial}{\partial \bar{r}}\left(\psi\frac{1-kr^2-H^2\bar{r}^2}{1-kr^2}\right) - \frac{\partial}{\partial t}\left(\psi\frac{H\bar{r}}{1-kr^2}\right) = 0 \qquad [12]$$

and the time coordinate $\bar{t} = \bar{t}(t, \bar{r})$ is defined by the exact differential

$$\mathrm{d}\bar{t} = \left(\psi\frac{1-kr^2-H^2\bar{r}^2}{1-kr^2}\right)\mathrm{d}t + \left(\psi\frac{H\bar{r}}{1-kr^2}\right)\mathrm{d}\bar{r} \qquad [13]$$

Now using [10] in [7], it follows that

$$M(t, \bar{r}) = \frac{\kappa}{2}\int_0^{\bar{r}} \rho(t)s^2\mathrm{d}s = \frac{1}{3}\frac{\kappa}{2}\rho\bar{r}^3 \qquad [14]$$

Since in the FRW metric, $\bar{r} = Rr$ measures arclength along radial geodesics at fixed time, we see from [14] that $M(t, \bar{r})$ has the physical interpretation as the total mass inside radius $\bar{r}$ at time $t$ in the FRW metric. Restricting to the case of critical expansion $k = 0$, we see from [7], [14], and [13] that $\bar{r} = H^{-1}$ is equivalent to $2M/\bar{r} = 1$, and so at fixed time $t$, the following equivalences are valid:

$$\bar{r} = H^{-1} \quad \text{iff} \quad \frac{2M}{\bar{r}} = 1 \quad \text{iff} \quad A = 0 \qquad [15]$$

We conclude that $\bar{r} = H^{-1}$ is the critical length scale for the FRW metric at fixed time $t$ in the sense that $A = 1 - 2M/\bar{r}$ changes sign at $\bar{r} = H^{-1}$, and so the universe lies inside a black hole beyond $\bar{r} = H^{-1}$, as claimed above. Now, we proved in Smoller and Temple (1998) that the standard TOV metric outside the black hole cannot be continued into $A = 0$ except in the very special case $\rho = 0$. (It takes an infinite pressure to hold up a static configuration at the event horizon of a black hole.) Thus, shock matching beyond one Hubble length requires a metric of a different character, and for this purpose, we introduce the TOV metric inside the black hole – a metric of TOV form, with $A < 0$, whose fluid is comoving with the timelike radial coordinate $\bar{r}$ (Smoller and Temple 2004).

The Hubble length $\bar{r}_{\mathrm{crit}} = c/H$ is also the critical distance at which the outward expansion of the FRW metric exactly cancels the inward advance of a radial light ray impinging on an observer positioned at the origin of a $k = 0$ FRW metric. Indeed, by [1], a light ray traveling radially inward toward the center of an FRW coordinate system satisfies the condition

$$c^2\,\mathrm{d}t^2 = R^2\,\mathrm{d}r^2 \qquad [16]$$

so that

$$\frac{\mathrm{d}\bar{r}}{\mathrm{d}t} = \dot{R}r + R\dot{r} = H\bar{r} - c = H\left(\bar{r} - \frac{c}{H}\right) > 0 \qquad [17]$$

if and only if

$$\bar{r} > \frac{c}{H}$$

Thus, the arclength distance from the origin to an inward moving light ray at fixed time $t$ in a $k = 0$ FRW metric will actually increase as long as the light ray lies beyond the Hubble length. An inward moving light ray will, however, eventually cross the Hubble length and reach the origin in finite proper time, due to the increase in the Hubble length with time.

We now calculate the infinite redshift limit in terms of the Hubble length. It is well known that light emitted at $(t_e, r_e)$ at wavelength $\lambda_e$ in an FRW spacetime will be observed at $(t_0, r_0)$ at wavelength $\lambda_0$ if

$$\frac{R_0}{R_e} = \frac{\lambda_0}{\lambda_e}$$

Moreover, the redshift factor $z$ is defined by

$$z = \frac{\lambda_0}{\lambda_e} - 1$$

Thus, infinite redshifting occurs in the limit $R_e \to 0$, where $R = 0, t = 0$ is the big bang. Consider now a light ray emitted at the instant of the big bang, and observed at the FRW origin at present time $t = t_0$. Let $r_\infty$ denote the FRW coordinate at time $t \to 0$ of the furthest objects that can be observed at the FRW origin before time $t = t_0$. Then $r_\infty$ marks the position of objects at time $t = 0$ whose radiation would be observed as infinitly redshifted (assuming no scattering). Note then that a shock wave emanating from $\bar{r} = 0$ at the instant of the big bang, will be observed at the FRW origin before present time $t = t_0$ only if its position $r$ at the instant of the big bang satisfies the condition $r < r_\infty$. To estimate $r_\infty$, note first that from [16] it follows that an incoming radial light ray in an FRW metric follows a lightlike trajectory $r = r(t)$ if

$$r - r_e = -\int_{t_e}^{t} \frac{d\tau}{R(\tau)}$$

and thus

$$r_\infty = \int_0^{t_0} \frac{d\tau}{R(\tau)} \qquad [18]$$

Using this, the following theorem can be proved (Smoller and Temple 2004).

**Theorem 1** *If the pressure p satisfies the bounds*

$$0 \le p \le \tfrac{1}{3}\rho \qquad [19]$$

*then, for any equation of state, the age of the universe $t_0$ and the infinite red shift limit $r_\infty$ are bounded in terms of the Hubble length by*

$$\frac{1}{2H_0} \le t_0 \le \frac{2}{3H_0} \qquad [20]$$

$$\frac{1}{H_0} \le r_\infty \le \frac{2}{H_0} \qquad [21]$$

(We have assumed in Theorem 1 that $R = 0$ when $t = 0$ and $R = 1$ when $t = t_0, H = H_0$.)

The next theorem gives closed-form solutions of the FRW equations [7], [8] in the case when $\sigma = \text{const.}$ As a special case, we recover the bounds in [20] and [21] from the cases $\sigma = 0$ and 1/3.

**Theorem 2** *Assume $k = 0$ and the equation of state*

$$p = \sigma\rho \qquad [22]$$

*where $\sigma$ is taken to be constant,*

$$0 \le \sigma \le 1$$

*then (assuming an expanding universe $\dot{R} > 0$), the solution of system [7], [8] satisfying $R = 0$ at $t = 0$ and $R = 1$ at $t = t_0$ is given by*

$$\rho = \frac{4}{3\kappa(1+\sigma)^2}\frac{1}{t^2} \qquad [23]$$

$$R = \left(\frac{t}{t_0}\right)^{2/[3(1+\sigma)]} \qquad [24]$$

$$\frac{H}{H_0} = \frac{t_0}{t} \qquad [25]$$

*Moreover, the age of the universe $t_0$ and the infinite red shift limit $r_\infty$ are given exactly in terms of the Hubble length by*

$$t_0 = \frac{2}{3(1+\sigma)}\frac{1}{H_0} \qquad [26]$$

$$r_\infty = \frac{2}{1+3\sigma}\frac{1}{H_0} \qquad [27]$$

From [27] we conclude that a shock wave will be observed at the FRW origin before present time $t = t_0$ only if its position $r$ at the instant of the big bang satisfies the condition

$$r < \frac{2}{1+3\sigma}\frac{1}{H_0}$$

Note that $r_\infty$ ranges from one-half to two Hubble lengths as $\sigma$ ranges from 1 to 0, taking the intermediate value of one Hubble length at $\sigma = 1/3$ (cf. [21]).

Note that using [23] and [24] in [14], it follows that

$$\begin{aligned} M &= \frac{\kappa}{2}\int_0^{\bar{r}} \rho(t)s^2 ds \\ &= \frac{2\bar{r}^3}{9(1+\sigma)^2 t_0^{2/(1+\sigma)}} t^{-2\sigma/(1+\sigma)} \end{aligned} \qquad [28]$$

so $\dot{M} < 0$ if $\sigma > 0$. It follows that if $p = \sigma\rho$, $\sigma = \text{const.} > 0$, then the total mass inside radius $r = \text{const.}$ decreases in time.

## The General Theory of Shock Matching

The matching of the FRW and TOV metrics in the next two sections is based on the following theorems that were derived in Smoller and Temple (1994) (Theorems 3 and 4 apply to non-lightlike shock surfaces. The lightlike case was discussed by Scott (2002).)

**Theorem 3** *Let $\Sigma$ denote a smooth, three-dimensional shock surface in spacetime with spacelike*

*normal vector* $\boldsymbol{n}$ *relative to the spacetime metric* $g$*; let* $K$ *denote the second fundamental form on* $\Sigma$*; and let* $G$ *denote the Einstein curvature tensor. Assume that the components* $g_{ij}$ *of the gravitational metric* $g$ *are smooth on either side of* $\Sigma$ *(continuous up to the boundary on either side separately), and Lipschitz continuous across* $\Sigma$ *in some fixed coordinate system. Then the following statements are equivalent*:

(*i*) $[K]=0$ *at each point of* $\Sigma$.
(*ii*) *The curvature tensors* $R^i_{jkl}$ *and* $G_{ij}$*, viewed as second-order operators on the metric components* $g_{ij}$*, produce no* $\delta$*-function sources on* $\Sigma$.
(*iii*) *For each point* $P\in\Sigma$*, there exists a* $C^{1,1}$ *coordinate transformation defined in a neighborhood of* $P$*, such that, in the new coordinates (which can be taken to be the Gaussian normal coordinates for the surface), the metric components are* $C^{1,1}$ *functions of these coordinates.*
(*iv*) *For each* $P\in\Sigma$*, there exists a coordinate frame that is locally Lorentzian at* $P$*, and can be reached within the class of* $C^{1,1}$ *coordinate transformations.*

*Moreover, if any one of these equivalencies hold, then the Rankine–Hugoniot jump conditions,* $[G]^{\sigma}_{i}n_{\sigma}=0$ *(which express the weak form of conservation of energy and momentum across* $\Sigma$ *when* $G=\kappa T$*), hold at each point on* $\Sigma$.

Here $[f]$ denotes the jump in the quantity $f$ across $\Sigma$ (this being determined by the metric separately on each side of $\Sigma$ because $g_{ij}$ is only Lipschitz continuous across $\Sigma$), and by $C^{1,1}$ we mean that the first derivatives are Lipschitz continuous.

In the case of spherical symmetry, the following stronger result holds. In this case, the jump conditions $[G^{ij}]n_i=0$, which express the weak form of conservation across a shock surface, are implied by a single condition $[G^{ij}]n_in_j=0$, so long as the shock is non-null, and the areas of the spheres of symmetry match smoothly at the shock and change monotonically as the shock evolves. Note that, in general, assuming that the angular variables are identified across the shock, we expect conservation to entail two conditions, one for the time and one for the radial components. The fact that the smooth matching of the spheres of symmetry reduces conservation to one condition can be interpreted as an instance of the general principle that directions of smoothness in the metric imply directions of conservation of the sources.

**Theorem 4** *Assume that* $g$ *and* $\bar{g}$ *are two spherically symmetric metrics that match Lipschitz continuously across a three-dimensional shock interface* $\Sigma$ *to form the matched metric* $g\cup\bar{g}$*. That is, assume that* $g$ *and* $\bar{g}$ *are Lorentzian metrics given by*

$$\mathrm{d}s^2=-a(t,r)\mathrm{d}t^2+b(t,r)\mathrm{d}r^2+c(t,r)\mathrm{d}\Omega^2 \qquad [29]$$

*and*

$$\mathrm{d}\bar{s}^2=-\bar{a}(\bar{t},\bar{r})\mathrm{d}\bar{t}^2+\bar{b}(\bar{t},\bar{r})\mathrm{d}\bar{r}^2+\bar{c}(\bar{t},\bar{r})\mathrm{d}\Omega^2 \qquad [30]$$

*and that there exists a smooth coordinate transformation* $\Psi:(t,r)\to(\bar{t},\bar{r})$*, defined in a neighborhood of a shock surface* $\Sigma$ *given by* $r=r(t)$*, such that the metrics agree on* $\Sigma$*. (We implicitly assume that* $\theta$ *and* $\varphi$ *are continuous across the surface.) Assume that*

$$c(t,r)=\bar{c}(\Psi(t,r)) \qquad [31]$$

*in an open neighborhood of the shock surface* $\Sigma$*, so that, in particular, the areas of the 2-spheres of symmetry in the barred and unbarred metrics agree on the shock surface. Assume also that the shock surface* $r=r(t)$ *in unbarred coordinates is mapped to the surface* $\bar{r}=\bar{r}(\bar{t})$ *by* $(\bar{t},\bar{r}(\bar{t}))=\Psi(t,r(t))$*. Assume, finally, that the normal* $\boldsymbol{n}$ *to* $\Sigma$ *is non-null, and that*

$$\boldsymbol{n}(c)\neq 0 \qquad [32]$$

*where* $\boldsymbol{n}(c)$ *denotes the derivative of the function* $c$ *in the direction of the vector* $\boldsymbol{n}$*. Then the following are equivalent to the statement that the components of the metric* $g\cup\bar{g}$ *in any Gaussian normal coordinate system are* $C^{1,1}$ *functions of these coordinates across the surface* $\Sigma$:

$$[G^i_j]n_i=0 \qquad [33]$$

$$[G^{ij}]n_in_j=0 \qquad [34]$$

$$[K]=0 \qquad [35]$$

*Here again,* $[f]=\bar{f}-f$ *denotes the jump in the quantity* $f$ *across* $\Sigma$*, and* $K$ *is the second fundamental form on the shock surface.*

We assume in Theorem 4 that the areas of the 2-spheres of symmetry change monotonically in the direction normal to the surface. For example, if $c=r^2$, then $\partial c/\partial t=0$, so the assumption $\boldsymbol{n}(c)\neq 0$ is valid except when $\boldsymbol{n}=\partial/\partial t$, in which case the rays of the shock surface would be spacelike. Thus, the shock speed would be faster than the speed of light if our assumption $\boldsymbol{n}(c)\neq 0$ failed in the case $c=r^2$.

## FRW–TOV Shock Matching Outside the Black Hole – The Case $r_*=0$

To construct the family of shock wave solutions for parameter values $0<\sigma\leq 1$ and $r_*=0$, we match the exact solution [23]–[25] of the FRW metric [1] to the TOV metric [2] outside the black hole,

assuming $A > 0$. In this case, we can bypass the problem of deriving and solving the ODEs for the shock surface and constraints discussed above, by actually deriving the exact solution of the Einstein equations of TOV form that meets these equations. This exact solution represents the general-relativistic version of a static, singular isothermal sphere – singular because it has an inverse square density profile, and isothermal because the relationship between the density and pressure is $\bar{p} = \bar{\sigma}\bar{\rho}$, $\bar{\sigma} = \text{const}$.

Assuming the stress tensor for a perfect fluid, and assuming that the density and pressure depend only on $\bar{r}$, the Einstein equations for the TOV metric [2] outside the black hole (i.e., when $A = 1 - 2M/\bar{r} > 0$) are equivalent to the Oppenheimer–Volkoff system

$$\frac{dM}{d\bar{r}} = 4\pi\bar{r}^2\bar{\rho} \qquad [36]$$

$$-\bar{r}^2\frac{d}{d\bar{r}}\bar{p} = \mathcal{G}M\bar{\rho}\left\{1 + \frac{\bar{p}}{\bar{\rho}}\right\} \times \left\{1 + \frac{4\pi\bar{r}^3\bar{p}}{M}\right\}\left\{1 - \frac{2\mathcal{G}M}{\bar{r}}\right\}^{-1} \qquad [37]$$

Integrating [36], we obtain the usual interpretation of $M$ as the total mass inside radius $\bar{r}$,

$$M(\bar{r}) = \int_0^{\bar{r}} 4\pi\xi^2\bar{\rho}(\xi)d\xi \qquad [38]$$

The metric component $B \equiv B(\bar{r})$ is determined from $\bar{\rho}$ and $M$ through the equation

$$\frac{B'(\bar{r})}{B} = -2\frac{\bar{p}'(\bar{r})}{\bar{p} + \bar{\rho}} \qquad [39]$$

Assuming

$$\bar{p} = \bar{\sigma}\bar{\rho}, \qquad \bar{\rho}(\bar{r}) = \frac{\gamma}{\bar{r}^2} \qquad [40]$$

for some constants $\bar{\sigma}$ and $\gamma$, and substituting into [3], we obtain

$$M(\bar{r}) = 4\pi\gamma\bar{r} \qquad [41]$$

Putting [40] and [41] into [37] and simplifying yields the identity

$$\gamma = \frac{1}{2\pi\mathcal{G}}\left(\frac{\bar{\sigma}}{1 + 6\bar{\sigma} + \bar{\sigma}^2}\right) \qquad [42]$$

From [38] we obtain

$$A = 1 - 8\pi\mathcal{G}\gamma < 1 \qquad [43]$$

Applying [39] leads to

$$B = B_0\left(\frac{\bar{\rho}}{\bar{\rho}_0}\right)^{-2\bar{\sigma}/(1+\bar{\sigma})} = B_0\left(\frac{\bar{r}}{\bar{r}_0}\right)^{4\bar{\sigma}/(1+\bar{\sigma})} \qquad [44]$$

By rescaling the time coordinate, we can take $B_0 = 1$ at $\bar{r}_0 = 1$, in which case [44] reduces to

$$B = \bar{r}^{4\bar{\sigma}/(1+\bar{\sigma})} \qquad [45]$$

We conclude that when [42] holds, [40]–[43] and [44] provide an exact solution of the Einstein field equations of TOV type, for each $0 \le \bar{\sigma} \le 1$. (In this case, an exact solution of TOV type was first found by Tolman (1939), and rediscovered in the case $\bar{\sigma} = 1/3$ by Misner and Zapolsky (cf. Weinberg (1972 p. 320)).) By [43], these solutions are defined outside the black hole, since $2M/\bar{r} < 1$. When $\bar{\sigma} = 1/3$, [42] yields $\gamma = 3/56\pi\mathcal{G}$ (cf. Weinberg (1972, equation (11.4.13))).

To match the FRW exact solution [23]–[25] with equation of state $p = \sigma\rho$ to the TOV exact solution [40]–[45] with equation of state $\bar{p} = \bar{\sigma}\bar{\rho}$ across a shock interface, we first set $\bar{r} = Rr$ to match the spheres of symmetry, and then match the timelike and spacelike components of the corresponding metrics in standard Schwarzschild coordinates. The matching of the $d\bar{r}^2$ coefficient $A^{-1}$ yields the conservation of mass condition that implicitly gives the shock surface $\bar{r} = \bar{r}(t)$,

$$M(\bar{r}) = \frac{4\pi}{3}\rho(t)\bar{r}^3 \qquad [46]$$

Using this together with [41] gives the following two relations that hold at the shock surface:

$$\bar{r} = \sqrt{\frac{3\gamma}{\rho(t)}}$$

$$\rho = \frac{3}{4\pi}\frac{M}{\bar{r}(t)^3} = \frac{3\gamma}{\bar{r}(t)^2} = 3\bar{\rho} \qquad [47]$$

Matching the coefficient $B$ of $d\bar{t}^2$ on the shock surface determines the integrating factor $\psi$ in a neighborhood of the shock surface by assigning initial conditions for [44]. Finally, the conservation constraint $[T_{ij}]n_i n_j = 0$ leads to the single condition

$$0 = (1 - A)(\rho + \bar{p})(p + \bar{\rho})^2 + \left(1 - \frac{1}{A}\right)(\bar{\rho} + \bar{p})(\rho + p)^2 + (p - \bar{p})(\rho - \bar{\rho})^2 \qquad [48]$$

which upon using $p = \sigma\rho$ and $\bar{p} = \bar{\sigma}\bar{\rho}$ is satisfied assuming the condition

$$\bar{\sigma} = \tfrac{1}{2}\sqrt{9\sigma^2 + 54\sigma + 49} - \tfrac{3}{2}\sigma - \tfrac{7}{2} \equiv H(\sigma) \qquad [49]$$

Alternatively, we can solve for $\sigma$ in [49] and write this relation as

$$\sigma = \frac{\bar{\sigma}(\bar{\sigma} + 7)}{3(1 - \bar{\sigma})} \qquad [50]$$

This guarantees that conservation holds across the shock surface, and so it follows from Theorem 4 that all of the equivalencies in Theorem 3 hold across the shock surface. Note that $H(0) = 0$, and to leading order $\bar{\sigma} = (3\sigma/7) + O(\sigma^2)$ as $\sigma \to 0$. Within the physical region $0 \le \sigma, \bar{\sigma} \le 1, H'(\sigma) > 0, \bar{\sigma} < \sigma$, and $H(1/3) = \sqrt{17} - 4 \approx 0.1231, H(1) = \sqrt{112}/2 - 5 \approx 0.2915$.

Using the exact formulas for the FRW metric in [23]–[25], and setting $R_0 = 1$ at $\rho = \rho_0, t = t_0$, we obtain the following exact formulas for the shock position:

$$\bar{r}(t) = \alpha t \tag{51}$$

$$r(t) = \bar{r}(t)R(t)^{-1} = \beta t^{(1+3\sigma)/(3+3\sigma)} \tag{52}$$

where

$$\alpha = 3(1+\sigma)\sqrt{\frac{\bar{\sigma}}{1+6\bar{\sigma}+\bar{\sigma}^2}}$$
$$\beta = \alpha^{(1+3\sigma)/(3+3\sigma)}\left(\frac{3\gamma}{\rho_0}\right)^{1/(3+3\sigma)} \tag{53}$$

It follows from [41] that $A > 0$, and from [52] that $r_* = \lim_{t\to 0} r(t) = 0$. The entropy condition that the shock wave be compressive follows from the fact that $\bar{\sigma} = H(\sigma) < \sigma$. Thus, we conclude that for each $0 < \sigma \le 1, r_* = 0$, the solutions constructed in [40]–[53] define a one-parameter family of shock wave solutions that evolve everywhere outside the black hole, which implies that the distance from the shock wave to the FRW center is less than one Hubble length for all $t > 0$.

Using [51] and [52], one can determine the shock speed, and check when the Lax characteristic condition (Smoller 1983) holds at the shock. The result is the following theorem. (Note that even when the shock speed is larger than $c$, only the wave, and not the sound speeds or any other physical motion, exceeds the speed of light. See Scott (2002) for the case when the shock speed is equal to the speed of light.) The reader is referred to Smoller and Temple (1995) for details.

**Theorem 5** *There exist values* $0 < \sigma_1 < \sigma_2 < 1$, $(\sigma_1 \approx 0.458, \sigma_2 = \sqrt{5}/3 \approx 0.745)$, *such that, for* $0 < \sigma \le 1$, *the Lax characteristic condition holds at the shock if and only if* $0 < \sigma < \sigma_1$; *and the shock speed is less than the speed of light if and only if* $0 < \sigma < \sigma_2$.

The explicit solution in the case $r_* = 0$ can be interpreted as a general-relativistic version of a shock wave explosion into a static, singular, isothermal sphere, known in the Newtonian case as a simple model for star formation (Smoller and Temple 2000). As the scenario goes, a star begins as a diffuse cloud of gas. The cloud slowly contracts under its own gravitational force by radiating energy out through the gas cloud as gravitational potential energy is converted into kinetic energy. This contraction continues until the gas cloud reaches the point where the mean free path for transmission of light is small enough that light is scattered, instead of being transmitted, through the cloud. The scattering of light within the gas cloud has the effect of equalizing the temperature within the cloud, and at this point the gas begins to drift toward the most compact configuration of the density that balances the pressure when the equation of state is isothermal. This configuration is a static, singular, isothermal sphere, the general-relativistic version of which is the exact TOV solution beyond the shock wave when $r_* = 0$. This solution in the Newtonian case is also inverse square in the density and pressure, and so the density tends to infinity at the center of the sphere. Eventually, the high densities at the center ingnite thermonuclear reactions. The result is a shock wave explosion emanating from the center of the sphere, and this signifies the birth of the star. The exact solutions when $r_* = 0$ represent a general-relativistic version of such a shock wave explosion.

## Shock Wave Solutions Inside the Black Hole – The Case $r_* > 0$

When the shock wave is beyond one Hubble length from the FRW center, we obtain a family of shock wave solutions for each $0 < \sigma \le 1$ and $r_* > 0$ by shock matching the FRW metric [1] to a TOV metric of form [2] under the assumption that

$$A(\bar{r}) = 1 - \frac{2M(\bar{r})}{\bar{r}} \equiv 1 - N(\bar{r}) < 0 \tag{54}$$

In this case, $\bar{r}$ is the timelike variable. Assuming that the stress tensor $T$ is taken to be that of a perfect fluid comoving with the TOV metric, the Einstein equations $G = \kappa T$, inside the black hole, take the form (see Smoller and Temple (2004) for details)

$$\bar{p}' = \frac{\bar{p}+\bar{\rho}}{2}\frac{N'}{N-1} \tag{55}$$

$$N' = -\left\{\frac{N}{\bar{r}} + \kappa\bar{p}\bar{r}\right\} \tag{56}$$

$$\frac{B'}{B} = -\frac{1}{N-1}\left\{\frac{N}{\bar{r}} + \kappa\bar{\rho}\right\} \tag{57}$$

The system [55]–[57] defines the simplest class of gravitational metrics that contain matter, evolve inside the black hole, and such that the mass function $M(\bar{r}) < \infty$ at each fixed time $\bar{r}$. System [55]–[57] for $A < 0$ differs substantially from the TOV equations for $A > 0$ because, for example, the energy density $T^{00}$ is equated with the timelike component $G^{rr}$ when $A < 0$, but with $G^{tt}$ when $A > 0$. In particular, this implies that, inside the black hole, the mass function $M(\bar{r})$ does not have the interpretation as a total mass inside the radius $\bar{r}$ as it does outside the black hole.

Equations [56], [57] do not have the same character as [54], [55] and the relation $\bar{p} = \bar{\sigma}\bar{\rho}$ with $\bar{\sigma} = \text{const.}$ is inconsistent with [56], [57] together with the conservation constraint and the FRW assumption $p = \sigma\rho$ for shock matching. Thus, instead of looking for an exact solution of [56], [57] ahead of time, as in the case $r_* = 0$, we assume the FRW solution [23]–[25], and derive the ODEs that describe the TOV metrics that match this FRW metric Lipschitz-continuously across a shock surface, and then impose the conservation, entropy, and equation of state constraints at the end. Matching a given $k = 0$ FRW metric to a TOV metric inside the black hole across a shock interface leads to the system of ODEs, (see Smoller and Temple (2004) for details),

$$\frac{\mathrm{d}u}{\mathrm{d}N} = -\left\{\frac{(1+u)}{2(1+3u)N}\right\} \times \left\{\frac{(3u-1)(\sigma-u)N + 6u(1+u)}{(\sigma-u)N + (1+u)}\right\} \qquad [58]$$

$$\frac{\mathrm{d}\bar{r}}{\mathrm{d}N} = -\frac{1}{1+3u}\frac{\bar{r}}{N} \qquad [59]$$

with conservation constraint

$$v = \frac{-\sigma(1+u) + (\sigma-u)N}{(1+u) + (\sigma-u)N} \qquad [60]$$

where

$$u = \frac{\bar{p}}{\rho}, \quad v = \frac{\bar{\rho}}{\rho}, \quad \sigma = \frac{p}{\rho} \qquad [61]$$

Here $\rho$ and $p$ denote the (known) FRW density and pressure, and all variables are evaluated at the shock. Solutions of [58]–[60] determine the (unknown) TOV metrics that match the given FRW metric Lipschitz-continuously across a shock interface, such that conservation of energy and momentum hold across the shock, and such that there are no $\delta$-function sources at the shock (Israel 1966, Smoller and Temple 1997). Note that the dependence of [58]–[60] on the FRW metric is only through the variable $\sigma$, and so the advantage of taking $\sigma = \text{const.}$ is that the whole solution is determined by the inhomogeneous scalar equation [58] when $\sigma = \text{const.}$ We take as the entropy constraint the condition that

$$0 < \bar{p} < p, \qquad 0 < \bar{\rho} < \rho \qquad [62]$$

and to insure a physically reasonable solution, we impose the equation of state constriant on the TOV side of the shock (this is equivalent to the dominant energy condition (Blau and Guth 1987))

$$0 < \bar{p} < \bar{\rho} \qquad [63]$$

Condition [62] implies that outgoing shock waves are compressive. Inequalities [62] and [63] are both implied by the single condition (Smoller and Temple 2004),

$$\frac{1}{N} < \left(\frac{1-u}{1+u}\right)\left(\frac{\sigma-u}{\sigma+u}\right) \qquad [64]$$

Since $\sigma$ is constant, eqn [58] uncouples from [59], and thus solutions of system [58]–[60] are determined by the scalar nonautonomous equation [58]. Making the change of variable $S = 1/N$, which transforms the "big bang" $N \to \infty$ over to a rest point at $S \to 0$, we obtain

$$\frac{\mathrm{d}u}{\mathrm{d}S} = \left\{\frac{(1+u)}{2(1+3u)S}\right\} \times \left\{\frac{(3u-1)(\sigma-u) + 6u(1+u)S}{(\sigma-u) + (1+u)S}\right\} \qquad [65]$$

Note that the conditions $N > 1$ and $0 < \bar{p} < p$ restrict the domain of [65] to the region $0 < u < \sigma < 1, 0 < S < 1$. The next theorem gives the existence of solutions for $0 < \sigma \leq 1, r_* > 0$, inside the black hole (Smoller and Temple 2003).

**Theorem 6** *For every $\sigma$, $0 < \sigma < 1$, there exists a unique solution $u_\sigma(S)$ of [65], such that [64] holds on the solution for all $S, 0 < S < 1$, and on this solution, $0 < u_\sigma(S) < \bar{u}$, $\lim_{S\to 0} u_\sigma(S) = \bar{u}$, where*

$$\bar{u} = \mathrm{Min}\{1/3, \sigma\} \qquad [66]$$

*and*

$$\lim_{S\to 1} \bar{p} = 0 = \lim_{S\to 1} \bar{\rho} \qquad [67]$$

*For each of these solutions $u_\sigma(S)$, the shock position is determined by the solution of [59], which in turn is determined uniquely by an initial condition which can be taken to be the FRW radial position of the shock wave at the instant of the big bang,*

$$r_* = \lim_{S\to 0} r(S) > 0 \qquad [68]$$

Concerning the shock speed, we have

**Theorem 7** *Let $0 < \sigma < 1$. Then the shock wave is everywhere subluminous, that is, the shock speed $s_\sigma(S) \equiv s(u_\sigma(S)) < 1$ for all $0 < S \leq 1$, if and only if $\sigma \leq 1/3$.*

Concerning the shock speed near the big bang $S=0$, the following is true:

**Theorem 8** *The shock speed at the big bang $S=0$ is given by*

$$\lim_{S\to 0} s_\sigma(S) = 0, \quad \sigma < 1/3 \qquad [69]$$

$$\lim_{S\to 0} s_\sigma(S) = \infty, \quad \sigma > 1/3 \qquad [70]$$

$$\lim_{S\to 0} s_\sigma(S) = 1, \quad \sigma = 1/3 \qquad [71]$$

Theorem 8 shows that the equation of state $p=\rho/3$ plays a special role in the analysis when $r_* > 0$, and only for this equation of state does the shock wave emerge at the big bang at a finite nonzero speed, the speed of light. Moreover, [66] implies that in this case, the correct relation $\bar{p}/\bar{\rho}=\bar{\sigma}$ is also achieved in the limit $S \to 0$. The result [67] implies that (neglecting the pressure $p$ at this time onward), the solution continues to a $k=0$ Oppenheimer–Snyder solution outside the black hole for $S > 1$.

It follows that the shock wave will first become visible at the FRW center $\bar{r}=0$ at the moment $t=t_0, (R(t_0)=1)$, when the Hubble length $H_0^{-1}=H^{-1}(t_0)$ satisfies

$$\frac{1}{H_0} = \frac{1+3\sigma}{2} r_* \qquad [72]$$

where $r_*$ is the FRW position of the shock at the instant of the big bang. At this time, the number of Hubble lengths $\sqrt{N_0}$ from the FRW center to the shock wave at time $t=t_0$ can be estimated by

$$1 \leq \frac{2}{1+3\sigma} \leq \sqrt{N_0} \leq \frac{2}{1+3\sigma} e^{\sqrt{3\sigma}((1+3\sigma)/(1+\sigma))}$$

Thus, in particular, the shock wave will still lie beyond the Hubble length $1/H_0$ at the FRW time $t_0$ when it first becomes visible. Furthermore, the time $t_{\text{crit}} > t_0$ at which the shock wave will emerge from the white hole given that $t_0$ is the first instant at which the shock becomes visible at the FRW center, can be estimated by

$$\frac{2}{1+3\sigma} e^{\sigma/4} \leq \frac{t_{\text{crit}}}{t_0} \leq \frac{2}{1+3\sigma} e^{2\sqrt{3\sigma}/(1+\sigma)} \qquad [73]$$

for $0 < \sigma \leq 1/3$, and by the better estimate

$$e^{\sqrt{6}/4} \leq \frac{t_{\text{crit}}}{t_0} \leq e^{3/2} \qquad [74]$$

in the case $\sigma=1/3$. Inequalities [73], [74] imply, for example, that at the Oppenheimer–Snyder limit $\sigma=0$,

$$\sqrt{N_0} = 2, \qquad \frac{t_{\text{crit}}}{t_0} = 2$$

and in the limit $\sigma=1/3$,

$$1.8 \leq \frac{t_{\text{crit}}}{t_0} \leq 4.5, \qquad 1 < \sqrt{N_0} \leq 4.5$$

We can conclude that at the moment $t_0$ when the shock wave first becomes visible at the FRW center, the shock wave must lie within 4.5 Hubble lengths of the FRW center. Throughout the expansion up until this time, the expanding universe must lie entirely within a white hole – the universe will eventually emerge from this white hole, but not until some later time $t_{\text{crit}}$, where $t_{\text{crit}}$ does not exceed $4.5t_0$.

## Conclusion

We believe that the existence of a wave at the leading edge of the expansion of the galaxies is the most likely possibility. The alternatives are that either the universe of expanding galaxies goes on out to infinity, or else the universe is not simply connected. Although the first possibility has been believed for most of the history of cosmology based on the Friedmann universe, we find this implausible and arbitrary in light of the shock wave refinements of the FRW metric discussed here. The second possibility, that the universe is not simply connected, has received considerable attention recently (Klarreich 2003). However, since we have not seen, and cannot create, any non-simply-connected 3-spaces on any other length scale, and since there is no observational evidence to support this, we view this as less likely than the existence of a wave at the leading edge of the expansion of the galaxies, left over from the big bang. Recent analysis of the microwave background radiation data shows a cutoff in the angular frequencies consistent with a length scale of around one Hubble length (Andy Abrecht, private communication). This certainly makes one wonder whether this cutoff is evidence of a wave at this length scale, especially given the consistency of this possibility with the case $r_* > 0$ of the family of exact solutions discussed here.

# Short-Range Spin Glasses: The Metastate Approach

**C M Newman**, New York University, New York, NY, USA
**D L Stein**, University of Arizona, Tucson, AZ, USA

## Introduction

The nature of the low-temperature spin glass phase in short-range models remains one of the central problems in the statistical mechanics of disordered systems (Binder and Young 1986, Chowdhury 1986, Mézard *et al.* 1987, Stein 1989, Fischer and Hertz 1991, Dotsenko 2001, Newman and Stein 2003). While many of the basic questions remain unanswered, analytical and rigorous work over the past decade have greatly streamlined the number of possible scenarios for pure state structure and organization at low temperatures, and have clarified the thermodynamic behavior of these systems.

The unifying concept behind this work is that of the "metastate." It arose independently in two different constructions (Aizenman and Wehr 1990, Newman and Stein 1996b), which were later shown to be equivalent (Newman and Stein 1998a). The metastate is a probability measure on the space of all thermodynamic states. Its usefulness arises in situations where multiple "competing" pure states may be present. In such situations it may be difficult to construct individual states in a measurable and canonical way; the metastate avoids this difficulty by focusing instead on the statistical properties of the states.

An important aspect of the metastate approach is that it relates, by its very construction (Newman and Stein 1996b), the observed behavior of a system in large but finite volumes with its thermodynamic properties. It therefore serves as a (possibly indispensable) tool for analyzing and understanding both the infinite-volume and finite-volume properties of a system, particularly in cases where a straightforward interpolation between the two may be incorrect, or their relation otherwise difficult to analyze.

We will focus on the Edwards–Anderson (EA) Ising spin glass model (Edwards and Anderson

1975), although most of our discussion is relevant to a much larger class of realistic models. The EA model is described by the Hamiltonian

$$\mathcal{H}_{\mathcal{J}} = -\sum_{\langle x,y\rangle} J_{xy}\sigma_x\sigma_y \qquad [1]$$

where $\mathcal{J}$ denotes a particular realization of all of the couplings $J_{xy}$ and the brackets indicate that the sum is over nearest-neighbor pairs only, with $x, y \in \mathbf{Z}^d$. We will take Ising spins $\sigma_x = \pm 1$; although this will affect the details of our discussion, it is unimportant for our main conclusions. The couplings $J_{xy}$ are quenched, independent, identically distributed random variables whose common distribution $\mu$ is symmetric about zero.

## States and Metastates

We are interested in both finite-volume and infinite-volume Gibbs states. For the cube of length scale $L$, $\Lambda_L = \{-L, -L+1, \ldots, L\}^d$, we define $\mathcal{H}_{\mathcal{J},L}$ to be the restriction of the EA Hamiltonian to $\Lambda_L$ with a specified boundary condition such as free, fixed, or periodic. Then the finite-volume Gibbs distribution $\rho_{\mathcal{J}}^{(L)} = \rho_{\mathcal{J},\beta}^{(L)}$ on $\Lambda_L$ (at inverse temperature $\beta = 1/T$) is

$$\rho_{\mathcal{J},\beta}^{(L)}(\sigma) = Z_L^{-1}\exp\{-\beta\mathcal{H}_{\mathcal{J},L}(\sigma)\} \qquad [2]$$

where the partition function $Z_L(\beta)$ is such that the sum of $\rho_{\mathcal{J},\beta}^{(L)}$ over all $\sigma$ yields 1. (In this and all succeeding definitions, the dependence on spatial dimension $d$ will be suppressed.)

Thermodynamic states are described by infinite-volume Gibbs measures. At fixed inverse temperature $\beta$ and coupling realization $\mathcal{J}$, a thermodynamic state $\rho_{\mathcal{J},\beta}$ is the limit, as $L \to \infty$, of some sequence of such finite-volume measures (each with a specified boundary condition, which may remain the same or may change with $L$). A thermodynamic state $\rho_{\mathcal{J},\beta}$ can also be characterized intrinsically through the Dobrushin–Lanford–Ruelle (DLR) equations (see, e.g., Georgii 1988): for any $\Lambda_L$, the conditional distribution of $\rho_{\mathcal{J},\beta}$ (conditioned on the sigma-field generated by $\{\sigma_x : x \in \mathbf{Z}^d \backslash \Lambda_L\}$ is $\rho_{\mathcal{J},\beta}^{(L),\overline{\sigma}}$, where $\overline{\sigma}$ is given by the conditioned values of $\sigma_x$ for $x$ on the boundary of $\Lambda_L$.

Consider now the set $\mathcal{G} = \mathcal{G}(\mathcal{J},\beta)$ of all thermodynamic states at a fixed $(\mathcal{J},\beta)$. The set of extremal, or pure, Gibbs states is defined by

$$\text{ex}\,\mathcal{G} = \mathcal{G} \setminus \{a\rho_1 + (1-a)\rho_2 : \\ a \in (0,1);\ \rho_1, \rho_2 \in \mathcal{G};\ \rho_1 \neq \rho_2\} \qquad [3]$$

and the number of pure states $\mathcal{N}(\mathcal{J},\beta)$ at $(\mathcal{J},\beta)$ is the cardinality $|\text{ex}\,\mathcal{G}|$ of ex $\mathcal{G}$. It is not hard to show that, in any $d$ and for a.e. $\mathcal{J}$, the following two statements are true: (1) $\mathcal{N} = 1$ at sufficiently low $\beta > 0$; (2) at any fixed $\beta$, $\mathcal{N}$ is constant a.s. with respect to the $\mathcal{J}$'s. (The last assertion follows from the measurability and translation invariance of $\mathcal{N}$, and the translation ergodicity of the disorder distribution of $\mathcal{J}$.)

A pure state $\rho_\alpha$ (where $\alpha$ is a pure-state index) can also be intrinsically characterized by a "clustering property"; for two-point correlation functions, this reads

$$\langle\sigma_x\sigma_y\rangle_{\rho_\alpha} - \langle\sigma_x\rangle_{\rho_\alpha}\langle\sigma_y\rangle_{\rho_\alpha} \to 0 \qquad [4]$$

as $|x - y| \to \infty$. A simple observation (Newman and Stein 1992), with important consequences for spin glasses, is that if many pure states exist, a sequence of $\rho_{\mathcal{J},\beta}^{(L)}$'s, with boundary conditions and $L$'s chosen independently of $\mathcal{J}$, will generally not have a (single) limit. We call this phenomenon "chaotic size dependence" (CSD).

We will be interested in the properties of ex $\mathcal{G}$ at low temperatures. If the spin-flip symmetry present in the EA Hamiltonian equation [1] is spontaneously broken above some dimension $d_0$ and below some temperature $T_c(d)$, there will be at least a pair of pure states such that their even-spin correlations are identical and their odd-spin correlations have the opposite sign. Assuming that such broken spin-flip symmetry indeed exists for $d > d_0$ and $T < T_c(d)$, the question of whether there exists more than one such pair (of spin-flip related extremal infinite-volume Gibbs distributions) is a central unresolved issue for the EA and related models. If many such pairs should exist, we can ask about the structure of their relations with one another, and how this structure would manifest itself in large but finite volumes. To do this, we use an approach, introduced by Newman and Stein (1996b), to study inhomogeneous and other systems with many competing pure states. This approach, based on an analogy with chaotic dynamical systems, requires the construction of a new thermodynamic quantity which is called the "metastate" – a probability measure $\kappa_{\mathcal{J}}$ on the thermodynamic states. The metastate allows an understanding of CSD by analyzing the way in which $\rho_{\mathcal{J},\beta}^{(L)}$ "samples" from its various possible limits as $L \to \infty$.

The analogy with chaotic dynamical systems can be understood as follows. In dynamical systems, the chaotic motion along a deterministic orbit is analyzed in terms of some appropriately selected probability measure, invariant under the dynamics. Time along the orbit is replaced, in our context, by $L$ and the phase space of the dynamical system is replaced by the space of Gibbs states.

Newman and Stein (1996b) considered a "microcanonical ensemble" (as always, at fixed $\beta$, which will hereafter be suppressed for ease of notation) $\kappa_N$ in which each of the finite-volume Gibbs states

$\rho_{\mathcal{J}}^{(L_1)}, \rho_{\mathcal{J}}^{(L_2)}, \ldots, \rho_{\mathcal{J}}^{(L_N)}$ has weight $N^{-1}$. The ensemble $\kappa_N$ converges to a metastate $\kappa_{\mathcal{J}}$ as $N \to \infty$, in the following sense: for every (nice) function $g$ on states (e.g., a function of finitely many correlations),

$$\lim_{N\to\infty} N^{-1} \sum_{\ell=1}^{N} g(\rho^{(L_\ell)}) = \int g(\Gamma)\, \mathrm{d}\kappa_{\mathcal{J}}(\Gamma) \qquad [5]$$

The information contained in $\kappa_{\mathcal{J}}$ effectively specifies the fraction of cube sizes $L_\ell$ which the system spends in different (possibly mixed) thermodynamic states $\Gamma$ as $\ell \to \infty$.

A different, but in the end equivalent, approach based on $\mathcal{J}$-randomness is due to Aizenman and Wehr (1990). Here one considers the random pair $(\mathcal{J}, \rho_{\mathcal{J}}^{(L)})$, defined on the underlying probability space of $\mathcal{J}$, and takes the limit $\kappa^\dagger$ (with conditional distribution $\kappa_{\mathcal{J}}^\dagger$, given $\mathcal{J}$), via finite-dimensional distributions along some subsequence. The details are omitted here, and the reader is referred to the work by Aizenman and Wehr (1990) and Newman and Stein (1998a). We note, however, the important result that a "deterministic" subsequence of volumes can be found on which [5] is valid and also $(\mathcal{J}, \rho_{\mathcal{J}}^{(L)})$ converges, with $\kappa_{\mathcal{J}}^\dagger = \kappa_{\mathcal{J}}$ (Newman and Stein 1998a).

In what follows we use the term "metastate" as shorthand for the $\kappa_{\mathcal{J}}$ constructed using periodic boundary conditions on a sequence of volumes chosen independently of the couplings, and along which $\kappa_{\mathcal{J}} = \kappa_{\mathcal{J}}^\dagger$. We choose periodic boundary conditions for specificity; the results and claims discussed are expected to be independent of the boundary conditions used, as long as they are chosen independently of the couplings.

## Low-Temperature Structure of the EA Model

There have been several scenarios proposed for the spin-glass phase of the Edwards–Anderson model at sufficiently low temperature and high dimension. These remain speculative, because it has not even been proved that a phase transition from the high-temperature phase exists at positive temperature in any finite dimension.

As noted earlier, at sufficiently high temperature in any dimension (and at all nonzero temperatures in one and presumably two dimensions, although the latter assertion has not been proved), there is a unique Gibbs state. It is conceivable that this remains the case in all dimensions and at all nonzero temperatures, in which case the metastate $\kappa_{\mathcal{J}}$ is, for a.e. $\mathcal{J}$, supported on a single, pure Gibbs state $\rho_{\mathcal{J}}$. (It is important to note, however, that in principle such a trivial metastate could occur even if $\mathcal{N} > 1$; indeed, just such a situation of "weak uniqueness" (van Enter and Fröhlich 1985, Campanino *et al.* 1987) happens in very long range spin glasses at high temperatures (Fröhlich and Zegarlinski 1987, Gandolfi *et al.* 1993).)

A phase transition has been proved to exist (Aizenman *et al.* 1987) in the Sherrington–Kirkpatrick (SK) model (Sherrington and Kirkpatrick 1975), which is the infinite-range version of the EA model. Numerical (Ogielski 1985, Ogielski and Morgenstern 1985, Binder and Young 1986, Kawashima and Young 1996) and some analytical (Fisher and Singh 1990, Thill and Hilhorst 1996) work has led to a general consensus that above some dimension (typically around three or four) there does exist a positive-temperature phase transition below which spin-flip symmetry is broken, that is, in which pure states come in pairs, as discussed below eqn [4]. Because much of the literature has focused on this possibility, we assume it in what follows, and the metastate approach turns out to be highly useful in restricting the scenarios that can occur. The simplest such scenario is a two-state picture in which, below the transition temperature $T_c$, there exists a single pair of global flip-related pure states $\rho_{\mathcal{J}}^{\alpha}$ and $\rho_{\mathcal{J}}^{-\alpha}$. In this case, there is no CSD for periodic boundary conditions and the metastate can be written as

$$\kappa_{\mathcal{J}} = \delta_{\frac{1}{2}\rho_{\mathcal{J}}^{\alpha} + \frac{1}{2}\rho_{\mathcal{J}}^{-\alpha}} \qquad [6]$$

That is, the metastate is supported on a single (mixed) thermodynamic state.

The two-state scenario that has received the most attention in the literature is the "droplet/scaling" picture (McMillan 1984, Fisher and Huse 1986, 1988, Bray and Moore 1985). In this picture a low-energy excitation above the ground state in $\Lambda_L$ is a droplet whose surface area scales as $l^{d_s}$, with $l \sim O(L)$ and $d_s < d$, and whose surface energy scales as $l^\theta$, with $\theta > 0$ (in dimensions where $T_c > 0$). More recently, an alternative picture has arisen (Krzakala and Martin 2000, Palassini and Young 2000) in which the low-energy excitations differ from those of droplet/scaling, in that their energies scale as $l^{\theta'}$, with $\theta' = 0$.

The low-temperature picture that has perhaps generated the most attention in the literature is the replica symmetry breaking (RSB) scenario (Binder and Young 1986, Marinari *et al.* 1994, 1997, Franz *et al.* 1998, Marinari *et al.* 2000, Marinari and Parisi 2000, 2001, Dotsenko 2001), which assumes a rather complicated pure-state structure, inspired by Parisi's solution of the SK model (Parisi 1979, 1983, Mézard *et al.* 1984, 1987). This is a many-state picture ($\mathcal{N} = \infty$ for a.e.

$\mathcal{J}$) in which the ordering is described in terms of the "overlaps" between states. There has been some ambiguity in how to describe such a picture for short-range models; the prevailing, or standard, view. Consider any reasonably constructed thermodynamic state $\rho_{\mathcal{J}}$ (see Newman and Stein (1998a) for more details) – e.g., the "average" over the metastate $\kappa_{\mathcal{J}}$

$$\rho_{\mathcal{J}} = \int \Gamma \, d\kappa_{\mathcal{J}}(\Gamma) \qquad [7]$$

Now choose $\sigma$ and $\sigma'$ from the product distribution $\rho_{\mathcal{J}}(\sigma)\rho_{\mathcal{J}}(\sigma')$. The overlap $Q$ is defined as

$$Q = \lim_{L\to\infty} |\Lambda_L|^{-1} \sum_{x\in\Lambda_L} \sigma_x \sigma'_x \qquad [8]$$

and $P_{\mathcal{J}}(q)$ is defined to be its probability distribution.

In the standard RSB picture, $\rho_{\mathcal{J}}$ is a mixture of infinitely many pure states, each with a specific $\mathcal{J}$-dependent weight $W$:

$$\rho_{\mathcal{J}}(\sigma) = \sum_{\alpha} W^{\alpha}_{\mathcal{J}} \rho^{\alpha}_{\mathcal{J}}(\sigma) \qquad [9]$$

If $\sigma$ is drawn from $\rho^{\alpha}_{\mathcal{J}}$ and $\sigma'$ from $\rho^{\beta}_{\mathcal{J}}$, then the expression in eqn [8] equals its thermal mean,

$$q^{\alpha\beta}_{\mathcal{J}} = \lim_{L\to\infty} |\Lambda_L|^{-1} \sum_{x\in\Lambda_L} \langle\sigma_x\rangle_{\alpha} \langle\sigma_x\rangle_{\beta} \qquad [10]$$

and hence $P_{\mathcal{J}}$ is given by

$$P_{\mathcal{J}}(q) = \sum_{\alpha,\beta} W^{\alpha}_{\mathcal{J}} W^{\beta}_{\mathcal{J}} \delta(q - q^{\alpha\beta}_{\mathcal{J}}) \qquad [11]$$

The "self-overlap," or EA order parameter, is given by $q_{\mathrm{EA}} = q^{\alpha\alpha}_{\mathcal{J}}$ and (at fixed $T$) is thought to be independent of both $\alpha$ and $\mathcal{J}$ (with probability 1).

According to the standard RSB scenario, the $W^{\alpha}_{\mathcal{J}}$'s and $q^{\alpha\beta}_{\mathcal{J}}$'s are non-self-averaging (i.e., $\mathcal{J}$-dependent) quantities, except for $\alpha = \beta$ or its global flip, where $q^{\alpha\beta}_{\mathcal{J}} = \pm q_{\mathrm{EA}}$. The average $P_s(q)$ of $P_{\mathcal{J}}(q)$ over the disorder distribution of $\mathcal{J}$ is predicted to be a mixture of two delta-function components at $\pm q_{\mathrm{EA}}$ and a continuous part between them. However, it was proved by Newman and Stein (1996c) that this scenario cannot occur, because of the translation invariance of $P_{\mathcal{J}}(q)$ and the translation ergodicity of the disorder distribution. Nevertheless, the metastate approach suggests an alternative, nonstandard, RSB scenario, which is described next.

The idea behind the nonstandard RSB picture (referred to by us as the nonstandard SK picture in earlier papers) is to produce the finite-volume behavior of the SK model to the maximum extent possible. We therefore assume in this picture that in each $\Lambda_L$, the finite-volume Gibbs state $\rho^{(L)}_{\mathcal{J}}$ is well approximated deep in the interior by a mixed thermodynamic state $\Gamma^{(L)}$, decomposable into many pure states $\rho_{\alpha_L}$ (explicit dependence on $\mathcal{J}$ is suppressed for ease of notation). More precisely, each $\Gamma$ in $\kappa_{\mathcal{J}}$ satisfies

$$\Gamma = \sum_{\alpha_\Gamma} W^{\alpha_\Gamma}_{\Gamma} \rho_{\alpha_\Gamma} \qquad [12]$$

and is presumed to have a nontrivial overlap distribution for $\sigma, \sigma'$ from $\Gamma(\sigma)\Gamma(\sigma')$:

$$P_{\Gamma}(q) = \sum_{\alpha_\Gamma,\beta_\Gamma} W^{\alpha_\Gamma}_{\Gamma} W^{\beta_\Gamma}_{\Gamma} \delta(q - q_{\alpha_\Gamma\beta_\Gamma}) \qquad [13]$$

as did $\rho_{\mathcal{J}}$ in the standard RSB picture.

Because $\kappa_{\mathcal{J}}$, like its counterpart $\rho_{\mathcal{J}}$ in the standard SK picture, is translation covariant, the resulting ensemble of overlap distributions $P_{\Gamma}$ is independent of $\mathcal{J}$. Because of the CSD present in this scenario, the overlap distribution for $\rho^{(L)}_{\mathcal{J}}$ varies with $L$, no matter how large $L$ becomes. So, instead of averaging the overlap distribution over $\mathcal{J}$, the averaging must now be done over the states $\Gamma$ within the metastate $\kappa_{\mathcal{J}}$, all at fixed $\mathcal{J}$:

$$P_{\mathrm{ns}}(q) = \int P_{\Gamma}(q) \kappa_{\mathcal{J}}(\Gamma) d\Gamma \qquad [14]$$

The $P_{\mathrm{ns}}(q)$ is the same for a.e. $\mathcal{J}$, and has a form analogous to the $P_{\mathrm{s}}(q)$ in the standard RSB picture.

However, the nonstandard RSB scenario seems rather unlikely to occur in any natural setting, because of the following result:

**Theorem** Newman and Stein 1998b). (*Consider two metastates constructed along (the same) deterministic sequence of $\Lambda_L$'s, using two different sequences of flip-related, coupling-independent boundary conditions (such as periodic and antiperiodic). Then with probability one, these two metastates are the same.*

The proof is given by Newman and Stein (1998b), but the essential idea can be easily described here. As discussed earlier, $\kappa_{\mathcal{J}} = \kappa^{\dagger}_{\mathcal{J}}$; but $\kappa^{\dagger}_{\mathcal{J}}$ is constructed by a limit of finite-dimensional distributions, which means averaging over other couplings including the ones near the system boundary, and hence gives the same metastate for two flip-related boundary conditions.

This invariance with respect to different sequences of periodic and antiperiodic boundary conditions means essentially that the frequency of appearance of various thermodynamic states $\Gamma^{(L)}$ in finite volumes $\Lambda_L$ is independent of the choice of boundary conditions. Moreover, this same

invariance property holds among any two sequences of fixed boundary conditions (and the fixed boundary condition of choice may even be allowed to vary arbitrarily along any single sequence of volumes)! It follows that, with respect to changes of boundary conditions, the metastate is extraordinarily robust.

This should rule out all but the simplest overlap structures, and in particular the nonstandard RSB and related pictures (for a full discussion, see Newman and Stein 1998b). It is therefore natural to ask whether the property of metastate invariance allows any many-state picture.

There is one such picture, namely the "chaotic pairs" picture, which is fully consistent with metastate invariance (our belief is that it is the only many-state picture that fits naturally and easily into results obtained about the metastate.)

Here the periodic boundary condition metastate is supported on infinitely many pairs of pure states, but instead of eqn [12] one has

$$\Gamma = (1/2)\rho_{\alpha_\Gamma} + (1/2)\rho_{-\alpha_\Gamma} \qquad [15]$$

with overlap

$$P_\Gamma = (1/2)\delta(q - q_{\mathrm{EA}}) + (1/2)\delta(q + q_{\mathrm{EA}}) \qquad [16]$$

So there is CSD in the states but not in the overlaps, which have the same form as a two-state picture in every volume. The difference is that, while in the latter case, one has the "same" pair of states in every volume, in chaotic pairs the pure-state pair varies chaotically as volume changes. If the chaotic pairs picture is to be consistent with metastate invariance in a natural way, then the number of pure-state pairs should be "uncountable." This allows for a "uniform" distribution (within the metastate) over all of the pure states, and invariance of the metastate with respect to boundary conditions could follow naturally.

## Open Questions

We have discussed how the metastate approach to the EA spin glass has narrowed considerably the set of possible scenarios for low-temperature ordering in any finite dimension, should broken spin-flip symmetry occur. The remaining possibilities are either a two-state scenario, such as droplet/scaling, or the chaotic-pairs picture if there exist many pure states at some $(\beta, d)$. Both have simple overlap structures. The metastate approach appears to rule out more complicated scenarios such as RSB, in which the approximate pure-state decomposition in a typical large, finite volume is a nontrivial mixture of many pure-state pairs.

Of course, this does not answer the question of which, if either, of the remaining pictures actually does occur in real spin glasses. In this section we list a number of open questions relevant to the above discussion.

**Open Question 1** Determine whether a phase transition occurs in any finite dimension greater than one. If it does, find the lower critical dimension.

Existence of a phase transition does not necessarily imply two or more pure states below $T_c$. It could happen, for example, that in some dimension there exists a single pure state at all nonzero temperatures, with two-point spin correlations decaying exponentially above $T_c$ and more slowly (e.g., as a power law) below $T_c$. This leads to:

**Open Question 2** If there does exist a phase transition above some lower critical dimension, determine whether the low-temperature spin-glass phase exhibits broken spin-flip symmetry.

If broken symmetry does occur in some dimension, then of course an obvious open question is to determine the number of pure-state pairs, and hence the nature of ordering at low temperature. A (possibly) easier question (but still very difficult), and one which does not rely on knowing whether a phase transition occurs, is to determine the zero-temperature – i.e., ground state – properties of spin glasses as a function of dimensionality. A ground state is an infinite-volume spin configuration whose energy (governed by eqn [1]) cannot be lowered by flipping any finite subset of spins. That is, all ground state spin configurations must satisfy the constraint

$$\sum_{\langle x,y\rangle \in \mathcal{C}} J_{xy}\sigma_x\sigma_y \geq 0 \qquad [17]$$

along any closed loop $\mathcal{C}$ in the dual lattice.

**Open Question 3** How many ground state pairs is the $T = 0$ periodic boundary condition metastate supported on, as a function of $d$?

The answer is known to be one for 1D, and a partial result (Newman and Stein 2000, 2001a) points towards the answer being one for 2D as well. There are no rigorous, or even heuristic (except based on underlying "ansätze") arguments in higher dimension.

An interesting – but unrealistic – spin-glass model in which the ground state structure can be exactly solved (although not yet completely rigorously) was proposed by the authors (Newman and Stein 1994, 1996a) (see also Banavar 1994). This "highly disordered" spin glass is one in which the coupling magnitudes scale nonlinearly with the volume (and so are no longer distributed independently of the volume, although they remain independent and identically distributed for each volume). The model

displays a transition in ground state multiplicity: below eight dimensions, it has only a single pair of ground states, while above eight it has uncountably many such pairs. The mechanism behind the transition arises from a mapping to invasion percolation and minimal spanning trees (Lenormand and Bories 1980, Chandler *et al*. 1982, Wilkinson and Willemsen 1983): the number of ground state pairs can be shown to equal $2^{\mathcal{N}}$, where $\mathcal{N} = \mathcal{N}(d)$ is the number of distinct global components in the "minimal spanning forest." The zero-temperature free boundary condition metastate above eight dimensions is supported on a uniform distribution (in a natural sense) on uncountably many ground state pairs.

Interestingly, the high-dimensional ground state multiplicity in this model can be shown to be unaffected by the presence of frustration, although frustration still plays an interesting role: it leads to the appearance of chaotic size dependence when free boundary conditions are used.

Returning to the more difficult problem of ground state multiplicity in the EA model, we note as a final remark that there could, in principle, exist ground state pairs that are not in the support of metastates generated through the use of coupling-independent boundary conditions. If such states exist, they may be of some interest mathematically, but are not expected to play any significant physical role. A discussion of these putative "invisible states" is given by Newman and Stein (2003).

**Open Question 4** If there exists broken spin-flip symmetry at a range of positive temperatures in some dimensions, then what is the number of pure-state pairs as a function of $(\beta, d)$?

Again, the answer to this is not known above one dimension; indeed, the prerequisite existence of spontaneously broken spin-flip symmetry has not been proved in any dimension. A speculative paper by the authors (Newman and Stein 2001b), using a variant of the highly disordered model, suggests that there is at most one pair of pure states in the EA model below eight dimensions; but no rigorous arguments are known at this time.

# Sine-Gordon Equation

**S N M Ruijsenaars**, Centre for Mathematics and Computer Science, Amsterdam, The Netherlands

## Introduction

The sine-Gordon equation

$$\left(\frac{\partial^2}{\partial x^2} - \frac{\partial^2}{\partial t^2}\right)\phi = \sin \phi \qquad [1]$$

may be viewed as a prototype for a nonlinear integrable field theory. It is manifestly invariant under spacetime translations and Lorentz boosts,

$$\begin{aligned}(x,t) &\mapsto (x-\alpha, t-\beta)\\ (x,t) &\mapsto (x\cosh\theta - t\sinh\theta, t\cosh\theta - x\sinh\theta)\end{aligned} \qquad [2]$$

It shares this relativistic invariance property with the linear Klein–Gordon equation, which is obtained upon replacing $\sin\phi$ by $\phi$. (The name sine-Gordon equation is derived from this relation, and was introduced by Kruskal.) The sine-Gordon equation can also be defined and studied in the form

$$\frac{\partial^2}{\partial u\,\partial v}\tilde{\phi} = \sin\tilde{\phi}, \quad \tilde{\phi}(u,v) = \phi(t,x) \qquad [3]$$

where

$$u = (x+t)/2, \quad v = (x-t)/2 \qquad [4]$$

are the so-called light-cone variables.

There are two interpretations of the field $\phi(t,x)$ that are quite different, both from a physical and from a mathematical viewpoint. The first one consists in viewing it as a real-valued function, so

that [1] is simply a nonlinear PDE in two variables. In the second version, one views $\phi(t,x)$ as an operator-valued distribution on a Hilbert space. (Thus, one should smear $\phi(t,x)$ with a test function $f(t,x)$ in Schwartz space to obtain a genuine operator on the Hilbert space.) In spite of their different character, the classical and quantum field theory versions have several striking features in common, including the presence of an infinite number of conservation laws and the occurrence of solitonic excitations.

The classical sine-Gordon equation has been used as a model for various wave phenomena, including the propagation of dislocations in crystals, phase differences across Josephson junctions, torsion waves in strings and pendula, and waves along lipid membranes. It was already studied in the nineteenth century in connection with the theory of pseudospherical surfaces. The quantum version is used as a simple model for solid-state excitations.

The designation "sine-Gordon" is also used for various equations that generalize [1] or bear resemblance to it. These include the so-called homogeneous and symmetric space sine-Gordon models, discrete and supersymmetric versions, and generalizations to higher-dimensional spacetimes (i.e., in [1] the spatial derivative is replaced by the Laplace operator in several variables). In this contribution we focus on [1], however.

Our main goal is to discuss the integrability and solitonic properties, both at the classical and at the quantum level. First, we sketch the inverse-scattering transform (IST) solution to the Cauchy problem for [1]. Following Faddeev and Takhtajan, we emphasize the interpretation of the IST as an action-angle transformation for an infinite-dimensional Hamiltonian system. Next, the particle-like solutions are surveyed by using a description in terms of variables that may be viewed as relativistic action-angle coordinates. This is followed by a section on the quantum field theory version, paying special attention to the factorized scattering that is the quantum analog of the solitonic classical scattering. Finally, we sketch the intimate relation between the $N$-particle subspaces of the classical and quantum sine-Gordon field theory and certain integrable relativistic systems of $N$ point particles on the line.

## The Classical Version: An Integrable Hamiltonian System

In order to tie in the hyperbolic evolution equation [1] with the notion of infinite-dimensional integrable system, it is necessary to restrict attention to initial data $\phi(0,x)=\phi(x)$ and $\partial_t\phi(0,x)=\pi(x)$ with special properties. First of all, the energy functional

$$H=\int_{-\infty}^{\infty}\left(\frac{1}{2}\pi(x)^2+\frac{1}{2}\partial_x\phi(x)^2+(1-\cos\phi(x))\right)\mathrm{d}x \qquad [5]$$

and symplectic form

$$\omega=\int_{-\infty}^{\infty}\mathrm{d}\pi(x)\wedge\mathrm{d}\phi(x)\,\mathrm{d}x \qquad [6]$$

should be well defined on the phase space of initial data. Indeed, in that case [1] amounts to the Hamilton equation associated to [5] via [6].

Second, there exists a sequence of functionals

$$I_{2l+1}(\phi,\pi),\quad l\in\mathbb{Z} \qquad [7]$$

that formally Poisson-commute with $H$ and among themselves.

In particular, $H$ equals $2(I_1+I_{-1})$, whereas $2(I_1-I_{-1})$ equals the momentum functional

$$P=-\int_{-\infty}^{\infty}\pi(x)\partial_x\phi(x)\,\mathrm{d}x \qquad [8]$$

The functional $I_{2l+1}$ contains $x$-derivatives of order up to $|2l+1|$, so one needs to require that the functions $\partial_x\phi(x)$ and $\pi(x)$ be smooth and that all of their derivatives have sufficient decrease for $x\to\pm\infty$.

A natural choice guaranteeing the latter requirements is

$$\partial_x\phi(x),\pi(x)\in S_{\mathbb{R}}(\mathbb{R}) \qquad [9]$$

where $S_{\mathbb{R}}(\mathbb{R})$ denotes the Schwartz space of real-valued functions on the line. To render the integral over $1-\cos\phi(x)$ (and similar integrals occurring for the sequence [7]) finite, one also needs to require

$$\phi(x)\to 2\pi k_{\pm},\quad x\to\pm\infty,\ k_{\pm}\in\mathbb{Z} \qquad [10]$$

On this phase space $\Omega$ of initial data, the Cauchy problem for the evolution equation [1] is not only well posed, but can be solved in explicit form by using the IST. More generally, the Hamiltonians $I_{2l+1}$ give rise to evolution equations that are simultaneously solved via the IST, yielding an infinite sequence of commuting Hamiltonian flows on $\Omega$.

Before sketching the overall picture resulting from the IST, it should be mentioned at this point that [1] admits explicit solutions of interest that do not belong to $\Omega$. First, there is a class of algebro-geometric solutions that have no limits as $x\to\pm\infty$. These solutions can be obtained via finite-gap integration methods, yielding formulas involving

the Riemann theta functions associated to compact Riemann surfaces. Second, there are the tachyon solutions. They arise from the particle-like solutions that do belong to $\Omega$ by the transformation

$$\phi(t,x) \to \phi(x,t) + \pi \qquad [11]$$

(Observe that the equation of motion [1] is invariant under [11], whereas due to the finite-energy requirement [10] this is not true for solutions evolving in $\Omega$.)

The IST via which the above Cauchy problem can be solved starts from an auxiliary system of two linear ordinary differential equations involving $\phi(0,x)$ and $\partial_t\phi(0,x)$. It is beyond our scope to describe the system in detail. The results derived from it, however, are to a large extent the same as those obtained via a simpler auxiliary linear operator that is associated to the light-cone Cauchy problem. The latter operator is of the Ablowitz–Kaup–Newell–Segur (AKNS) form. That is, the linear operator is an ordinary differential operator of Dirac type given by

$$L = \begin{pmatrix} \mathrm{i}\frac{\mathrm{d}}{\mathrm{d}x} & -\mathrm{i}q \\ \mathrm{i}r & -\mathrm{i}\frac{\mathrm{d}}{\mathrm{d}x} \end{pmatrix} \qquad [12]$$

where the external potentials $r(u)$ and $q(u)$ depend on the evolution equation at hand. For the light-cone sine-Gordon equation [3], one needs to choose

$$r = -q = (\partial_u\tilde{\phi})(u,0)/2 \qquad [13]$$

In both settings, the associated spectral features are invariant under the sine-Gordon evolution and all of the evolutions generated by the Hamiltonians $I_{2l+1}$, yielding the so-called isospectral flows. More specifically, if the initial data give rise to bound-state solutions of the linear problem (square-integrable wave functions), then the corresponding eigenvalues are time independent. Furthermore, due to the decay requirements on the potential in the linear system, there exist scattering solutions with plane-wave asymptotics for all initial data in $\Omega$. A suitable normalization leads to the so-called Jost solutions $\Psi(x,\lambda)$. (Here $\lambda$ is the spectral parameter, which varies over the real line for scattering solutions.) Their $x \to \pm\infty$ asymptotics is encoded in transition coefficients $a(\lambda)$ and $b(\lambda)$, with $a(\lambda)$ and $|b(\lambda)|$ being time independent, whereas $\arg b(\lambda)$ has a linear dependence on time when the potential evolves according to the sine-Gordon equation. The bound states correspond to special $\lambda$-values $\lambda_1, \ldots, \lambda_N$ with positive imaginary part (namely the zeros of the coefficient $a(\lambda)$, which is analytic in the upper-half $\lambda$-plane); their normalization coefficients $\nu_1, \ldots, \nu_N$ have an essentially linear time evolution, just as $b(\lambda)$.

The crux of the IST is now that the potentials can be reconstructed from the spectral data

$$\{b(\lambda), \lambda_1, \ldots, \lambda_N, \nu_1, \ldots, \nu_N\} \qquad [14]$$

by solving a linear integral equation of Gelfand–Levitan–Marchenko (GLM) type. (Alternatively, Riemann–Hilbert problem techniques can be used.) Hence, the nonlinear Cauchy problem can be replaced by the far simpler linear problems of determining the spectral data [14] of a linear operator (the direct problem) and then solving the linear GLM equation for the time-evolved scattering data (the inverse problem).

From the Hamiltonian perspective, the IST may be reinterpreted as a transformation to action-angle variables. The action variables are defined in terms of $|b(\lambda)|$ and $\lambda_1, \ldots, \lambda_N$. They are time independent under the sine-Gordon and higher Hamiltonian flows. The angle variables are $\arg b(\lambda)$ and suitable functions of the normalization coefficients. They depend linearly on the evolution times of the flows. The Hamiltonians can be explicitly expressed in action variables.

Next, we point out that there is a large subspace of Cauchy data $(\phi(x), \pi(x))$ that do not give rise to bound states in the auxiliary linear problem. The associated solutions are the so-called radiation solutions: they decrease to 0 for large times. These solutions can be obtained from the inverse transform involving the GLM equation by only taking $b(\lambda)$ into account.

The other extreme is to choose $b(\lambda) = 0$ and arbitrary bound states and normalization coefficients in the GLM equation. This special case of vanishing reflection leads to the particle-like solutions that are studied in the next section. For general Cauchy data, one has both $b(\lambda) \neq 0$ and a finite number of bound states. These so-called mixed solutions have a radiation component (encoded in $b(\lambda)$) which decays for asymptotic times, whereas the bound states show up for $t \to \pm\infty$ as isolated solitons, antisolitons, and breathers.

## Classical Solitons, Antisolitons, and Breathers

Just as for other classical soliton equations, the case of reflectionless data can be handled in complete detail, since the GLM equation reduces to an $N \times N$ system of linear equations. The case $N = 1$ yields the 1-soliton and 1-antisoliton solutions. Resting at the origin, these one-particle solutions are given by

$$\pm 4 \arctan(\mathrm{e}^{-x}) \qquad [15]$$

and have energy 8 (cf. [5]). (We normalize all solutions by requiring

$$\lim_{x\to\infty}\phi(t,x)=0 \qquad [16]$$

Note that one can add arbitrary multiples of $2\pi$ without changing the energy $H$ [5].) A spatial translation and Lorentz boost then yields the general solutions

$$\phi_{\pm}(t,x) = \pm 4\arctan(\exp(q - x\cosh\theta + t\sinh\theta)) \qquad [17]$$

with energy $8\cosh\theta$ and momentum $8\sinh\theta$ (cf. [8]).

Defining the topological charge of a solution (with normalization [16]) by

$$Q=\frac{1}{2\pi}\lim_{x\to-\infty}\phi(t,x) \qquad [18]$$

the different charges $Q=1$ and $Q=-1$ of the soliton and antisoliton reflect a signature associated to the special value of the spectral parameter on the imaginary axis for which a bound state in the linear problem occurs. More generally, for bound-state eigenvalues on the imaginary axis these signatures must be specified in the IST setting, a point glossed over in the previous section.

Bound states in the linear problem can also arise from $\lambda$-values off the imaginary axis, which come in pairs $\mathrm{i}a\pm b$, with $a,b>0$. Such pairs give rise to solutions containing breathers, which can be viewed as bound states of a soliton and an antisoliton. The one-breather solution breathing at the origin is given by

$$4\arctan\left(\cot\eta\frac{\sin(t\sin\eta)}{\cosh(x\cos\eta)}\right), \quad \eta\in(0,\pi/2) \qquad [19]$$

and has energy $16\cos\eta$. A spacetime translation and Lorentz boost then yields the general solution

$$\phi_b(t,x) = 4\arctan\left(\cot\eta\frac{\sin[-\gamma/2+\sin\eta(t\cosh\theta-x\sinh\theta)]}{\cosh[y/2-\cos\eta(x\cosh\theta-t\sinh\theta)]}\right) \qquad [20]$$

which has energy $16\cosh\theta\cos\eta$ and momentum $16\sinh\theta\cos\eta$. It may be obtained by analytic continuation from the solution describing a collision between a soliton with velocity $\tanh\theta_1$ and an antisoliton with velocity $\tanh\theta_2$, taking $\theta_2<\theta_1$. The latter is given by

$$\phi_{+-}(t,x) = 4\arctan\left(\coth((\theta_1-\theta_2)/2)\frac{\sinh((\mu_1-\mu_2)/2)}{\cosh((\mu_1+\mu_2)/2)}\right) \quad \theta_2<\theta_1 \qquad [21]$$

where

$$\mu_j = q_j - x\cosh\theta_j + t\sinh\theta_j, \quad q_j,\theta_j\in\mathbb{R} \qquad [22]$$

and $\phi_b$ results from $\phi_{+-}$ by substituting

$$\theta_{\substack{1\\2}}\to\theta\pm\mathrm{i}\eta, \qquad q_{\substack{1\\2}}\to(y\mp\mathrm{i}\gamma)/2 \qquad [23]$$

(For the case $\theta_1<\theta_2$, one needs an extra minus sign on the right-hand side of [21].)

There is yet another possibility for an eigenvalue on the imaginary axis we have not mentioned thus far: it may have an arbitrary multiplicity, giving rise to the so-called multipole solutions. This is illustrated by the breather solution $\phi_b$: when one sets $\gamma=-2q_0\eta$ and lets $\eta$ tend to 0, one obtains a solution

$$\phi_{\mathrm{sep}}(t,x) = 4\arctan\left(\frac{q_0+t\cosh\theta-x\sinh\theta}{\cosh[y/2-x\cosh\theta+t\sinh\theta]}\right) \qquad [24]$$

From a physical viewpoint, the soliton and antisoliton have just enough energy to prevent a bound state from being formed. Notice that in this case the distance between soliton and antisoliton diverges logarithmically in $|t|$ as $t\to\pm\infty$, whereas for $\phi_{+-}$ one obtains linear increase.

The 2-soliton and 2-antisoliton solutions can also be obtained by analytic continuation of $\phi_{+-}$. They read

$$\phi_{\pm\pm} = \mp 4\arctan\left(\coth((\theta_1-\theta_2)/2) \times\frac{\cosh((\mu_1-\mu_2)/2)}{\sinh((\mu_1+\mu_2)/2)}\right), \quad \theta_2<\theta_1 \qquad [25]$$

where $\mu_j$ is given by [22]. Thus, they arise by taking $q_2\to q_2+\mathrm{i}\pi$ and $q_1\to q_1+\mathrm{i}\pi$ in [21], resp. The equal-signature eigenvalues corresponding to these two solutions cannot collide and move off the imaginary axis; physically speaking, equal-charge particles repel each other. The energy and momentum of the solutions [25] and [21] are given by $8\cosh\theta_1+8\cosh\theta_2$ and $8\sinh\theta_1+8\sinh\theta_2$, respectively.

Up to scale factors, the above variables $\theta_1,\theta_2$ and $\theta,\eta$ are the action variables resulting from the IST, whereas $q_1,q_2$ and $y,\gamma$ are the canonically conjugated angle variables. Accordingly, the time and space translation flows (generated by $H$ [5] and $P$ [8], resp.) shift the angles linearly in the evolution parameters $t$ and $x$.

We conclude this section with a description of the $N$-soliton solution and its large time asymptotics. It can be expressed in terms of the $N\times N$ matrix

$$\mathcal{L}_{jk} = \exp(\mu_j)\frac{\prod_{l\neq j}|\coth((\theta_j-\theta_l)/2)|}{\cosh((\theta_j-\theta_k)/2)} \qquad [26]$$

where $\mu_j$ is given by [22] with

$$q_1, \ldots, q_N \in \mathbb{R}, \qquad \theta_N < \cdots < \theta_1 \qquad [27]$$

Specifically, one has

$$\begin{aligned}\phi_{N+}(t,x) &= 4\,\mathrm{tr}\arctan(\mathcal{L}) \\ &= -2\mathrm{i}\,\ln(|\mathbf{1}_N + \mathrm{i}\mathcal{L}|/|\mathbf{1}_N - \mathrm{i}\mathcal{L}|) \\ &= -2\mathrm{i}\,\ln\left(\left(1 + \sum_{l=1}^{N} \mathrm{i}^l S_l(\mathcal{L})\right)/\mathrm{c.c.}\right)\end{aligned} \qquad [28]$$

where $S_l$ is the $l$th symmetric function of $\mathcal{L}$. Using Cauchy's identity, one obtains the explicit formula

$$S_l = \sum_{\substack{I\subset\{1,\ldots,N\}\\|I|=l}} \exp\left(\sum_{j\in I}\mu_j\right) \prod_{\substack{j\in I\\k\notin I}} |\coth((\theta_j - \theta_k)/2)| \qquad [29]$$

In order to specify the $t \to \pm\infty$ asymptotics of $\phi_{N+}$, we introduce the 1-soliton solutions

$$\phi_j^{\pm}(t,x) = 4\,\arctan(\exp(\mu_j \mp \Delta_j/2)) \qquad [30]$$

where

$$\Delta_j = \left(\sum_{k<j} - \sum_{k>j}\right)\delta(\theta_j - \theta_k) \qquad [31]$$

$$\delta(\theta) = \ln\left(\coth(\theta/2)^2\right) \qquad [32]$$

Then, one has

$$\sup_{x\in\mathbb{R}}\left|\phi_{N+}(t,x) - \sum_{j=1}^{N}\phi_j^{\pm}(t,x)\right| = O(\exp(-|t|r)) \qquad t \to \pm\infty \qquad [33]$$

where the decay rate is given by

$$r = \min_{j\neq k}(\cosh(\theta_j)|\tanh\theta_j - \tanh\theta_k|) \qquad [34]$$

Thus, the soliton profile with velocity $\tanh\theta_j$ incurs a shift $\Delta_j/\cosh\theta_j$ as a result of the collision. The factor $1/\cosh\theta_j$ may be viewed as a Lorentz contraction factor.

## The Quantum Version: A Soliton Quantum Field Theory

From a perturbation-theoretic viewpoint, the quantum sine-Gordon Hamiltonian is given by

$$H = \int_{-\infty}^{\infty} : \left(\frac{1}{2}(\partial_t\phi)^2 + \frac{1}{2}(\partial_x\phi)^2 + \frac{m^2}{\beta^2}(1 - \cos\beta\phi)\right) : \mathrm{d}x, \quad m, \beta > 0 \qquad [35]$$

Here, $\phi(0,x)$ is a neutral Klein–Gordon field with mass $m$ and the double dots denote a suitable ordering prescription. The associated equation of motion

$$\phi_{xx} - \phi_{tt} = \frac{m^2}{\beta}\sin\beta\phi \qquad [36]$$

is equivalent to [1] on the classical level, but not on the quantum level. (If $\phi(t,x)$ is a classical solution to [36], then $\beta\phi(t/m, x/m)$ solves [1].) This difference is due to the extremely singular character of interacting relativistic quantum field theory, a context in which "solving" the field theory has slowly acquired a meaning that is vastly different from the classical notion. Indeed, one can at best hope to verify [36] in the sense of expectation values in suitable quantum states, and this is precisely what has been achieved within the form-factor program sketched later on.

From the perspective of functional analysis, the existence of a well-defined Wightman field theory with all of the features mentioned below is wide open. More precisely, beginning with pioneering work by Fröhlich some 30 years ago, various authors have contributed to a mathematically rigorous construction of a sine-Gordon quantum field theory version, but to date it seems not feasible to verify that the resulting Wightman field theory has any of the explicit features we are going to sketch. (For example, not even the free character of the field theory for $\beta^2 = 4\pi$ has been established; cf. below.)

That said, we proceed to sketch some highlights of the impressive, but partly heuristic lore that has been assembled in a great many theoretical physics papers. A key result we begin with is the equivalence to a field theory that looks very different at face value. This is the massive Thirring model, formally given by the Hamiltonian

$$H_{\mathrm{T}} = \int_{-\infty}^{\infty} : \left(\Psi^*(-\mathrm{i}\gamma^5\partial_x + \gamma^0 M)\Psi + \frac{g}{2}(J_0^2 - J_1^2)\right) : \mathrm{d}x \qquad M \in (0,\infty),\ g \in \mathbb{R} \qquad [37]$$

Here, $\Psi(0,x)$ is the charged Dirac field with mass $M$ and the double dots stand for normal ordering. For the $\gamma$-algebra, one may choose

$$\gamma^0 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \qquad \gamma^1 = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$$
$$\gamma^5 = \gamma^0\gamma^1 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \qquad [38]$$

and $J_\mu$ is the Dirac current,

$$J_0 = \Psi^*\Psi, \qquad J_1 = \Psi^*\begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix}\Psi \qquad [39]$$

The equivalence argument (due to Coleman) consists in showing that the quantities

$$-\frac{\beta}{2\pi}\epsilon_{\mu\nu}\partial^{\nu}\phi, \qquad \frac{m^2}{\beta^2} : \cos\beta\phi : \qquad [40]$$

in the sine-Gordon theory have the same vacuum expectation values (in perturbation theory) as the massive Thirring quantities

$$: J_{\mu} :, \qquad -M : \Psi^{*}\gamma^{0}\Psi : \qquad [41]$$

resp., provided the parameters are related by

$$\frac{4\pi}{\beta^2} = 1 + \frac{g}{\pi} \qquad [42]$$

This yields an equivalence between the charge-0 sector of the massive Thirring model and the sector of the sine-Gordon theory obtained by the action of the fields [40] on the vacuum vector. But the charged sectors of the Thirring model can also be viewed as new sectors in the sine-Gordon theory, obtained by a solitonic field construction (first performed by Mandelstam).

In this picture, the fermions and antifermions in the massive Thirring model correspond to new excitations in the sine-Gordon theory, the quantum solitons and antisolitons. The latter are viewed as coherent states of the sine-Gordon "mesons" in the vacuum sector, the rest masses being related by

$$M = \frac{8m}{\beta^2}\left(1 - \frac{\beta^2}{8\pi}\right) \qquad [43]$$

in the semiclassical limit $\beta^2 \to 0$.

Even at the formal level involved in the correspondence, the theories are not believed to exist for $\beta^2 > 8\pi$ and $g < -\pi/2$, since there is positivity breakdown for this range of couplings. The free Dirac case $g = 0$ corresponds to $\beta^2 = 4\pi$. In particular, there is no interaction between the sine-Gordon solitons and antisolitons for this $\beta$-value. In the range $\beta^2 \in (4\pi, 8\pi)$ there is interaction, but bound soliton–antisoliton pairs (quantum breathers, alias sine-Gordon mesons) do not occur.

By contrast, for $\beta^2 < 4\pi$ there exist breathers with rest masses

$$m_n = 2M\sin(n+1)\alpha, \quad \alpha \equiv m/2M,$$
$$n+1 = 1, 2, \ldots, L < \pi/2\alpha \qquad [44]$$

Thus, the "particle spectrum" consists of solitons and antisolitons with mass $M$ and mesons $C_1, \ldots, C_L$ with masses $m_1, \ldots, m_L$ given by [44]. The latter formula was first established by semiclassical quantization of the classical breathers (Dashen–Hasslacher–Neveu), and ever since is usually called the DHN formula. Notice that for $\alpha$ near zero $m_1$ and $m$ are nearly equal, and that for $\beta^2 \geq 4\pi$ there are no longer any sine-Gordon mesons present in the theory.

*A priori*, the existence of infinitely many classical conserved Hamiltonians does not even formally imply the same feature for the quantum field theory, as anomalies may occur. For the sine-Gordon and massive Thirring cases, anomalies have been shown to be absent, however. This entails not only that the number of solitons, antisolitons, and breathers in a scattering process is conserved, but also that the set of incoming rapidities equals the set of outgoing rapidities.

The latter stability features and the DHN formula [44] are corroborated by the $S$-matrix, which is known in complete detail. The two-body amplitudes involving solitons and antisolitons can be written in terms of the function

$$u(z) = \exp\left(\mathrm{i}\int_0^{\infty}\frac{\mathrm{d}x}{x}\frac{\sinh(\alpha - \pi/2)x}{\sinh\alpha x\cosh\pi x/2}\sin 2xz\right) \qquad [45]$$

They are given by

$$(u_{++}, t_{+-}, r_{+-}, u_{--})(\theta) = u(\theta/2)\left(1, \frac{\sinh(\pi\theta/2\alpha)}{\sinh(\pi(\mathrm{i}\pi - \theta)/2\alpha)}, \frac{\mathrm{i}\sin(\pi^2/2\alpha)}{\sinh(\pi(\mathrm{i}\pi - \theta)/2\alpha)}, 1\right) \qquad [46]$$

where $\theta$ denotes the rapidity difference. (Due to fermion statistics, one gets only one amplitude for a soliton or antisoliton pair. But a soliton and an antisoliton have opposite charge, so they can be distinguished. In that case, therefore, the notion of reflection and transmission coefficients makes sense.)

The $S$-matrix involving an arbitrary number of solitons, antisolitons, and their bound states is also explicitly known. The amplitudes involving no breathers are readily described in terms of the above two-body amplitudes. Indeed, the $S$-matrix factorizes as a sum of products of the amplitudes [46], yielding a picture of particles scattering independently in pairs, just as at the classical level. The factorization can be performed irrespective of the temporal ordering assumed for the pair scattering processes, since the four functions occurring inside the parentheses of [46] satisfy the Yang–Baxter equations.

Roughly speaking, the $S$-matrix for processes involving breathers can be calculated by analytic continuation from the soliton–antisoliton $S$-matrix. The details are however quite substantial. We only add that scattering amplitudes involving solely breathers can be expressed using only hyperbolic functions.

Since the 1980s, a lot of information has also been gathered concerning matrix elements of suitable sine-Gordon field quantities between special quantum states (form factors). Unfortunately, the correlation functions involve infinite sums of form factors that are quite difficult to control analytically. Hence, it is not known whether the correlation functions associated with the form factors give rise to a Wightman field theory with the usual axiomatic properties.

## The Relation to Relativistic Calogero–Moser Systems

The behavior of the special classical solutions discussed earlier is very similar to that of classical point particles. Furthermore, the picture of classical solitons, antisolitons, and their bound states scattering independently in pairs is essentially preserved on the quantum level, just as one would expect for the quantization of an integrable particle system.

Next, we note that from the quantum viewpoint there is no physical distinction between wave functions and point particles, whereas a classical wave is a physical entity that is clearly very different from a point particle. Even so, it is a natural question whether there exist classical Hamiltonian systems of $N$ point particles on the line whose physical characteristics (charges, bound states, scattering, etc.) are the same as those of the particle-like sine-Gordon solutions. If so, a second question is equally obvious: does the quantum version of the $N$-particle systems still have the same features as that of the quantum sine-Gordon excitations?

As we now sketch, the first question has been answered in the affirmative, whereas the second one has not been completely answered yet. However, all of the information on the pertinent quantum $N$-particle systems collected thus far points to an affirmative answer. The systems at issue are relativistic versions of the well-known nonrelativistic Calogero–Moser $N$-particle systems.

To begin with the classical two-particle system, its Hamiltonian is given by

$$H = (\cosh p_1 + \cosh p_2)\coth((x_1 - x_2)/2) \qquad [47]$$

on the phase space

$$\Omega = \{(x, p) \in \mathbb{R}^4 | x_2 < x_1\}, \quad \omega = \mathrm{d}x \wedge \mathrm{d}p \qquad [48]$$

Taking $x_2 \to x_2 + \mathrm{i}\pi$ yields the particle–antiparticle Hamiltonian

$$\tilde{H} = (\cosh p_1 + \cosh p_2)|\tanh((x_1 - x_2)/2)| \qquad [49]$$

on the phase space

$$\tilde{\Omega} = \{(x, p) \in \mathbb{R}^4\}, \quad \omega = \mathrm{d}x \wedge \mathrm{d}p \qquad [50]$$

The two-antiparticle Hamiltonian is again given by [47] and [48]. The interaction potential in [47] is repulsive, whereas it is attractive in [49]. Hence, any initial point in $\Omega$ gives rise to a scattering state, whereas points in $\tilde{\Omega}$ yield scattering states if and only if the reduced Hamiltonian

$$\tilde{H}_{\mathrm{r}} = \cosh p|\tanh(x/2)|, \quad p = (p_1 - p_2)/2$$
$$x = x_1 - x_2 \qquad [51]$$

satisfies $\tilde{H}_{\mathrm{r}} > 1$. More specifically, in both cases the distance $|x_1(t) - x_2(t)|$ increases linearly as $t \to \pm\infty$, the scattering (position shift) being encoded by the same function [32] as for the sine-Gordon solitons. The phase-space points on the separatrix $\{\tilde{H}_{\mathrm{r}} = 1\}$ have the same temporal asymptotics as the multipole solution [24], whereas the bound-state oscillations for $\tilde{H}_{\mathrm{r}} < 1$ match those of the breathers [20].

More generally, the Hamiltonian for $N_+$ particles and $N_-$ antiparticles is given by the function

$$\sum_{j=1}^{N_+} \cosh(p_j^+) \prod_{\substack{k=1 \\ k \neq j}}^{N_+} |\coth((x_j^+ - x_k^+)/2)|$$
$$\times \prod_{l=1}^{N_-} |\tanh((x_j^+ - x_l^-)/2)| + \sum_{l=1}^{N_-} \cosh(p_l^-)$$
$$\times \prod_{\substack{m=1 \\ m \neq l}}^{N_-} |\coth((x_l^- - x_m^-)/2)|$$
$$\times \prod_{j=1}^{N_+} |\tanh((x_l^- - x_j^+)/2)| \qquad [52]$$

on the phase space

$$\Omega_{N_+,N_-} = \Big\{(x^+, p^+) \in \mathbb{R}^{2N_+}, (x^-, p^-) \in \mathbb{R}^{2N_-} | x_{N_+}^+ < \cdots < x_1^+, x_{N_-}^- < \cdots < x_1^- \Big\} \qquad [53]$$

$$\omega_{N_+,N_-} = \mathrm{d}x^+ \wedge \mathrm{d}p^+ + \mathrm{d}x^- \wedge \mathrm{d}p^- \qquad [54]$$

This defining Hamiltonian can be supplemented by $(N_+ + N_- - 1)$ independent Hamiltonians that pairwise commute. The action-angle map of this integrable system can be used to relate the scattering and bound-state behavior to that of the sine-Gordon solutions from an earlier section, yielding an exact correspondence. Indeed, the variables we used to describe the particle-like sine-Gordon solutions amount to the action-angle variables associated to [52]. Moreover, the matrix $\mathcal{L}$ [26] with $t = x = 0$

equals the Lax matrix for the $N$-particle system, which is the manifestation of a remarkable self-duality property of the equal-charge case. There is an equally close relation between the general particle-like solutions and the general systems encoded in [52].

As a matter of fact, the connection can be further strengthened by introducing spacetime trajectories for the solitons, antisolitons, and breathers, which are defined in terms of the evolution of an initial point in $\Omega_{N_+,N_-}$ under the time translation generator [52] and the space translation generator, obtained from [52] by the replacement $\cosh \to \sinh$. These point particle and antiparticle trajectories make it possible to follow the motion of the solitons, antisolitons, and breathers during the temporal interval in which the nonlinear interaction takes place, whereas for large times the trajectories are located at the (then) clearly discernible positions of the individual solitons, antisolitons, and breathers.

Before sketching the soliton-particle correspondence at the quantum level, we add a remark on the finite-gap solutions of the classical sine-Gordon equation, already mentioned in the paragraph containing [11]. These solutions may be viewed as generalizations of the particle-like solutions discussed earlier, and they can also be obtained via relativistic $N$-particle Calogero–Moser systems. The pertinent systems are generalizations of the hyperbolic systems just described to the elliptic level.

Turning now to the quantum level, we begin by mentioning that the Poisson-commuting Hamiltonians admit a quantization in terms of commuting analytic difference operators. This involves a special ordering choice of the $p$-dependent and $x$-dependent factors in the classical Hamiltonians, which is required to preserve commutativity. The resulting quantum two-body problem can be explicitly solved in terms of a generalization of the Gauss hypergeometric function. For the case of equal charges, the scattering is encoded in the sine-Gordon amplitudes $u_{\pm\pm}(\theta)$ (cf. [45] and [46]). For the unequal-charge case, one should distinguish an even and odd channel. The scattering on these channels is encoded in the sine-Gordon amplitudes $t_{+-}(\theta) \pm r_{+-}(\theta)$. Moreover, the bound-state spectrum agrees with the DHN formula [44] and the bound-state wave functions are given by hyperbolic functions.

As a consequence of these results, the physics encoded in the two-body subspace of the sine-Gordon quantum field theory is indistinguishable from that of the corresponding two-body relativistic Calogero–Moser systems. To extend this equivalence to the arbitrary-$N$ case, one needs first of all sufficiently explicit solutions to the $N$-body Schrödinger equation. To date, this has only been achieved for the case of $N$ equal charges and the special couplings for which the reflection amplitude $r_{+-}$ vanishes. The asymptotics of the pertinent solutions is factorized in terms of $u_{\pm\pm}(\theta)$, in agreement with the sine-Gordon picture.

# Singularities of the Ricci Flow

**M Anderson**, State University of New York at Stony Brook, Stony Brook, NY, USA

## Introduction

Fix a closed $n$-dimensional manifold $M$, and let $\mathbb{M}$ be the space of Riemannian metrics on $M$. As in the reasoning leading to the Einstein equations in general relativity, there is basically a unique simple and natural vector field on the space $\mathbb{M}$. Namely, the tangent space $T_g\mathbb{M}$ consists of symmetric bilinear forms; besides multiples of the metric itself, the Ricci curvature $\mathrm{Ric}_g$ of $g$ is the only symmetric form that depends on at most the second derivatives of the metric, and is invariant under coordinate changes, that is, a (0, 2)-tensor formed from the metric. Thus, consider

$$X_g = \mu \mathrm{Ric}_g + \lambda g$$

where $\mu, \lambda$ are scalars. Setting $\mu = -2$, the corresponding equation for the flow of $X$ is

$$\frac{\mathrm{d}}{\mathrm{d}t} g(t) = -2\mathrm{Ric}_{g(t)} + \lambda g(t) \qquad [1]$$

The Ricci flow, introduced by Hamilton (1982), is obtained by setting $\lambda = 0$:

$$\frac{\mathrm{d}}{\mathrm{d}t} g(t) = -2\mathrm{Ric}_{g(t)} \qquad [2]$$

Rescaling the metric and time variable $t$ transforms [2] into [1], with $\lambda = \lambda(t)$. For example, rescaling the Ricci flow [2] so that the volume of $(M, g(t))$ is preserved leads to the flow equation [1] with $\lambda = 2 \oint R$, twice the mean value of the scalar curvature $R$.

The Ricci flow [2] bears some relation with the metric part of the $\beta$-function or renormalization group (RG) flow equation

$$\frac{\mathrm{d}}{\mathrm{d}t} g(t) = \beta(g(t))$$

for the two-dimensional sigma model of maps $\Sigma^2 \to M$. The $\beta$-function is a vector field on $\mathbb{M}$, invariant under diffeomorphisms, which has an expansion of the form

$$-\beta(g) = \mathrm{Ric}_g + \varepsilon \mathrm{Riem}^2 + \cdots$$

where $\mathrm{Riem}^2$ is quadratic in the Riemann curvature tensor. The Ricci flow corresponds to the one-loop term or semiclassical limit in the RG flow (cf. D'Hoker (1999) and Friedan (1985)).

Recently, G Perelman (2002, 2003a, b) has developed new insights into the geometry of the Ricci flow which has led to a solution of long-standing mathematical conjectures on the structure of 3-manifolds, namely the Thurston geometrization conjecture (Thurston 1982), and hence the Poincaré conjecture.

## Basic Properties of the Ricci Flow

In charts where the coordinate functions are locally defined harmonic functions in the metric $g(t)$, [2] takes the form

$$\frac{\mathrm{d}}{\mathrm{d}t} g_{ij} = \Delta g_{ij} + Q_{ij}(g, \partial g)$$

where $\Delta$ is the Laplace operator on functions with respect to the metric $g = g(t)$ and $Q$ is a lower-order term quadratic in $g$ and its first-order partial derivatives. This is a nonlinear heat-type equation for $g_{ij}$ and leads to the existence and uniqueness of solutions to the Ricci flow on some time interval starting at any smooth initial metric. This is the reason for the minus sign in [2]; a plus sign gives a backwards heat-type equation, which has no solutions in general.

The flow [2] gives a natural method to try to construct canonical metrics on the manifold $M$. Stationary points of the flow [2] are Ricci-flat metrics, while stationary points of the flow [1] are (Riemannian) Einstein metrics, where $\mathrm{Ric}_g = (R/n)g$, with $R$ the scalar curvature of $g$. One of Hamilton's motivations for studying the Ricci flow were results on an analogous question for nonlinear sigma models. Consider maps $f$ between Riemannian manifolds $M$, $N$ with Lagrangian given by the Dirichlet energy. Eells–Sampson studied the heat equation for this action and proved that when the target $N$ has nonpositive curvature, the flow exists for all time and converges to a stationary point of the action, that is, a harmonic map $f_\infty : M \to N$. The idea is to see if an analogous program can be developed on the space of metrics $\mathbb{M}$.

There are a number of well-known obstructions to the existence of Einstein metrics on manifolds, in particular, in dimensions 3 and 4. Thus, the Ricci flow will not exist for all time on a general manifold. Hence, it must develop singularities. A fundamental issue is to try to relate the structure of the singularities of the flow with the topology of the underlying manifold $M$.

A few simple qualitative features of the Ricci flow [2] are as follows: if $\mathrm{Ric}(x, t) > 0$, then the flow contracts the metric $g(t)$ near $x$, to the future, while

if $\text{Ric}(x,t) < 0$, then the flow expands $g(t)$ near $x$. At a general point, there will be directions of positive and negative Ricci curvature, along which the metric locally contracts or expands. The flow preserves product structures of metrics, and preserves the isometry group of the initial metric.

The form of [2] shows that the Ricci flow continues as long as Ricci curvature remains bounded. On a bounded time interval where $\text{Ric}_{g(t)}$ is bounded, the metrics $g(t)$ are quasi-isometric, that is, they have bounded distortion compared with the initial metric $g(0)$. Thus, one needs to consider evolution equations for the curvature, induced by the flow for the metric. The simplest of these is the evolution equation for the scalar curvature $R$:

$$\frac{\mathrm{d}}{\mathrm{d}t}R = \Delta R + 2|\text{Ric}|^2 \qquad [3]$$

Evaluating [3] at a point realizing the minimum $R_{\min}$ of $R$ on $M$ shows that $R_{\min}$ is monotone nondecreasing along the flow. In particular, the Ricci flow preserves positive scalar curvature. Moreover, if $R_{\min}(0) > 0$, then

$$t \leq \frac{n}{2R_{\min}(0)} \qquad [4]$$

Thus, the Ricci flow exists only up to a maximal time $T \leq n/2R_{\min}(0)$ when $R_{\min}(0) > 0$. In contrast, in regions where the Ricci curvature stays negative definite, the flow exists for infinite time.

The evolution of the Ricci curvature has the same general form as [3]:

$$\frac{\mathrm{d}}{\mathrm{d}t}R_{ij} = \Delta R_{ij} + \widetilde{Q}_{ij} \qquad [5]$$

The expression for $\widetilde{Q}$ is much more complicated than the Ricci curvature term in [3] but involves only quadratic expressions in the curvature. However, $\widetilde{Q}$ involves the full Riemann curvature tensor Riem of $g$, and not just the Ricci curvature (as [3] involves Ricci and not just scalar curvature). An important feature of dimension 3 is that the full Riemann curvature Riem is determined algebraically by the Ricci curvature. So the Ricci flow has a much better chance of "working" in dimension 3. For example, an analysis of $\widetilde{Q}$ shows that the Ricci flow preserves positive Ricci curvature in dimension 3; if $\text{Ric}_{g(0)} > 0$, then $\text{Ric}_{g(t)} > 0$, for $t > 0$. This is not the case in higher dimensions. On the other hand, in any dimension $>2$, the Ricci flow does not preserve negative Ricci curvature, or even a general lower bound $\text{Ric} \geq -\lambda$, for $\lambda > 0$. For the remainder of the article, we usually assume then that $\dim M = 3$.

The first basic result on the Ricci flow is the following, due to Hamilton (1982).

*Space-form theorem*. If $g(0)$ is a metric of positive Ricci curvature on a 3-manifold $M$, then the volume normalized Ricci flow exists for all time, and converges to the round metric on $S^3/\Gamma$, where $\Gamma$ is a finite subgroup of SO(4), acting freely on $S^3$.

Thus, the Ricci flow "geometrizes" 3-manifolds of positive Ricci curvature. There are two further important structural results on the Ricci flow.

*Curvature pinching estimate* (Hamilton 1982, Ivey 1993). For $g(t)$ a solution to the Ricci flow on a closed 3-manifold $M$, there is a nonincreasing function $\phi : (-\infty, \infty) \to \mathbb{R}$, tending to 0 at $\infty$, and a constant $C$, depending only on $g(0)$, such that,

$$\text{Riem}(x,t) \geq -C - \phi(R(x,t)) \cdot |R(x,t)| \qquad [6]$$

This estimate does not imply a lower bound on $\text{Riem}(x,t)$ uniform in time. However, when combined with the fact that the scalar curvature $R(x,t)$ is uniformly bounded below (cf. [3]), it implies that $|\text{Riem}|(x,t) \gg 1$ only where $R(x,t) \gg 1$. To control the size of $|\text{Riem}|$, it thus suffices to obtain just an upper bound on $R$. This is remarkable, since the scalar curvature is a much weaker invariant of the metric than the full curvature. Moreover, at points where the curvature is sufficiently large, [6] shows that $\text{Riem}(x,t)/R(x,t) \geq -\delta$, for $\delta$ small. Thus, if one scales the metric to make $R(x,t) = 1$, then $\text{Riem}(x,t) \geq -\delta$. In such a scale, the metric then has almost non-negative curvature near $(x,t)$.

*Harnack estimate* (Hamilton 1982). Let $(N, g(t))$ be a solution to the Ricci flow with bounded and non-negative curvature $\text{Riem} \geq 0$, and suppose $g(t)$ is a complete Riemannian metric on $N$. Then for $0 < t_1 \leq t_2$,

$$R(x_2,t_2) \geq \frac{t_1}{t_2}\exp\left(-\frac{d_{t_1}^2(x_1,x_2)}{2(t_2-t_1)}\right)R(x_1,t_1) \qquad [7]$$

where $d_{t_1}$ is the distance function on $(M, g_{t_1})$. This allows one to control the geometry of the solution at different spacetime points, given control at an initial point.

## Singularity Formation

The deeper analysis of the Ricci flow is concerned with the singularities that arise in finite time. Equation [3] shows that the Ricci flow will not exist for arbitrarily long time in general. In the case of initial metrics with positive Ricci curvature, this is resolved by rescaling the Ricci flow to constant volume. However, the general situation is necessarily much more complicated. For example, any manifold which is a connected sum of $S^3/\Gamma$ or $S^2 \times S^1$ factors has metrics of positive scalar curvature. For obvious

topological reasons, the volume normalized Ricci flow then cannot converge nicely to a round metric; even the renormalized flow must develop singularities.

The usual method to understand the structure of singularities, particularly in geometric PDEs, is to rescale or renormalize the solution on a sequence converging to the singularity to make the solution bounded, and try to pass to a limit of the renormalization. Such a limit solution models the singularity formation, and one hopes (or expects) that the singularity models have special features making them much simpler than an arbitrary solution of the flow.

A singularity forms for the Ricci flow only where the curvature becomes unbounded. Suppose then that $\lambda_i^2 = |\mathrm{Riem}|(x_i, t_i) \to \infty$, on a sequence of points $x_i \in M$, and times $t_i \to T < \infty$. Consider the rescaled or blow-up metrics and times

$$\bar{g}_i(\bar{t}_i) = \lambda_i^2 \phi_i^* g(t), \quad \bar{t}_i = \lambda_i^2 (t - t_i) \qquad [8]$$

where $\phi_i$ are diffeomorphisms giving local dilations of the manifold near $x_i$ by the factor $\lambda_i$.

The flow $\bar{g}_i$ is also a solution of the Ricci flow, and has bounded curvature at $(x_i, 0)$. For suitable choices of $x_i$ and $t_i$, the curvature will be bounded near $x_i$, and for nearby times to the past, $\bar{t}_i \le 0$; for example, one might choose points $(x_i, t_i)$ where the curvature is maximal on $(M, g(t)), t \le t_i$.

The rescaling [8] expands all distances by the factor $\lambda_i$, and time by the factor $\lambda_i^2$. Thus, in effect one is studying very small regions, of spatial size on the order of $r_i = \lambda_i^{-1}$ about $(x_i, t_i)$, and "using a microscope" to examine the small-scale features in this region on a scale of size about 1.

A limit solution of the Ricci flow, defined at least locally in space and time, will exist provided that the local volumes of the rescalings are bounded below (Gromov compactness). In terms of the original unscaled flow, this requires that the metric $g(t)$ should not be locally collapsed on the scale of its curvature, that is,

$$\mathrm{vol}\, B_{x_i}(r_i, t_i) \ge \nu r_i^n \qquad [9]$$

for some fixed but arbitrary $\nu > 0$. A maximal connected limit $(N, \bar{g}(\bar{t}), x)$ containing the base point $x = \lim x_i$, is then called a "singularity model." Observe that the topology of the limit $N$ may well be distinct from the original manifold $M$, most of which may have been blown off to infinity in the rescaling.

To see the potential usefulness of this process, suppose one does have local noncollapse on the scale of the curvature, and that base points of maximal curvature in space and time $t \le t_i$ have been chosen. At least in a subsequence, one then obtains a limit solution to the Ricci flow $(N, \bar{g}(\bar{t}), x)$, based at $x$, defined at least for times $(-\infty, 0]$, with $\bar{g}(\bar{t})$ a complete Riemannian metric on $N$. Such solutions are called ancient solutions of the Ricci flow. The estimate [6] shows that the limit has non-negative curvature in dimension 3, and so [7] holds on $N$. Thus, the limit is indeed quite special. The topology of complete manifolds $N$ of non-negative curvature is completely understood in dimension 3. If $N$ is noncompact, then $N$ is diffeomorphic to $\mathbb{R}^3, S^2 \times \mathbb{R}$, or a quotient of these spaces. If $N$ is compact, then a slightly stronger form of the space-form theorem implies $N$ is diffeomorphic to $S^3/\Gamma, S^2 \times S^1$, or $S^2 \times_{\mathbb{Z}_2} S^1$.

The study of the formation of singularities in the Ricci flow was initiated by Hamilton (1995). Recently, Perelman has obtained an essentially complete understanding of the singularity behavior of the Ricci flow, at least in dimension 3.

## Perelman's Work

### Noncollapse

Consider the Einstein–Hilbert action

$$\mathcal{R}(g) = \int_M R(g)\, \mathrm{d}V_g \qquad [10]$$

as a functional on $\mathbb{M}$. Critical points of $\mathcal{R}$ are Ricci-flat metrics. It is natural and tempting to try to relate the Ricci flow with the gradient flow of $\mathcal{R}$ (with respect to a natural $L^2$ metric on the space $\mathbb{M}$). However, it has long been recognized that this cannot be done directly. In fact, the gradient flow of $\mathcal{R}$ does not even exist, since it implies a backwards heat-type equation for the scalar curvature $R$ (similar to [3] but with a minus sign before $\Delta$).

Consider however the following functional extending $\mathcal{R}$:

$$\mathcal{F}(g, f) = \int_M (R + |\nabla f|^2) \mathrm{e}^{-f}\, \mathrm{d}V_g \qquad [11]$$

as a functional on the larger space $\mathbb{M} \times C^\infty(M, \mathbb{R})$, or equivalently a family of functionals on $\mathbb{M}$, parametrized by $C^\infty(M, \mathbb{R})$. The functional [11] also arises in string theory as the low-energy effective action; the scalar field $f$ is called the dilaton. Fix any smooth measure $\mathrm{d}m$ on $M$ and define the Perelman coupling by requiring that $(g, f)$ satisfy

$$\mathrm{e}^{-f}\, \mathrm{d}V_g = \mathrm{d}m \qquad [12]$$

The resulting functional

$$\mathcal{F}^m(g, f) = \int_M (R + |\nabla f|^2)\, \mathrm{d}m \qquad [13]$$

becomes a functional on $\mathbb{M}$. (This coupling does not appear to have been considered in string theory.) The $L^2$ gradient flow of $\mathcal{F}^m$ is given simply by

$$\frac{\mathrm{d}\widetilde{g}}{\mathrm{d}t} = -2(\mathrm{Ric}_{\widetilde{g}} + \widetilde{D}^2 f) \qquad [14]$$

where $\widetilde{D}^2 f$ is the Hessian of $f$ with respect to $\widetilde{g}$. The evolution equation [14] for $\widetilde{g}$ is just the Ricci flow [2] modified by an infinitesimal diffeomorphism: $\widetilde{D}^2 f = (\mathrm{d}/\mathrm{d}t)(\phi_t^* \widetilde{g})$, where $(\mathrm{d}/\mathrm{d}t)\phi_t = \widetilde{\nabla} f$. Thus, the gradient flow of $\mathcal{F}^m$ is the Ricci flow, up to diffeomorphisms. The evolution equation for the scalar field $f$,

$$f_t = -\widetilde{\Delta} f - \widetilde{R} \qquad [15]$$

is a backward heat equation (balancing the forward evolution of the volume form of $\widetilde{g}(t)$). Thus, this flow will not exist for general $f$, going forward in $t$. However, one of the basic points of view is to let the (pure) Ricci flow [2] flow for a time $t_0 > 0$. At $t_0$, one may then take an arbitrary $f = f(t_0)$ and flow this $f$ backward in time $(\tau = t_0 - t)$ to obtain an initial value $f(0)$ for $f$. The choice of $f(t_0)$ determines, together with the choice of volume form of $g(0)$), (or $g(t_0)$), the measure $\mathrm{d}m$ and so the choice of $\mathcal{F}^m$. The process of passing from $\mathcal{F}$ to $\mathcal{F}^m$ corresponds to a reduction of the symmetry group of all diffeomorphisms $\mathcal{D}$ of $\mathcal{F}$ to the group $\mathcal{D}_0$ of volume-preserving diffeomorphisms; the quotient space $\mathcal{D}/\mathcal{D}_0$ has been decoupled into a space $C^\infty(M, \mathbb{R})$ of parameters.

The functionals $\mathcal{F}^m$ are not scale invariant. To achieve scale invariance, Perelman includes an explicit insertion of the scale parameter, related to time, by setting

$$\mathcal{W}(g, f, \tau) = \int \Big(\tau(|\nabla f|^2 + R) + f - n\Big) \times (4\pi\tau)^{-n/2}\, \mathrm{e}^{-f}\, \mathrm{d}V \qquad [16]$$

with coupling so that $\mathrm{d}m = (4\pi\tau)^{-n/2}\, \mathrm{e}^{-f}\, \mathrm{d}V$ is fixed. The entropy functional $\mathcal{W}$ is invariant under simultaneous rescaling of $\tau$ and $g$, and $\tau_t = -1$. Again, the gradient flow of $\mathcal{W}$ is the Ricci flow modulo diffeomorphisms and rescalings and the stationary points of the gradient flow are the gradient Ricci solitons,

$$\mathrm{Ric}_g + D^2 f - \frac{1}{2\tau} g = 0$$

for which the metrics evolve by diffeomorphisms and rescalings. Gradient solitons arise naturally as singularity models, due to the rescalings and diffeomorphisms in the blow-up procedure [8]. An important example is the cigar soliton on $\mathbb{R}^2 \times \mathbb{R}$, (or $\mathbb{R}^2 \times S^1$),

$$g = (1 + r^2)^{-1} g_{\mathrm{Eucl}} + \mathrm{d}s^2 \qquad [17]$$

Perelman then uses the scalar field $f$ to probe the geometry of $g(t)$. For instance, the collapse or noncollapse of the metric $g(t)$ near a point $x \in M$ can be detected from the size of $\mathcal{W}(g(t))$ by choosing $\mathrm{e}^{-f}$ to be an approximation to a delta function centered at $(x, t)$. The more collapsed $g(t)$ is near $x$, the more negative the value of $\mathcal{W}(g(t))$. The collapse of the metric $g(t)$ on any scale in finite time is then ruled out by combining this with the fact that the entropy functional $\mathcal{W}$ is increasing along the Ricci flow.

Much more detailed information can be obtained by studying the path integral associated to the evolution equation [15] for $f$, given by

$$\mathcal{L}(\gamma) = \int_\gamma \sqrt{\tau}[|\dot{\gamma}(\tau)|^2 + R(\gamma(\tau))]\, \mathrm{d}\tau$$

where $R$ and $|\dot{\gamma}(\tau)|$ are computed with respect to the evolving metrics $g(\tau)$. In particular, the study of the geodesics and the associated variational theory of the length functional $\mathcal{L}$ are important in understanding the geometry of the Ricci flow near the singularities.

## Singularity Models

A major accomplishment of Perelman is essentially a classification of all complete singularity models $(N, g(t))$ that arise in finite time. In the simple case where $N$ is compact, then as noted above, $N$ is diffeomorphic to $S^3/\Gamma$, $S^2 \times S^1$, or $S^2 \times_{\mathbb{Z}_2} S^1$.

In the much more important case where $N$ is complete and noncompact, Perelman proves that the geometry of $N$ near infinity is that of a union of $\varepsilon$-necks. Thus, at time 0, and at points $x$ with $r(x) = \mathrm{dist}(x, x_0) \gg 1$, for a fixed base point $x_0$, a region of radius $\varepsilon^{-1}$ about $x$, in the scale where $R(x) = 1$, is $\varepsilon$-close to such a region in the standard round product metric on $S^2 \times \mathbb{R}$; $\varepsilon$ may be made arbitrarily small by choosing $r(x)$ sufficiently large. For example, this shows that the cigar soliton [17] cannot arise as a singularity model. Moreover, this structure also holds on a time interval on the order of $\varepsilon^{-1}$ to the past, so that on such regions the solution is close to the (backwards) evolving Ricci flow on $S^2 \times \mathbb{R}$.

Perelman shows that this structural result for the singularity models themselves also holds for the solution $g(t)$ very near any singularity time $T$. Thus, at any base point $(x, t)$ where the curvature is sufficiently large, the rescaling as in [8] of the spacetime by the curvature is smoothly close, on large compact domains, to corresponding large domains in a complete singularity model. The "ideal" complete singularity models do actually describe the geometry and topology near any singularity. Consequently, one has a detailed understanding of the small-scale geometry and topology in a neighborhood of every point where the curvature is large on $(M, g(t))$, for $t$ near $T$.

The main consequence of this analysis is the existence of canonical, almost round 2-spheres $S^2$ in any region of $(M, g(t))$ where the curvature is sufficiently large; the radius of the $S^2$'s is on the order of the curvature radius. One then disconnects the manifold $M$ into pieces, by cutting $M$ along a judicious choice of such 2-spheres, and gluing in round 3-balls in a natural way. This surgery process allows one to excise out the regions of $(M, g(t))$ where the Ricci flow is almost singular, and thus leads to a naturally defined Ricci flow with surgery, valid for all times $t \in [0, \infty)$.

The surgery process disconnects the original connected 3-manifold $M$ into a collection of disjoint (connected) 3-manifolds $M_i$, with the Ricci flow running on each. However, topologically, there is a canonical relation between $M$ and the components $M_i$; $M$ is the connected sum of $\{M_i\}$. An analysis of the long-time behavior of the volume-normalized Ricci flow confirms the expectation that the flow approaches a fixed point, that is, an Einstein metric, or collapses along 3-manifolds admitting an $S^1$ fibration. This then leads to the proof of Thurston's geometrization conjecture for 3-manifolds and consequently the proof of the Poincaré conjecture. It gives a full classification of all closed 3-manifolds, much like the classification of surfaces given by the classical uniformization theorem.

## Introduction

Dynamical systems first developed from the geometry of Newton's equations (see Goodstein and Goodstein (1997)) and the question of the stability of the solar system motivated further researches inspired by celestial mechanics (cf. Siegel and Moser (1971)). Then dynamical systems developed intensively from stability theory (Lyapunov's theory) to generic properties (based on functional analysis techniques,) hyperbolic structures (Anosov's flows, Smale axiom A) and to perturbation theory (Pugh's closing lemma, KAM theorem). There are many links with ergodic theory dating back to Birkhoff's ergodic theorem (motivated by Boltzmann–Gibbs contributions to thermodynamics). These aspects have been developed in several articles of the encyclopedia (*see* Generic Properties of

Dynamical Systems; Ergodic Theory; Hyperbolic Dynamical Systems). This article develops another aspect of dynamical systems, namely bifurcation theory. In contrast, the mathematics involved relates more to local analytic geometry in the broad sense and provides local models like normal forms, uses blow-up techniques and asymptotic developments. This contains the singularity theory of functions (related to singularities of gradient flows). A recent development of the whole subject deals with bifurcation theory of fast-slow systems.

## Singularity Theory of Functions

A singular point of a gradient dynamics

$$\frac{\mathrm{d}x}{\mathrm{d}t} = \operatorname{grad} V(x)$$

is a critical point of the function $V$. Assume that the function $V: U \to R$ is defined and infinitely differentiable on an open set $U$. Let $x_0 \in U$ be a critical point of $V$.

**Definition 1** The critical point $x_0$ is said to be of Morse type if the Hessian of $V$ at $x_0 : D_x^2 V(x_0)$ is of maximal rank $n$. The corank of a singular point $x_0$ is the corank of the matrix $D_x^2 V(x_0)$.

Denote by O the local ring of germs of $C^\infty$ functions at point $x_0$.

**Definition 2** The Jacobian ideal of the function $V$ at $x_0$, denoted as Jac(V), is the ideal generated in the ring $O$ by the partial derivatives of $V: \partial V/\partial x_i, i = 1, \ldots, n$, considered as elements of the local ring $O$.

The singularity (or the singular point) is isolated if

$$\dim_R O/\mathrm{Jac}(V) < \infty$$

In that case, the Milnor number is defined as the dimension

$$\mu = \dim_R O/\mathrm{Jac}(V)$$

Local models of singularities at a point are simple expressions that germs of functions singular at this point have in local coordinates.

R Thom proposed to focus more particularly on the singularities whose Milnor number is less than or equal to 4 and whose corank is less than or equal to 2.

The list of local models $V_\lambda(x)$ of functions whose singularities at 0 display a Milnor number less than or equal to 4 and a corank less than or equal to 2 is the following:

$V_\lambda(x) = \frac{1}{3}x^3 + \lambda_1 x$, the *fold*,
$V_\lambda(x) = \frac{1}{4}x^4 + \frac{1}{2}\lambda_1 x^2 + \lambda_2 x$, the *cusp*,
$V_\lambda(x) = \frac{1}{5}x^5 + \frac{1}{3}\lambda_1 x^3 + \frac{1}{2}\lambda_2 x^2 + \lambda_3 x$, the *swallow tail*,
$V_\lambda(x) = \frac{1}{6}x^6 + \frac{1}{4}\lambda_1 x^4 + \frac{1}{3}\lambda_2 x^3 + \frac{1}{2}\lambda_3 x^2 + \lambda_4 x$, the *butterfly*,
$V_\lambda(x) = x^3 - 3xy^2 + \lambda_1(x^2 + y^2) + \lambda_2 x + \lambda_3 y$, the *elliptic umbilic*,
$V_\lambda(x) = x^3 + y^3 + \lambda_1 xy + \lambda_2 x + \lambda_3 y$, the *hyperbolic umbilic*, and
$V_\lambda(x) = y^4 + x^2 y + \lambda_1 x^2 + \lambda_2 y^2 + \lambda_3 x + \lambda_4 y$, the *parabolic umbilic*.

Consider more particularly the first four cases. The "state equation" defines the critical points of $V_\lambda$:

$$\frac{\partial V_\lambda}{\partial x} = 0$$

which contains the subset of the stable equilibrium points of the associated gradient dynamics. The nature of these equilibrium states changes at points contained in the set defined by the equation

$$\frac{\partial^2 V_\lambda}{\partial x^2} = 0$$

The projection of this set on the space of parameters contains the set of values of the parameters for which the equilibrium position is susceptible to change of topological type (in other terms to undergo a bifurcation). This set is called the catastrophe set (see Figure 1).

Consider now the case of umbilics where there are two state equations:

$$\frac{\partial V}{\partial x} = \frac{\partial V}{\partial y} = 0$$

The catastrophe set $S$ is determined by one further equation:

$$\text{Hess } V = \frac{\partial^2 V}{\partial x^2}\frac{\partial^2 V}{\partial y^2} - \left(\frac{\partial^2 V}{\partial x \partial y}\right)^2 = 0$$

In both cases of hyperbolic and elliptic umbilics, the set $S$ is a singular surface. For the last case of the parabolic umbilic, the set $S$ is of dimension 3 and again it is only possible to represent it by a family of its sections by a variable hyperplane (see Figure 2).

All possible deformations (in the space of functions) of a function with an isolated singularity can be induced by a single $\mu$-dimensional family of deformations named the "universal deformation." In general, the "codimension" of a bifurcation is the minimal number of parameters needed to display all possible phase diagrams of all possible unfoldings. Several deep mathematical techniques, like the Malgrange division theorem and preparation theorem, allowed J Mather to prove the theorem (local, then global) of existence of the universal unfolding.

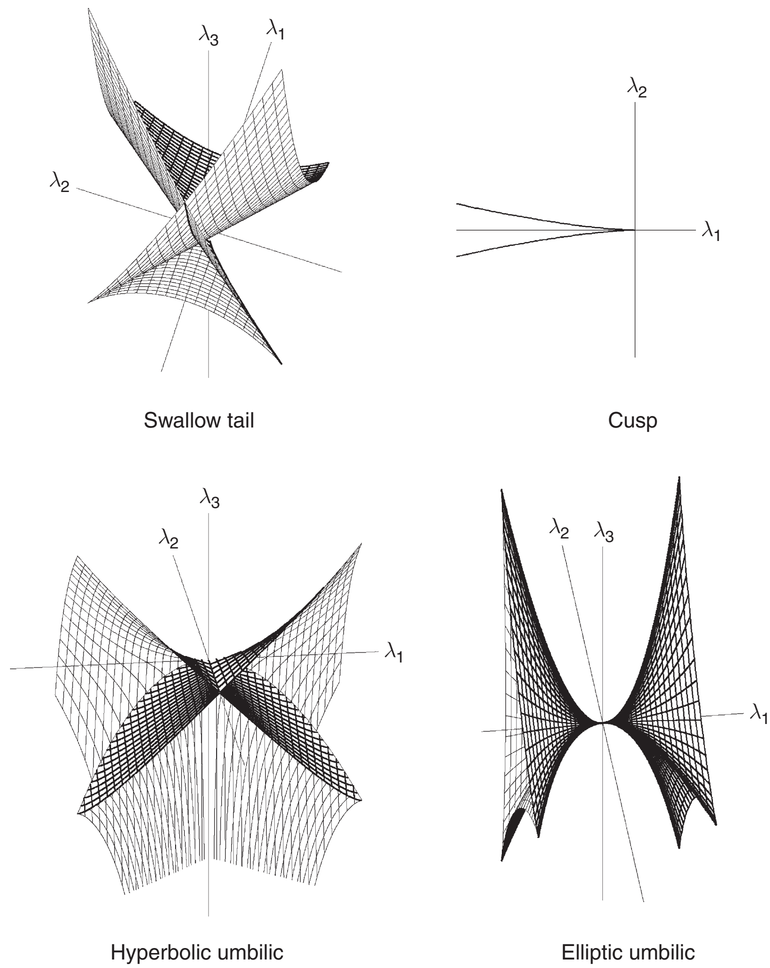

**Figure 1** Examples of catastrophe sets. Adapted with permission from Françoise J-P (2005) *Oscillations en Biologie: Analyse Qualitative et Modèles* (Mathématiques et Applications, vol. 46). Heidelberg: Springer.

The theory of unfoldings of singularities can be used, for instance, to provide asymptotic expression of stationary phase integrals when critical points of the phase are not of Morse type. This relates to monodromy, Bernstein polynomials, Milnor fibration near a singular point, and simultaneous local models of forms and functions (cf. Malgrange (1974)) and *see* Feynman Path Integrals).

## Singularity Theory of Vector Fields

### Transcritical Bifurcation

The transcritical bifurcation is the standard mechanism for changes in stability. The local model is given by

$$\dot{x} = rx - x^2$$

For $r < 0$, there is an unstable fixed point at $x^* = r$ and a stable fixed point at $x^* = 0$. As $r$ increases, the unstable and the stable fixed points coalesce when $r = 0$ and when $r > 0$, they exchange their stability. A simplified model of the essential physics of a laser is due to Haken (1983). It is given by

$$\dot{n} = GnN - kn$$

were $n$ is the number of photons in the laser field, $N$ is the number of excited atoms, and the gain term comes from the process of stimulated emission which occurs at a rate proportional to the product $n.N$. Furthermore, the number of excited atoms drops down by the emission of photons $N = N_0 - \alpha n$. Then we obtain

$$\dot{n} = (GN_0 - k)n - \alpha G n^2$$

This model displays a transcritical bifurcation, which explains in elementary terms the laser threshold.

### Pitchfork Bifurcation

The local model for supercritical pitchfork bifurcation is

$$\dot{x} = rx - x^3$$

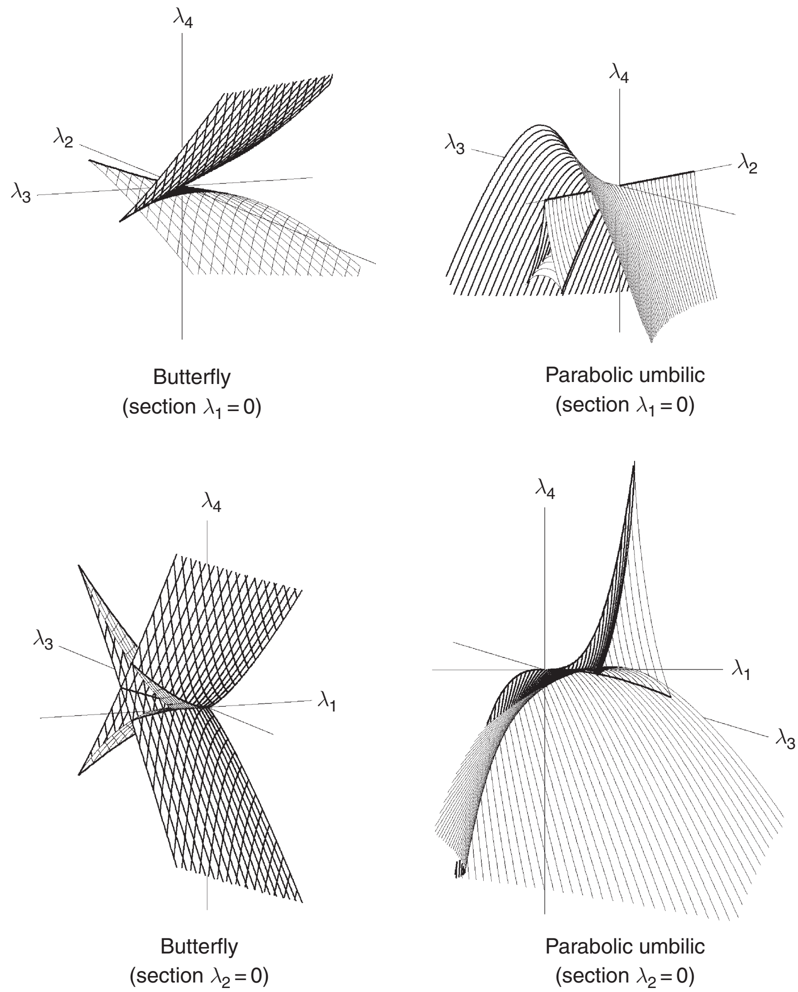

**Figure 2** Sections of catastrophe sets. Adapted with permission from Françoise J-P (2005) *Oscillations en Biologie: Analyse Qualitative et Modèles* (Mathématiques et Applications, vol. 46). Heidelberg: Springer.

When the parameter $r < 0$, it displays one stable equilibrium position. As $r$ increases, this equilibrium bifurcates (for $r > 0$) into two stable equilibria and an unstable equilibrium. Its drawing suggests "the pitchfork." In case of subcritical pitchfork bifurcation

$$\dot{x} = rx + x^3$$

there is a single stable state for $r < 0$ that bifurcates into two stable states and one unstable as $r > 0$.

### Normal Forms

Local analysis of vector fields proceeds with local models called normal forms. A local vector field near a singular point (zero) is seen as a derivation of the local ring of functions which preserves the unique maximal ideal (of the functions which vanish at the singular point). It yields a linear operator of the finite-dimensional vector spaces of truncated Taylor expansions of functions. This leads to decomposition of the vector fields into semisimple and nilpotent parts (at the level of formal series). A normal form is a formal coordinate system in which the semisimple part is linear. If the vector field preserves a structure (like volume form or symplectic form) the change of coordinates which brings it to its normal form is also (volume-preserving, symplectic). The simplicity of the normal form depends on the number of allowed resonances for the eigenvalues of the first-order jet of the vector field at the singular point. The best-known example is the Birkhoff normal form of Hamiltonian vector fields that we recall now, but we should also mention the Sternberg normal form of volume-preserving vector fields.

Local analysis of a Hamiltonian vector field under symplectic changes of coordinates is the same as the local analysis of functions (namely its associated Hamiltonian). Birkhoff normal form deals with the

case of a Hamiltonian that is a perturbation at the origin:

$$H_0(p) = \sum_{j=1}^{m} \lambda_j p_j$$

$$p_j = x_j^2 + y_j^2, \quad j = 1, \ldots, m$$

where the symplectic form is

$$\omega = \sum_{j=1}^{m} \mathrm{d}x_j \wedge \mathrm{d}y_j$$

If the eigenvalues $\lambda_j$ are assumed to be independent over the integers (no resonances), then there is a formal system of symplectic coordinates $\hat{p}_j, \hat{q}_j$, $j = 1, \ldots, m$, called action-angle variables, in which the Hamiltonian only depends of the action variables $\hat{p}_j$. Such a coordinate system is generically divergent because, under generic assumptions on the 3-jet of the Hamiltonian, the system displays isolated periodic orbits in any neighborhood of the origin (see Moser, Vey, Francoise). Normal forms are normally used in applications (e.g., Nekhoroshev theorem, Hopf bifurcation theorem) in their truncated versions. Birkhoff normal form was conjectured (A Weinstein) to enter in the asymptotic expansion of the fundamental solution of the wave equation on a Riemannian manifold near elliptic geodesics. This conjecture was recently proved by V Guillemin.

### Stability Theory of Hamiltonian Systems, Nekhoroshev Theorem, Arnol'd Diffusion

The generic divergence of the Birkhoff normal form does not allow one to conclude about the stability of the elliptic singular point. In the case where it is convergent, the motion is trapped inside invariant tori (conservation of the actions). The KAM theorem (see Gallavotti (1983)) provides the existence of many invariant tori but, except in low dimensions, this does not exclude the existence of trajectories that would escape to infinity. Arnol'd indeed provided a mechanism and examples of such situations (this is now called Arnol'd diffusion) (*see* Introductory Articles: Classical Mechanics). This diffusion process needs some time, which is estimated below by a theorem of Nekhoroshev.

Consider the Hamiltonian

$$H_\epsilon(p, q) = h(p) + \epsilon f(p, q)$$

where $h(p)$ is strictly convex, analytic, anisochronous on the closure $\overline{U}$ of an open bounded region $U$ of $R^m$ and the perturbation $f(p, q)$ is analytic on $\overline{U} \times R^m$. Nekhoroshev's theorem tells that there are positive constants $a, b, d, g, \tau$ such that for any initial data $p_0, q_0$, the actions $p$ do not change by more than $a\epsilon^g$ before a time bounded below by $\tau e^{b/\epsilon^d}$ (see Gallavotti (1983)).

### Bifurcations of Periodic Orbits

Consider a one-parameter family of vector fields $X_\lambda$ of class $C^k, k \geq 3$,

$$\dot{x} = F(x, \lambda)$$

Assume that $X_\lambda(0) = 0$ and that the linear part of the vector field at 0 has two complex-conjugated eigenvalues $\mu(\lambda)$ and $\overline{\mu(\lambda)}$ such that $\mathrm{Re}(\mu(\lambda)) > 0$ for $\lambda > 0, \mathrm{Re}(\mu(0)) = 0$ and $(\mathrm{Re}(\mu(\lambda)))/d\lambda|_{\lambda=0} \neq 0$. Then, for $\lambda > 0$ but small enough, the vector field $X_\lambda$ has a periodic orbit $\gamma_\lambda$ which tends to 0 as $\lambda$ tends to 0.

This bifurcation of codimension 1 is named Hopf bifurcation and it occurs in many models.

When several oscillators (conservative or dissipative) are weakly coupled, they may display frequency locking (existence of an attractive periodic orbit) phase locking, and synchronization. The fact that we always see the same face of the Moon from the Earth can be explained by a synchronization of the rotation of the Moon onto itself with its rotation around the Earth. Synchronization also plays a fundamental role in living organisms (e.g., heart, population dynamics: see D Attenborough's movie "The Trials of Life"). It is sometimes possible to be convinced of synchronization via computer experiments, but the main theoretical approach is due to Malkin. *See* Bifurcations of Periodic Orbits, where a full mathematical proof is included.

### Homoclinic Bifurcation, Newhouse's Phenomenon

Homoclinic bifurcation occurs in the family $X_\lambda$ at the bifurcation value of the parameter $\lambda = 0$ if $X_0$ displays a singular orbit which tends to 0 both for $t \to +\infty$ and for $t \to -\infty$. In dimension 2, if $\lambda$ is slightly deformed around 0, one periodic orbit may appear (or disappear). For planar systems, the Bogdanov–Takens bifurcation is the codimension-2 bifurcation, which mixes the homoclinic and the Hopf bifurcations. In dimension 3, more complicated phase diagrams may occur (such as in the Shilnikov bifurcation) with the appearance of infinitely many periodic orbits or homoclinic loops (in a stable way: Newhouse phenomenon). This eventually gives rise to strange attractors (the Roessler attractor).

### The Poincaré Center-Focus Problem, Local Hilbert's 16th Problem, Abel Equations, Algebraic Moments

Hopf bifurcation theory for two-dimensional systems deals with the first case of a general situation

often referred to as degeneracies of Hopf bifurcations or alternatively Hopf–Takens bifurcations. Consider more generally a planar vector field, tangent at the origin to a linear focus:

$$\dot{x} = y + \mu x + f(x, y)$$
$$\dot{y} = -x + \mu y + g(x, y)$$

The Poincaré center-focus problem asks for necessary and sufficient conditions on the perturbation terms so that all orbits are periodic in a neighborhood of the origin. This problem is still pending in the case, for instance, where $f$ and $g$ are homogeneous of degrees 4 and 5. It was solved a long time ago for degrees 2 and 3. Part (b) of Hilbert's 16th Problem asks for finding a bound in terms of the degrees of polynomial perturbations for the number of limit cycles (isolated periodic orbits) in the neighborhood of the origin. In the case of homogeneous perturbations, a Cherkas transformation allows the reduction of both problems to the so-called one-dimensional periodic Abel equations:

$$\mathrm{d}y/\mathrm{d}x = p(x)y^2 + q(x)y^3$$

where $p$ and $q$ are trigonometric polynomials in $x$. A perturbative approach was developed for several years and yields a theory of algebraic moments related to Livsic's generalized problem of moments.

## Fast–Slow Systems

Fast–slow systems

$$\epsilon\,\dot{x} = f(x, y), \qquad \dot{y} = g(x, y)$$

are characterized by the existence of two timescales. Variables $x$ are called fast variables and $y$ are called slow variables. Different approximation techniques can be used (averaging method, multiscale approach (*see* Multiscale Approaches)). The behavior of solutions is approximated as follows (when the scale $\epsilon$ is small). The orbit jumps to an attractor of the fast dynamics. This attractor may eventually lose its stability and/or bifurcate as time evolves. Then the orbit jumps to another attractor of the fast dynamics. Once again, this attractor may evolve/bifurcate/disappear, depending on the slow variables $y$. This explains why bifurcation theory enters in the process in a crucial way, and it has to be adapted to this special context where some new phenomena may occur (e.g., singular Hopf bifurcation theory, Canards, etc.). Fundamental tools to be used in this context are Takens theorem, Fenichel central manifold theorem, blowing-up (Dumortier–Roussarie).

Excitability is also an important feature which occurs in some fast–slow systems. Consider initial data in a neighborhood of an excitable attractive point. For some initial data, the orbit goes very quickly to the attractor. For some others instead (usually below some threshold), the orbit undergoes a long incursion in the phase diagram before turning back to the attractive point.

Singular Hopf bifurcation, hysteresis, and excitability can, for instance, occur in the electrodissolution and passivation of iron in sulfuric acid (see Alligood *et al.* (1997)).

Sometimes, the orbit leaves the neighborhood of a first attractor to jump to a second one and then this second one disappears and the orbit jumps back to the initial attractor as the slow variables have undergone a cycle. This is called a hysteresis cycle. In case one of the attractors is a point while the other is an attractive periodic orbit, it may lead to bursting oscillations. These oscillations are characterized by the periodic succession of silent phases (attractor of the fast dynamics) and active (pulsatile) phases (periodic attractor of the fast dynamics). They are ubiquitous in physiology, where they were first discovered and can be also observed in physics (laser beams) and in population dynamics.

### Example

The Hindmarsh–Rose model displays bursting oscillations:

$$\epsilon\dot{x} = y - x^3 + 3x^2 + I - z$$
$$\epsilon\dot{y} = 1 - 5x^2 - y$$
$$\dot{z} = s(x - x_1) - z$$

The fast dynamics is two dimensional. For some values of the parameters, it displays an attractive node, a saddle and a repulsive focus. Under the slow variation of $z$, the fast dynamics displays a saddle–node bifurcation, a Hopf bifurcation from which emerges a stable limit cycle which disappears into a homoclinic bifurcation. The fast–slow system undergoes a hysteresis loop which yields to bursting oscillations.

## Conclusions

Over the past three decades, mathematical techniques gathered under the names of singularity theory and bifurcation theory of dynamical systems have offered a powerful means to explore nonlinear phenomena in diverse settings. These include mechanical vibrations, lasers, superconducting circuits, and chemical oscillators. Many such instances are further developed in this encyclopedia.

# Solitons and Kac–Moody Lie Algebras

**E Date**, Osaka University, Osaka, Japan

## Introduction

Solitons and Kac–Moody Lie algebras were born at almost the same time in the 1960s, although they did not have a connection at first. They both have roots in the history of mathematics. From the 1970s on, they became intersection points for many (previously known and new) results.

The notion of solitons has many facets and it is difficult to give a mathematically precise definition; closely related to solitons is the notion of "completely integrable systems." The latter is usually used in a much broader sense.

The terminology "soliton" was originally used for a particular phenomenon in shallow water waves. Now, in its broadest sense, it is used to represent an area of research relating to this particular phenomenon in direct or indirect ways. From the viewpoint of solitons, particular solutions of differential equations are of special interest. Although particular solutions have been studied for a long time, interest in them was overshadowed by the method of functional analysis in the 1950s. In the late nineteenth century, in parallel with the theory of algebraic functions, several studies undertook the solution of mechanical problems by elliptic or hyperelliptic integrals. Subsequently, however, there was a drop in activity in this area of work.

Originally it was hoped that this kind of phenomenon could be used for practical applications. No mention of practical application of solitons will be made in this article.

First we list several topics which constitute the main body of the notion of solitons in the early stages; we will then explain relations with Kac–Moody Lie algebras.

## Birth of Solitons

The name "soliton" itself was coined by Martin D Kruskal around 1965. It was originally employed for the solitary wave solution Korteweg–de Vries (KdV) equation

$$u_t - \frac{1}{4}(6uu_x + u_{xxx}) = 0, \quad u = u(x,t) \qquad [1]$$

The coefficients here are not important. We can change them arbitrarily. The unknown function $u$, or rather $-u$, represents the height of the wave.

The solitary wave solution in question is given by

$$u(x,t) = -2c\ \mathrm{sech}^2\left(\sqrt{c}(x - ct - d)\right) \qquad [2]$$

This is a traveling-wave solution with the height of the wave proportional to the speed. This is one feature of the nonlinearity of this differential equation.

A reason for this nomenclature comes from the particle-like property of solitary wave observed via numerical computations. That is, if we have two solitons [2] with different speeds, with the faster one on the left and the slower one on the right, then after some time they collide and their shapes are distorted. After a long enough time, they are separated and recover their original shapes, the only difference being in the change of the phase shift $d$ in [2].

Solitary waves in shallow water (like a canal) were first observed by Scott Russell in Scotland in the middle of the nineteenth century. Differential equations which possess solitary waves in shallow water as solutions were sought after Scott Russell's report. Boussinesq derived one (now called the Boussinesq equation, which contains second partial derivatives with respect to time) from the Euler equation of water wave; then in 1895 Korteweg and his student de Vries derived the KdV equation. They also showed that the KdV equation possesses solutions expressible in terms of elliptic functions.

In the 1960s Kruskal and Zabusky carried out numerical computations for the Fermi–Pasta–Ulam problem; they also came across the KdV equation and found the aforementioned phenomenon.

## Inverse-Scattering Method

Kruskal and his co-workers further pursued the origin of the particle-like property of solitons and proposed the so-called inverse-scattering method.

The inverse problem of scattering theory of the one-dimensional Schrödinger operator

$$L = -\left(\frac{\mathrm{d}}{\mathrm{d}x}\right)^2 + u(x)$$

was studied by Gelfand–Dikii, Marchenko, and Krein in the 1950s, motivated by scattering theory in quantum mechanics.

It gives a one-to-one correspondence between rapidly decreasing potentials $u(x)$ and scattering data which consist of discrete eigenvalues $-\eta_j^2$ and normalization $c_j, j = 1, \ldots, n$, of the eigenfunctions corresponding to them and the reflection coefficient $r(\xi)$. The reflection coefficient represents the ratio of reflection of the unit plane wave $\mathrm{e}^{\mathrm{i}\xi x}$ by the potential field. The scattering data $\{r(\xi), \eta_j, c_i, j = 1, \ldots, n\}$ are a mathematical idealization of observable data in quantum scattering. The procedure of reconstructing a potential from given scattering data is called the inverse problem. The heart of this procedure is solving an integral equation (the Gelfand–Dikii–Marchenko equation). In the reflectionless case ($r(\xi) = 0$), this integral equation reduces to a system of linear algebraic equations.

Kruskal and co-workers found that the scattering data of these operators with solutions of [1] as potentials depend very simply on $t$:

$$\begin{aligned} \eta_j(t) &= \eta_j(0), \qquad c_j(t) = c_j(0)\,\mathrm{e}^{2\mathrm{i}\eta^3 t} \\ r(\xi,t) &= r(\xi,0)\,\mathrm{e}^{2\mathrm{i}\xi^3 t} \end{aligned} \qquad [3]$$

It was realized at the same time that soliton solutions correspond to a reflectionless potential ($r(\xi) = 0$) with only one discrete eigenvalue, while reflectionless potentials correspond to a nonlinear "superposition" of soliton solutions (called multisoliton solutions) and describe the interaction of solitons.

As was pointed out by Zakharov and others, the inverse-scattering method has an intimate relation with the Riemann–Hilbert problem.

## Lax Representation

Looking at this invariance of the spectrum, Lax reformulated the KdV equation [1] as an evolution equation for the one-dimensional Schrödinger operator:

$$\begin{aligned} \frac{\mathrm{d}L}{\mathrm{d}t} &= [A, L], \quad L = \left(\frac{\mathrm{d}}{\mathrm{d}x}\right)^2 + u \\ A &= \left(\frac{\partial}{\partial x}\right)^3 + \frac{3}{4}\left(u\frac{\partial}{\partial x} + \frac{\partial}{\partial x}u\right) \end{aligned} \qquad [4]$$

Here we have changed the sign of the operator for later convenience. This form of representation together with the inverse-scattering method gave a framework for finding nonlinear differential (difference) equations that have solutions with properties similar to solitons (soliton equations).

Among such are the sine-Gordon equation

$$u_{tt} - u_{xx} = \sin u$$

the nonlinear Schrödinger equation

$$\mathrm{i}u_t + u_{xx} + |u|^2 u = 0$$

the modified KdV equation

$$u_t - \frac{1}{6}\left(6u^2 u_x + u_{xxx}\right) = 0$$

the Toda lattice equation

$$\begin{aligned}\frac{\mathrm{d}Q_n}{\mathrm{d}t} &= P_n \\ \frac{\mathrm{d}P_n}{\mathrm{d}t} &= -\exp(Q_n - Q_{n+1}) + \exp(Q_{n-1} - Q_n)\end{aligned} \qquad [5]$$

and so on. The first three are obtained by replacing $L$ by a $2 \times 2$ matrix differential operator of first order. For eqn [5], the linear operator corresponding to $L$ in the case of the KdV equation is a difference operator of order 2 and has a connection with the theory of orthogonal polynomials in one variable as well as with the theory of moment problems.

Later it was remarked that the differential operator $A$ in eqn [4] is nothing but the differential operator part of the fractional power of $L: A = (L^{3/2})_+$. By replacing $A$ in [4] by $(L^{(2n+1)/2})_+$ we obtain higher ($n$th) KdV equations.

## Basic Representations of Affine Lie Algebras

In the 1960s Kac and Moody introduced independently a class of infinite-dimensional Lie algebras which are in many respects close to finite-dimensional semisimple Lie algebras. Each of them is constructed for a given generalized Cartan matrix (GCM),

$$\begin{aligned}C = \left(a_{ij}\right), \quad a_{ii} = 2,\ a_{ij} \leq 0 \text{ for } i \neq j \\ \text{and if } a_{ij} = 0 \text{ then } a_{ji} = 0\end{aligned} \qquad [6]$$

There is a special class of Kac–Moody Lie algebras that are now called affine Lie algebras. They correspond to positive-semidefinite GCM and are realized as central extensions of loop algebras (current algebras)

$$\mathbf{C}[\lambda, \lambda^{-1}] \otimes \mathfrak{g}$$

of finite-dimensional semisimple Lie algebras $\mathfrak{g}$. They have many applications in physics, in particular as current algebras. The Sugawara construction in current algebra plays an essential role in conformal field theory. Note that finite-dimensional semisimple Lie algebras correspond to positive-definite GCMs.

In the late 1970s, there was interest in constructing representations of these algebras after the general theory of representations was constructed. Among them was the work of Lepowsky–Wilson, who constructed basic representations of the affine Lie algebra $A_1^{(1)} (= \widehat{\mathfrak{sl}}_2)$ using differential operators of infinite order in infinitely many variables. These operators were called vertex operators by Garland, in view of the resemblance to objects in string theory. Character formulas for these new Lie algebras were intensively studied and many combinatorial identities were (re)derived.

## Geometric Interpretation

How do Kac–Moody Lie algebras enter into this picture?

In the early stages of the history of solitons Kac–Moody Lie algebras appeared rather artificially. Some authors tried to understand solitons from geometric viewpoints. A typical example is the sine-Gordon equation. This equation appears as the Gauß–Codazzi equation in the theory of embeddings of two-dimensional surfaces of constant negative curvature into three-dimensional Euclidean space, while the Gauß–Weingarten equation is the linear equation that appears in the Lax representation of the sine-Gordon equation. Another approach of a geometric nature, involving the prolongation structure, was the direction initiated by Wahlquist–Estabrook. In this approach, the Lie algebra appeared in a natural way, although the nature of such Lie algebras was not so clear. This direction of research is close in spirit to the method of Cartan for treating partial differential equations.

Several authors considered generalizations of the Toda lattice equation. Bogoyavlenskii and others observed that the original Toda lattice equation [5] is related to the Cartan matrix of the affine Lie algebra of type $A$. Viewed in this way, it was straightforward to generalize the Toda lattice equation to Cartan matrices of another type of affine Lie algebras and also to ordinary Cartan matrices. These were typical appearances of Kac–Moody Lie algebras in the theory of solitons; they were used to produce soliton equations. The climax of this is the work of Drinfel'd–Sokolov.

It needed some time to understand another role of affine Lie algebras in the theory of solitons.

## Bäcklund Transformation

In the theory of two-dimensional surfaces of constant negative curvature, a method of obtaining another surface of constant negative curvature from the given one with some parameter was known by the work of Bäcklund. If we apply this to the trivial solutions $u = 0$ of the sine-Gordon equation, we

obtain a one-soliton solution of the sine-Gordon equation. From this fact, the transformation of solutions of soliton equations to other solutions is called a Bäcklund transformation. The original Darboux transformation is a special case of a Bäcklund transformation.

## Hamiltonian Formalism

Another discovery of Gardner–Greene–Kruskal–Miura was the Hamiltonian structure of the KdV equation. In the process of showing the existence of infinitely many conservation laws, they used the so-called Miura transformation, which relates the KdV and the modified KdV equation. Faddeev–Zakharov showed that the transformation to scattering data is a canonical transformation, and conserved quantities are obtained from the expansion of the reflection coefficients.

Gelfand–Dikii studied Hamiltonian structures of the KdV equation using the formal variational calculus they initiated.

M Adler was the first to try to study the KdV equation by using the orbit method known for finite-dimensional Lie algebras. It was known by the works of Kostant and Kirillov or even earlier by Lie that the co-adjoint orbits of Lie algebras admit symplectic structures (the Kostant–Kirillov bracket). Adler considered the algebra of pseudodifferential operators in one variable. This acquires the structure of Lie algebra by the commutation relation. This algebra admits a natural triangular decomposition by order. He showed that the KdV equation can be viewed as a Hamiltonian system in the co-adjoint orbit of the one-dimensional Schrödinger operator with the Kostant–Kirillov bracket. By introducing the notion of residue of pseudodifferential operators he rederived conserved quantities. The work of Drinfeld–Sokolov can be regarded as a thorough generalization of this direction. Hamiltonian structures of the KdV equation and other soliton equations are now understood in this way.

The method is also applicable to finite-dimensional Lie algebras. Symes, Kostant, and others treated the finite Toda lattice in this way.

The motion of tops, including that of Kovalevskaya, was also studied in this way.

## Hirota's Method

There was another approach to soliton equations, quite different from the above. This was the method initiated by Hirota. He placed stress on the form of multisoliton solutions of the KdV equation, the sine-Gordon equation, and so on. He made a dependent-variable transformation of the KdV equation [1],

$$u = 2\left(\frac{\mathrm{d}}{\mathrm{d}x}\right)\log f$$

This form naturally arises when we reconstruct the potential of the one-dimensional Schrödinger operator from the scattering data by solving the Gelfand–Dikii–Marchenko integral equation. In this new dependent variable, eqn [1] takes the following form:

$$\left(D_x^4 - 4D_x D_t\right) f(x,t)\cdot f(x,t) = 0$$

where the operator $D_x$ is defined by

$$D_x(f\cdot g) = \frac{\mathrm{d}}{\mathrm{d}x'} f(x+x')\, g(x-x')|_{x'=0} \qquad [7]$$

This operator is called Hirota's bilinear differential operator. In such transformed form, he tried to solve the resulting equation in a perturbative way,

$$\begin{aligned} f = 1 &+ \sum_{j=1}^{n} \exp(2p_j x + 2p^3 t + q_j) \\ &+ \sum_{1\le j<k\le n} c_{ij}\exp(2(p_j+p_k)x \\ &+ 2(p_j^3+p_k^3)t + q_j + q_k) + \cdots \end{aligned} \qquad [8]$$

It is rather miraculous that in the soliton equation case we can truncate such a perturbative procedure at a finite point. The number of steps corresponds to the number of solitons.

Most of the soliton equations are rewritten in bilinear form with such bilinear differentiation after a suitable dependent-variable transformation. (Some equations need several new dependent variables.) Once we have a differential equation in Hirota's bilinear differential form, it always has two-soliton solutions.

Up to 1980, keywords characterizing solitons were; inverse-scattering method, Bäcklund transformation, multisolitons, Hirota's method, quasi-periodic solutions, etc. No explicit mention was made of representation theory.

## Hierarchy of Soliton Equations

As was stated above, soliton equations viewed as Hamiltonian systems have infinitely many conservation laws. This implies that we can introduce infinitely many independent time variables consistently. From this viewpoint, it is natural to consider the KdV equation and its higher-order analogs simultaneously. They have many properties in common. For example, the $t$-dependence of the scattering data of the higher

KdV equation is given by replacing $\xi^3$ by $\xi^{2n+1}$ and $\eta_j^3$ by $\eta_j^{2n+1}$ in eqn [3]. The totality of soliton equations organized in this way is called a hierarchy of soliton equations; in the KdV case, it is called the KdV hierarchy. This notion of hierarchy was introduced by M Sato. He tried to understand the nature of the bilinear method of Hirota. First, he counted the number of Hirota bilinear operators of given degree for hierarchies of soliton equations. For the number of bilinear equations, M Sato and Y Sato made extensive computations and made many conjectures that involve eumeration of partitions.

## Kadomtsev–Petviashvili Hierarchy

Although it was included in a family of soliton equations slightly later, the Kadomtsev–Petviashvili (KP) equation is a soliton equation in three independent variables, which first appeared in plasma physics:

$$\tfrac{3}{4}u_{yy} - \left(u_t - \tfrac{1}{4}(6uu_x + u_{xxx})\right) = 0 \qquad [9]$$

For this equation we have to replace the Lax representation by

$$\left[\left(\frac{\partial}{\partial x}\right)^2 + u - \frac{\partial}{\partial y}, \left(\frac{\partial}{\partial x}\right)^3 + \frac{3}{2}u\frac{\partial}{\partial x} + v - \frac{\partial}{\partial t}\right] = 0 \qquad [10]$$

This form of representation was introduced by Zakharov–Shabat. Sometimes it is referred to as the zero-curvature representation or the Zakharov–Shabat representation. The KP equation is universal in the sense that it contains the KdV equation [1] and the Boussinesq equation as special cases. If $u$ does not depend on $y$, resp. $t$, this gives the KdV, resp. the Boussinesq equation.

## Work of Sato

Sato stressed the importance of the study of the KP equation. He first introduced the KP hierarchy. Instead of the one-dimensional Schrödinger operator in the KdV case consider a pseudo- (micro) differential operator of first order,

$$\begin{aligned} L &= \partial + u_2(x)\partial^{-1} + u_3(x)\partial^{-3} + \cdots \\ \partial &= \frac{\partial}{\partial x_1}, \quad x = (x_1, x_2, x_3, \ldots) \end{aligned} \qquad [11]$$

Setting $B_n = (L^n)_+$, the KP hierarchy is defined by the Zakharov–Shabat representation

$$\left[\frac{\partial}{\partial x_m} - B_m, \frac{\partial}{\partial x_n} - B_n\right] = 0, \quad m, n = 2, 3, \ldots$$

If we assume that $L^2$ is a differential operator, we have the KdV hierarchy and the constraint that $L^3$ is a differential operator gives the Boussinesq hierarchy. This process is called reduction.

Sato found that character polynomials (Schur functions) solve the KP hierarchy and, based on this observation, he created the theory of the infinite-dimensional (universal) Grassmann manifold and showed that the Hirota bilinear equations are nothing but the Plücker relations for this Grassmann manifold.

Sato also gave an (infinite-dimensional) determinantal formula for Hirota's dependent variable and called the latter the $\tau$-function. Using this $\tau$-function, the wave function (the eigenfunction corresponding to the KP hierarchy) is expressed as

$$\begin{aligned} w(x,k) &= \exp\left(\sum_{n=1}^{\infty} x_n k^n\right)\frac{\tau(x - \epsilon(k^{-1}))}{\tau(x)} \\ \epsilon(k) &= \left(k, \frac{k^2}{2}, \frac{k^3}{3}, \ldots\right) \\ Lw &= kw \end{aligned} \qquad [12]$$

where $L$ is given by eqn [11].

## Affine Lie Algebras as Infinitesimal Transformation Groups for Soliton Equations

Date–Jimbo–Kashiwara–Miwa found another relation among soliton equations and affine Lie algebras. After noticing some similarity between the formula in the paper by Lepowsky–Wilson on the Rogers–Ramanujan identity using the vertex operators for $A_1^{(1)}$ and the formula in the computation of numbers of bilinear operators in Sato's paper, they applied the vertex operator for $A_1^{(1)}$,

$$X(p) = \exp\left(\sum_{j=1}^{\infty} 2x_{2j-1}p^{2j-1}\right) \times \exp\left(-\sum_{j=1} \frac{2}{jp^{2j-1}}\frac{\partial}{\partial x_{2j-1}}\right)$$

to 1 (which is the simplest $\tau$-function for the KdV hierarchy), where $p$ is a parameter. They found that the result is the $\tau$-function corresponding to the one-soliton solution of the KP hierarchy. They also found that successive application of $X(p)$'s to 1 produced all multisoliton $\tau$-functions. Therefore, applications of vertex operators are precisely

Bäcklund transformations. This implies that the affine Lie algebra $A_1^{(1)}$ is the infinitesimal transformation group for solutions of the KdV hierarchy.

After this discovery, it was realized that the totality of $\tau$-functions of the KdV hierarchy is the group orbit of the highest weight vector (=1) of the basic representation of $A_1^{(1)}$.

The vertex operators for the KP hierarchy were also found:

$$X(p,q) = \exp\left(\sum_{j=1}^{\infty} x_j(p^j + q^j)\right) \times \exp\left(-\sum_{j=1}\left(\frac{1}{jp^j} + \frac{1}{jq^j}\right)\frac{\partial}{\partial x_j}\right)$$

If we put $q = -p$, the vertex operator for $A_1^{(1)}$ ([12]) is recovered.

Viewed in this way the Lie algebra corresponding to the KP hierarchy is $\mathfrak{gl}_\infty(=A_\infty)$. And an embedding of $A_1^{(1)}$ into $A_\infty$ was also found. Subsequently, the method using free fermions (Clifford algebras) was established. Frenkel–Kac had already used free fermions to construct basic representations. In this approach, the $\tau$-functions are defined as vacuum expectation values. Based on this connection with affine Lie algebras, many conjectures of Sato on the number of bilinear equations are (re)proved by using specialized characters of affine Lie algebras.

The use of free fermions was exploited by Ishibashi–Matsuo–Ooguri to relate soliton equations with conformal field theory on Riemann surfaces. This aspect was further studied by Tsuchiya–Ueno–Yamada using $D$-modules.

Once such a viewpoint was established, it was easy to construct soliton equations corresponding to other affine Lie algebras. Hierarchies similar to the KP hierarchies (the simplest equation contains three variables) were also found, which correspond to Lie algebras like $\mathfrak{go}_\infty, \mathfrak{sp}_\infty$ (the BKP hierarchy, the CKP hierarchy, and so on).

Summarizing these developments, we can say that affine Lie algebras, or slightly larger ones like $\mathfrak{gl}_\infty$, appear naturally as infinitesimal transformation groups for soliton equations and the solution spaces are the (completed) group orbits of highest weight vector $\tau$-functions of level-1 representations. The Hirota bilinear equations are the equations describing these orbits (analogs of Plücker relations).

Soon afterwards, the notion of $\tau$-functions was introduced in the study of Painlevé equations by Okamoto, revealing Hamiltonian structures in Painlevé equations.

## The Method of Drinfeld–Sokolov

The KdV or the KP hierarchies are related to scalar linear differential operators. A parallel treatment using matrix differential operators is also possible. In fact, the nonlinear Schrödinger equation, modified KdV equation, the sine-Gordon equation, etc., are treated in this way.

Drinfel'd and Sokolov gave a general framework along these lines. The first step is to choose the starting (matrix-valued) linear differential operator of order one. For that they use the language of Lie algebras.

Let us start with a matrix realization of a Lie algebra (for an affine Lie algebra, the elements are Laurent polynomials in one variable). Consider a linear differential operator of the following form:

$$L = \frac{\mathrm{d}}{\mathrm{d}x} + q(x) + \Lambda$$

where $q(x)$ is an element of the Borel subalgebra and $\Lambda$ is a sum of positive Chevalley generators in the case of affine Lie algebras. By using gauge transformations (adjoint group), they consider several normal forms. One normal form is obtained by choosing a node of the corresponding Dynkin diagram. The resulting matrix system is equivalent to the one obtained by scalar Lax representation (or a slight generalization of it). In this way, the generalized KdV equations for affine Lie algebras are obtained. Another normal form is to make $q$ $\mathfrak{h}$-valued. Soliton equations obtained in this way are called the modified KdV equations. This is a generalization of the Miura transformation. They also comment on the construction of partially modified soliton equations, which correspond to taking various parabolic subalgebras. The Hamiltonian formalism is also treated from their viewpoint.

In summary, in their approach affine algebras are used to construct soliton equations, or one can say that they consider the space of initial values of soliton equations.

They also discuss two-dimensional Toda lattices in their setting and show that modified equations in their sense are symmetries of the two-dimensional Toda lattices.

## Common Features of the Roles of Affine Lie Algebras in Solitons

In $\tau$-function approach as well as in the method of Drinfeld–Sokolov, the existence of triangular decomposition of Lie algebras was essential. In the former case, it was basic when considering highest-weight representations and, for the latter, it was used for the setup.

## Special Solutions of Soliton Equations (Multisoliton and Rational Solutions)

One of the characteristic features of soliton equations is that they allow rich special solutions. Multisoliton solutions were the starting point of the whole story. They directly relate to vertex operators of affine Lie algebras.

Rational solutions (in terms of $\tau$-function polynomial solutions) can be viewed as degenerations of multisoliton solutions. Motions of poles (or zeros) of the solutions are interesting. Airault–McKean–Moser studied the motion of poles of rational solutions of the KdV equation and found that they are identical to the motion of particles on a line (Calogero–Moser–Sutherland system). This viewpoint has now been generalized by Veselov and others.

Another discovery of Sato was that polynomial $\tau$-functions of the KP hierarchy are precisely Schur functions (character polynomials).

In accordance with the process of reduction, polynomial $\tau$-functions of the KdV hierarchy are Schur functions of special type.

## Quasiperiodic Solutions of Soliton Equations

As mentioned above, the KdV equation admits solutions expressible in terms of elliptic functions. Dubrovin–Novikov and Its–Matveev, almost at the same time, studied solutions of the KdV equation with periodic initial condition.

To the Sturm–Liouville (i.e., one-dimensional Schrödinger) operator with periodic potential

$$L = \left(\frac{\partial}{\partial x}\right)^2 + u(x), \quad u(x+l) = u(x)$$

there corresponds the discriminant, which is an entire function of the spectral parameter. Its zeros represent the periodic and antiperiodic spectrum $\lambda_j$ of the operator:

$$Lf_j(x) = \lambda_j f_j(x), \quad f_j(x+l) = \pm f_j(x)$$

It turns out that, except for a finite number of zeros, other zeros are double. Such a potential is called a finite-zone potential. These zones correspond to the spectrum of the operator in the $L^2$-sense. To a finite-zone potential $u(x)$ there corresponds a hyperelliptic curve

$$\mu^2 = \prod_{j=0}^{2n} (\lambda - \lambda_j)$$

with simple zeros $\lambda_j$ of the discriminant as zeros of polynomials defining the curve. If we consider the Dirichlet boundary value problem for the operator $L$,

$$Lf = \mu, f$$
$$f(s, \mu) = 0 = f(s+l, \mu)$$

the eigenvalues are discrete and each eigenvalue $\mu_j$ is located in a zone:

$$\lambda_{2j-1} \le \mu_j(s) \le \lambda_{2j}$$

So, for the double zeros ($\lambda_{2j-1} = \lambda_{2j}$), the corresponding Dirichlet eigenvalue $\mu_j(s)$ does not depend on $s$.

Dubrovin–Novikov also showed that a finite-zone potential is a stationary solution of the higher-order KdV equation (the order being equal to the number of nontrivial zones) and the $n$-zonal potentials form a finite-dimensional integrable system. In other words, the linear operators $L$, $A_n$ defining the $n$th order KdV equations commute,

$$[L, A_n] = 0$$

In passing, it was later found that such a pair of commuting linear differential operators was first studied by Burchnall–Chaundy in the 1920s. H F Baker remarked on the corresponding simultaneous eigenfunctions by relating them to multiplicative functions on algebraic curves.

## The Work of Krichever

Krichever reversed the above argument, utilizing the properties of corresponding eigenfunctions as a function of the spectral parameter. In this approach, we start with a compact Riemann surface $C$ (= nonsingular algebraic curve) of genus $g$. Here we apply his method to the KP hierarchy. Take a point $P_0$ on $C$ together with the inverse of a local parameter $k^{-1}$. Also take a general divisor $\delta$ on C of degree $g$. Consider a function $\psi(x, P), x = (x_1, x_2, \ldots)$, with the following properties:

1. $\psi$ is meromorphic on $C \backslash P_0$ with the pole divisor $\delta$, and
2. near $P_0, \psi$ behaves like

$$\psi(x, P) = \exp\left(\sum_{j=1}^{\infty} x_j k^j\right)\left(1 + \mathcal{O}(k^{-1})\right)$$

Such a $\psi$ exists uniquely and can be constructed using the theory of abelian integrals and the Jacobi problems on algebraic curves. Such a function was called the Baker–Akhiezer function, since Akhiezer constructed it by using abelian integrals and Jacobi's

problem in his study of moment problems (orthogonal polynomials).

It was later realized that Schur had much earlier considered such functions in the study of ordinary differential equations.

It is easy to show that such a function satisfies the following linear differential equations:

$$\frac{\partial}{\partial x_n}\psi = \left(\left(\frac{\partial}{\partial x_1}\right)^n + \sum_{j=0}^{n-1} u_j(x)\left(\frac{\partial}{\partial x_1}\right)^j\right)\psi, \quad n = 2, 3, \ldots$$

In this way, we obtain a solution of the KP hierarchy.

If there exists a rational function $f(P)$ on $C$ with poles only at $P_0$ with singular part $k^n, \psi$ can be factorized as

$$\psi(x, P) = \exp f(P)\psi'(x', P)$$

where $x'$ indicates the set of variables other than $x_n$. Consequently, we have

$$\frac{\partial}{\partial x_n}\psi(x, P) = f(P)\psi(x, P)$$

In this way, for a hyperelliptic curve $C$ and a branch point of it, viewed as the double cover of $\mathbf{C}P^1$, we recover the case of the KdV hierarchy.

Multisolitons correspond to rational algebraic curves with ordinary double points, while rational solutions correspond to further degeneration.

The study of quasiperiodic solutions of soliton equations revealed an intimate relationship with the theory of algebraic curves. One particular outcome was the characterization of Jacobian varieties among abelian varieties. This was originally posed by Schottky and subsequently reformulated by S P Novikov using soliton equations (Schottky problem, Novikov conjecture). This problem was solved through studies by Shiota, Mulase, and Arbarello–De Concini.

Another aspect was finding commutative subalgebras in the ring of linear differential operators. This problem is related to the theory of stable vector bundles on algebraic curves.

## Similarity Solutions of Soliton Equations

Ablowitz and Segur have shown that the Painlevé transcendent of the second kind solves the KdV equation as a similarity solution. This was the starting point of the study of similarity solutions of soliton equations.

Flaschka and Newell tried to construct the theory of multisimilarity solutions. As a by-product, they discussed modulation of the KdV equation by using the averaging method of Whitham. This opens the way to study the quasiclassical limit of soliton equations. This aspect was further studied by Dubrovin and others in connection with topological field theory.

Quite recently, Noumi and Yamada gave a generalization of the Painlevé equation in many variables by using the idea of similarity solutions of soliton equations. In the work of Noumi–Yamada, the affine Weyl group and $\tau$-functions play an essential role in constructing generalizations of the Painlevé equation. The shift or the unit of difference corresponds to imaginary null roots of affine Lie algebras. The idea is further applied to elliptic Painlevé equations.

## Integrable Many-Body Problems

As mentioned in relation with the rational solutions of soliton equations, the theory of integrable many-body problems has an intimate relationship with the theory of solitons. Recently, Veselov and his co-workers introduced the notion of Baker–Akhiezer functions of many variables. This concerns a commutative subring of differential operators in many variables. The structure of vector bundles on algebraic varieties of higher dimensions is quite different from that of algebraic curves. For this reason, a naïve generalization of soliton equations to higher dimensions is not possible. Veselov and others have set up a class of functions which they call multidimensional Baker–Akhiezer functions. They are defined by giving a finite set of vectors in a Euclidean space. The first problem is the existence. For the existence of the multidimensional Baker–Akhiezer function the set must satisfy several constraints. This is quite different from the case of solitons. Root systems satisfy these constraints and the corresponding Baker–Akhiezer function becomes the common eigenfunction of linear differential operators appearing in the Calogero–Sutherland–Moser model corresponding to root systems.

## Ball–Box Systems

Satsuma–Takahashi found a soliton-like phenomenon in cellular automata. It took much time for a mathematical explanation of this. Now it is understand that these systems are obtained by a limiting procedure from soliton equations. Sometimes this is called ultra-discretization. The system thus obtained can also be obtained from the theory of crystal bases of affine Lie algebras. They are now called ball–box systems.

## Other Topics

A quantized version of the inverse-scattering method was initiated by Faddeev and his co-workers, which makes a connection with two-dimensional solvable lattice models and produced the notion of quantum groups. Through the Bethe ansatz, another relation of two-dimensional lattice models and ball–box systems has been discussed.

# Solitons and Other Extended Field Configurations

**R S Ward**, University of Durham, Durham, UK

## Introduction

A soliton is a localized lump (or string or wall, etc.) of energy, which can move without distortion, dispersion, or dissipation, and which is stable under perturbations (and collisions with other solitons). The word was coined by Zabusky and Kruskal in 1965 to describe a solitary wave with particle-like properties (as in electron, proton, etc.). Solitons are relevant to numerous areas of physics – condensed matter, cosmology, fluids/plasmas, biophysics (e.g., DNA), nuclear physics, high-energy physics, etc. Mathematically, they are modeled as solutions of appropriate partial differential equations.

Systems which admit solitons may be classified according to the mechanism by which stability is ensured. Such mechanisms include complete integrability, nontrivial topology plus dynamical balancing, and *Q*-balls/breathers.

Sometimes the term "soliton" is used in a restricted sense, to refer to stable localized lumps which have purely elastic interactions: solitons which collide without any radiation being emitted. This is possible only in very special systems, namely, those that are completely integrable. For these systems, soliton stability (and the elasticity of collisions) arises from a number of characteristic properties, including a precise balance between dispersion and nonlinearity, solvability by the inverse scattering transform from linear data, infinitely many conserved quantities, a Lax formulation (associated linear problem), and Bäcklund transformations. Examples of such integrable soliton systems are the sine-Gordon, Korteweg–deVries, and nonlinear Schrödinger equations.

The category of topological solitons is the most varied, and includes such examples as kinks, vortices, monopoles, skyrmions, and instantons. The requirement of dynamical balancing for these can be understood in terms of Derrick's theorem, which provides necessary conditions for a classical field theory to admit static localized solutions. The

Derrick argument involves studying what happens to the energy of a field when one changes the scale of space. If one has a scalar field (or multiplet of scalar fields) $\phi$, and/or a gauge field $F_{\mu\nu}$, then the static energy $E$ is the sum of terms such as

$$E_0 = \int V(\phi)\,\mathrm{d}^n x, \qquad E_d = \int T_d(D_j\phi)\,\mathrm{d}^n x,$$
$$E_F = \int F_{jk}F_{jk}\,\mathrm{d}^n x$$

where each integral is over ($n$-dimensional) space $\boldsymbol{R}^n$, $D_j\phi$ denotes the covariant spatial derivative of $\phi$, and $T_d(\xi_j)$ is a real-valued polynomial of degree $d$. In particular, for example, we could have $T_2(D_j\phi) = (D_j\phi)(D_j\phi)$, the standard gradient term. Under the dilation $x^j \mapsto \lambda x^j$, these functionals transform as

$$E_0 \mapsto \lambda^{-n}E_0, \qquad E_d \mapsto \lambda^{d-n}E_d, \qquad E_F \mapsto \lambda^{4-n}E_F$$

In order to have a static solution (critical point of the static energy functional), one needs to have a zero exponent on $\lambda$, and/or a balance between positive and negative exponents. A negative exponent indicates a compressing force (tending to implode a localized lump), whereas a positive exponent indicates an expanding force; so to have a static lump solution, these two forces have to balance each other. For $n=1$, a system involving only a scalar field, with terms of the form $E_0$ and $E_2$, can admit static solitons (e.g., kinks); the scaling argument implies a virial theorem, which in this case says that $E_0 = E_2$. For $n=2$, one can have a scalar system with only $E_2$, since in this case the relevant exponent is zero (e.g., the two-dimensional sigma model). Another $n=2$ example is that of vortices in the abelian Higgs model, where the energy contains terms $E_0, E_2$, and $E_F$. For $n=3$, interesting systems have $E_2$ together with either $E_4$ (e.g., skyrmions) or $E_F$ (e.g., monopoles). An $E_0$ term is optional in these cases; its presence affects, in particular, the long-range properties of the solitons. For $n=4$, one can have instantons in a pure gauge theory (term $E_F$ only).

It should be noted that if there are no restrictions on the fields $\phi$ and $A_j$ (such as those arising, e.g., from nontrivial topology), then there is a more obvious mode of instability, which will inevitably be present: $\phi \mapsto \mu\phi$ and/or $A_j \mapsto \mu A_j$, where $0 \le \mu \le 1$. In other words, the fields can simply be scaled away altogether, so that the height of the soliton (and its energy) go smoothly to zero. This can be prevented by nontrivial topology.

Another way of preventing solitons from shrinking is to allow the field to have some "internal" time dependence, so that it is stationary rather than static. For example, one could allow the complex scalar field $\phi$ to have the form $\phi = \psi \exp(\mathrm{i}\omega t)$, where $\psi$ is independent of time $t$. This leads to something like a centrifugal force, which can have a stabilizing effect in the absence of Skyrme or magnetic terms. The corresponding solitons are $Q$-balls.

## Kinks and Breathers

The simplest topological solitons are kinks, in systems involving a real-valued scalar field $\phi(x)$ in one spatial dimension. The dynamics is governed by the Lagrangian density

$$\mathcal{L} = \tfrac{1}{2}\left[(\phi_t)^2 - (\phi_x)^2 - W(\phi)^2\right]$$

where $W(\phi)$ is a (fixed) smooth function. The system can admit kinks if $W(\phi)$ has at least two zeros, for example, $W(A) = W(B) = 0$ with $W(\phi) > 0$ for $A < \phi < B$. Two well-known systems are: sine-Gordon (where $W(\phi) = 2\sin(\phi/2), A = 0$, and $B = 2\pi$) and $\phi^4$ (where $W(\phi) = 1 - \phi^2, A = -1$, and $B = 1$). The corresponding field equations are the Euler–Lagrange equations for $\mathcal{L}$; for example, the sine-Gordon equation is

$$\phi_{tt} - \phi_{xx} + \sin\phi = 0 \qquad [1]$$

Configurations satisfying the boundary conditions $\phi \to A$ as $x \to -\infty$ and $\phi \to B$ as $x \to \infty$ are called kinks (and the corresponding ones with $x = \infty$ and $x = -\infty$ interchanged are antikinks). For kink (or antikink) configurations, there is a lower bound, called the Bogomol'nyi bound, on the static energy $E[\phi]$; for kink boundary conditions, we have

$$\begin{aligned} E[\phi] &= \frac{1}{2}\int_{-\infty}^{\infty}\left[(\phi_x)^2 + W(\phi)^2\right]\mathrm{d}x \\ &= \frac{1}{2}\int_{-\infty}^{\infty}[\phi_x - W(\phi)]^2\,\mathrm{d}x + \int_{-\infty}^{\infty} W(\phi)\phi_x\,\mathrm{d}x \\ &\ge \int_A^B W(\phi)\,\mathrm{d}\phi \end{aligned}$$

with equality if and only if the Bogomol'nyi equation

$$\frac{\mathrm{d}\phi}{\mathrm{d}x} = W(\phi) \qquad [2]$$

is satisfied. A static solution of the Bogomol'nyi equation is a kink solution – it is a static minimum of the energy functional in the kink sector. For example, for the sine-Gordon system, we get $E[\phi] \ge 8$, with equality for the sine-Gordon kink

$$\phi(x) = 4\tan^{-1}\exp(x - x_0)$$

while for the $\phi^4$ system, we get $E[\phi] \ge 4/3$, with equality for the phi-four kink

$$\phi(x) = \tanh(x - x_0)$$

These kinks are stable topological solitons; the nontrivial topology corresponds to the fact that the boundary value of $\phi(t,x)$ at $x=\infty$ is different from that at $x=-\infty$. With trivial boundary conditions (say $\phi \to A$ as $x \to \pm\infty$), stable static solitons are unlikely to exist, but solitons with periodic time dependence (which in this context are called breathers) may exist. For example, the sine-Gordon equation and the nonlinear Schrödinger equation, both, admit breathers – but these owe their existence to complete integrability. By contrast, the $\phi^4$ system (which is not integrable) does not admit breathers; a collision between a $\phi^4$ kink and an antikink (with suitable impact speed) produces a long-lived state which looks like a breather, but eventually decays into radiation.

In lattice systems, however, breathers are more generic. In a one-dimensional lattice system, the continuous space $\boldsymbol{R}$ is replaced by the lattice $\boldsymbol{Z}$, so $\phi(t,x)$ is replaced by $\phi_n(t)$, where $n \in \boldsymbol{Z}$. The Lagrangian is

$$L = \frac{1}{2}\sum_n \left[(\dot{\phi}_n)^2 - h^{-2}(\phi_{n+1} - \phi_n)^2 - W(\phi_n)\right]$$

where $h$ is a positive parameter, corresponding to the dimensionless ratio between the lattice spacing and the size of a kink. The continuum limit is $h \to 0$. This system admits kink solutions as in the continuum case; and for $h$ large enough, it admits breathers as well, but these disappear as $h$ becomes small.

Interpreted in three dimensions, the kink becomes a domain wall separating two regions in which the order parameter $\phi$ takes distinct values; this has applications in such diverse areas as cosmology and condensed matter physics.

## Sigma Models and Skyrmions

In a sigma model or Skyrme system, the field is a map $\phi$ from spacetime to a Riemannian manifold $M$; generally, $M$ is taken to be a Lie group or a symmetric space. The energy density of a static field can be constructed as follows (the Lorentz-invariant extension of this gives a relativistic Lagrangian for fields on spacetime). Let $\phi^a$ be local coordinates on the $m$-dimensional manifold $M$, let $h_{ab}$ denote the metric of $M$, and let $x^j$ denote the spatial coordinates on space $\boldsymbol{R}^n$. An $m \times m$ matrix $D$ is defined by

$$D_a{}^b = (\partial_j\phi^c)h_{ac}(\partial_j\phi^b)$$

where $\partial_j$ denotes derivatives with respect to the $x^j$. Then the invariants $\mathcal{E}_2 = \mathrm{tr}(D) = |\partial_j\phi^a|^2$ and $\mathcal{E}_4 = (1/2)[(\mathrm{tr}\, D)^2 - \mathrm{tr}(D^2)]$ can be terms in the energy density, as well as a zeroth-order term $\mathcal{E}_0 = V(\phi^a)$ not involving derivatives of $\phi$. A term of the form $\mathcal{E}_4$ is called a Skyrme term.

The boundary condition on field configurations is that $\phi$ tends to some constant value $\phi_0 \in M$ as $|x| \to \infty$ in $\boldsymbol{R}^n$. From the topological point of view, this compactifies $\boldsymbol{R}^n$ to $S^n$. In other words, $\phi$ extends to a map from $S^n$ to $M$; and such maps are classified topologically by the homotopy group $\pi_n(M)$. For topological solitons to exist, this group has to be nontrivial.

In one spatial dimension ($n=1$) with $M=S^1$ (say), the expression $\mathcal{E}_4$ is identically zero, and we just have kink-type systems such as sine-Gordon. The simplest two-dimensional example ($n=2$) is the $O(3)$ sigma model, which has $M=S^2$ with its standard metric. In this system, the field is often expressed as a unit 3-vector field $\boldsymbol{\phi} = (\phi^1, \phi^2, \phi^3)$, with $\mathcal{E}_2 = (\partial_j\boldsymbol{\phi}) \cdot (\partial_j\boldsymbol{\phi})$. Here the configurations are classified topologically by their degree (or winding number, or topological charge) $N \in \pi_2(S^2) \cong \boldsymbol{Z}$, which equals

$$N = \frac{1}{4\pi}\int \boldsymbol{\phi} \cdot \partial_1\boldsymbol{\phi} \times \partial_2\boldsymbol{\phi}\, \mathrm{d}x^1\, \mathrm{d}x^2$$

Instead of $\boldsymbol{\phi}$, it is often convenient to use a single complex-valued function $W$ related to $\boldsymbol{\phi}$ by the stereographic projection $W = (\phi^1 + \mathrm{i}\phi^2)/(1-\phi^3)$. In terms of $W$, the formula for the degree $N$ is

$$N = \frac{\mathrm{i}}{2\pi}\int \frac{W_1\overline{W}_2 - W_2\overline{W}_1}{(1+|W|^2)^2}\, \mathrm{d}x^1\, \mathrm{d}x^2$$

and the static energy is (with $z = x^1 + \mathrm{i}x^2$)

$$\begin{aligned} E &= \int \mathcal{E}_2\, \mathrm{d}^2x \\ &= 8\int \frac{|W_z|^2 + |W_{\bar z}|^2}{(1+|W|^2)^2}\, \mathrm{d}^2x \\ &= 16\int \frac{|W_{\bar z}|^2}{(1+|W|^2)^2}\, \mathrm{d}^2x + 8\int \frac{|W_z|^2 - |W_{\bar z}|^2}{(1+|W|^2)^2}\, \mathrm{d}^2x \\ &= 16\int \frac{|W_{\bar z}|^2}{(1+|W|^2)^2}\, \mathrm{d}^2x + 8\pi N \end{aligned}$$

From this, one sees that $E$ satisfies the Bogomol'nyi bound $E \geq 8\pi N$, and that minimal-energy solutions correspond to solutions of the Cauchy–Riemann equations $W_{\bar z} = 0$. To have finite energy, $W(z)$ has to be a rational function, and so solutions with winding number $N$ correspond to rational meromorphic functions $W(z)$, of degree $|N|$. (If $N < 0$, then $W$ is a rational function of $\bar z$.) The energy is scale invariant (conformally invariant), and consequently these solutions are not solitons – they are not quite stable, since their size is not fixed. Adding terms $\mathcal{E}_4$ and $\mathcal{E}_0$

to the energy density fixes the soliton size, and the resulting two-dimensional Skyrme systems admit true topological solitons.

The three-dimensional case ($n=3$), with $M$ being a simple Lie group, is the original Skyrme model of nuclear physics. If $M=\mathrm{SU}(2)$, then the integer $N \in \pi_3(\mathrm{SU}(2)) \cong \boldsymbol{Z}$ is interpreted as the baryon number. The (quantum) excitations of the $\phi$-field correspond to the pions, whereas the (semiclassical) solitons correspond to the nucleons. This model emerges as an effective theory of quantum chromodynamics (QCD), in the limit where the number of colors is large. If we express the field as a function $U(x^j)$ taking values in a Lie group, then $L_j = U^{-1}\partial_j U$ takes values in the corresponding Lie algebra, and $\mathcal{E}_2$ and $\mathcal{E}_4$ take the form

$$\begin{aligned}\mathcal{E}_2 &= -\tfrac{1}{2}\,\mathrm{tr}(L_j L_j)\\ \mathcal{E}_4 &= -\tfrac{1}{16}\,\mathrm{tr}\big([L_j, L_k][L_j, L_k]\big)\end{aligned}$$

The static energy density in the basic Skyrme system is the sum of these two terms. The static energy satisfies a Bogomol'nyi bound $E \geq 12\pi^2|N|$, and it is believed that stable solitons (skyrmions) exist for each value of $N$. Classical skyrmions have been investigated numerically; for values of $N$ up to $\sim 25$, they turn out to resemble polyhedral shells. Comparison with nucleon phenomenology requires semiclassical quantization, and this leads to results which are at least qualitatively correct.

A variant of the Skyrme model is the Skyrme–Faddeev system, which has $n=3$ and $M=S^2$; the solitons in this case resemble loops which can be linked or knotted, and which are classified by their Hopf number $N \in \pi_3(S^2)$. In this case, the energy satisfies a lower bound of the form $E \geq cN^{3/4}$. Numerical experiments indicate that for each $N$, there is a minimal-energy solution with Hopf number $N$, and with energy close to this topological lower bound.

## Abelian Higgs Vortices

Vortices live in two spatial dimensions; viewed in three dimensions, they are string-like. Two of their applications are as cosmic strings and as magnetic flux tubes in superconductors. They occur as static topological solitons in the the abelian Higgs model (or Ginzburg–Landau model), and involve a magnetic field $B=\partial_1 A_2 - \partial_2 A_1$, coupled to a complex scalar field $\phi$, on the plane $\boldsymbol{R}^2$. The energy density is

$$\mathcal{E} = \tfrac{1}{2}(D_j\phi)(\overline{D_j\phi}) + \tfrac{1}{2}B^2 + \tfrac{1}{8}\lambda(1-|\phi|^2)^2 \qquad [3]$$

where $D_j\phi := \partial_j\phi - \mathrm{i}A_j\phi$, and where $\lambda$ is a positive constant. The boundary conditions are

$$D_j\phi = 0, \qquad B = 0, \qquad |\phi| = 1 \qquad [4]$$

as $r \to \infty$. If we consider a very large circle $C$ on $\boldsymbol{R}^2$, so that [4] holds on C, then $\phi|_C$ is a map from the circle $C$ to the circle of unit radius in the complex plane, and therefore it has an integer winding number $N$. Thus configurations are labeled by this vortex number $N$.

Note that if $\mathcal{E}$ vanishes, then $B=0$ and $|\phi|=1$: the gauge symmetry is spontaneously broken, and the photon "acquires a mass": this is a standard example of spontaneous symmetry breaking.

The total magnetic flux $\int B\,\mathrm{d}^2x$ equals $2\pi N$; a proof of this is as follows. Let $\theta$ be the usual polar coordinate around C. Because $|\phi|=1$ on C, we can write $\phi = \exp[\mathrm{i}f(\theta)]$ for some function $f$; this $f$ need not be single-valued, but must satisfy $f(2\pi) - f(0) = 2\pi N$ with $N$ being an integer (in order that $\phi$ be single-valued). In fact, this defines the winding number. Now since $D_j\phi = \partial_j\phi - \mathrm{i}A_j\phi = 0$ on C, we have

$$A_j = -\mathrm{i}\phi^{-1}\partial_j\phi = \partial_j f$$

on $C$. So, using Stokes' theorem, we get

$$\begin{aligned}\int_{\boldsymbol{R}^2} B\,\mathrm{d}^2x &= \int_C A_j\,\mathrm{d}x^j\\ &= \int_0^{2\pi} \frac{\mathrm{d}f}{\mathrm{d}\theta}\,\mathrm{d}\theta\\ &= 2\pi N\end{aligned}$$

If $\lambda=1$, then the total energy $E=\int \mathcal{E}\,\mathrm{d}^2x$ satisfies the Bogomol'nyi bound $E \geq \pi N; E=\pi N$ if and only if a set of partial differential equations (the Bogomol'nyi equations) are satisfied. Since like charges repel, the magnetic force between vortices is repulsive. However, there is also a force from the Higgs field, and this is attractive. The balance between the two forces is determined by $\lambda$: if $\lambda > 1$, the vortices repel each other; whereas if $\lambda < 1$, the vortices attract. In the critical case $\lambda = 1$, the force between vortices is exactly balanced, and there exist static multivortex solutions. In fact, one has the following: given $N$ points in the plane, there exists an $N$-vortex solution of the Bogomol'nyi equations (and hence of the full field equations) with $\phi$ vanishing at the chosen points (and nowhere else). All static solutions are of this form. These solutions cannot, however, be written down explicitly in terms of elementary functions (except of course for $N=0$).

## Monopoles

The abelian Higgs model does not admit three-dimensional solitons, but a nonabelian generalization does – such nonabelian Higgs solitons are called magnetic monopoles. The field content, in the simplest version, is as follows. First, there is a gauge (Yang–Mills) field $F_{\mu\nu}$, with gauge potential $A_\mu$, and with the gauge group being a simple Lie group $G$. Second, there is a Higgs scalar field $\phi$, transforming under the adjoint representation of $G$ (thus $\phi$ takes values in the Lie algebra of $G$). For simplicity, $G$ is taken to be SU(2) in what follows. So we may write $A_\mu = \mathrm{i}A_\mu^a \sigma_a, F_{\mu\nu} = \mathrm{i}F_{\mu\nu}^a \sigma_a$, and $\phi = \mathrm{i}\phi^a \sigma_a$, where $\sigma_a$ are the Pauli matrices. The energy of static ($\partial_0 \phi = 0 = \partial_0 A_j$), purely magnetic ($A_0 = 0$) configurations is

$$E = \int \left[\tfrac{1}{2} B_j^a B_j^a + \tfrac{1}{2}(D_j\phi)^a (D_j\phi)^a + \tfrac{1}{4}\lambda(1 - \phi^a\phi^a)^2\right] \mathrm{d}^3 x$$

where $B_j^a = (1/2)\epsilon_{jkl} F_{kl}$ is the magnetic field. The boundary conditions are $B_j^a \to 0$ and $\phi^a\phi^a \to 1$ as $r \to \infty$; so $\phi$ restricted to a large spatial 2-sphere becomes a map from $S^2$ to the unit 2-sphere in the Lie algebra su(2), and as such it has a degree $N \in \mathbf{Z}$. An analytic expression for $N$ is

$$\int B_j^a (D_j\phi)^a \, \mathrm{d}^3 x = 2\pi N \qquad [5]$$

At long range, the field resembles an isolated magnetic pole (a Dirac magnetic monopole), with magnetic charge $2\pi N$. Asymptotically, the SU(2) gauge symmetry is spontaneously broken to U(1), which is interpreted as the electromagnetic gauge group.

In 1974, it was observed that this system admits a smooth, finite-energy, stable, spherically symmetric $N = 1$ solution – this is the 't Hooft–Polyakov monopole. There is a Bogomol'nyi lower bound on the energy $E$: from $0 \le (B + D\phi)^2 = B^2 + (D\phi)^2 + 2B \cdot D\phi$, we get

$$E \ge 2\pi N + \int \tfrac{1}{4}\lambda(1 - \phi^a\phi^a)^2 \, \mathrm{d}^3 x \qquad [6]$$

where [5] has been used. The inequality [6] is saturated if and only if the Prasad–Sommerfield limit $\lambda = 0$ is used, and the Bogomol'nyi equations

$$(D_j\phi)^a = -B_j^a \qquad [7]$$

hold. The corresponding solitons are called Bogomol'nyi–Prasad–Sommerfield (BPS) monopoles.

The Bogomol'nyi equations [7], together with the boundary conditions described above, form a completely integrable elliptic system of partial differential equations. For any positive integer $N$, the space of BPS monopoles of charge $N$, with gauge freedom factored out, is parametrized by a $(4N - 1)$-dimensional manifold $\mathcal{M}_N$. This is the moduli space of $N$ monopoles. Roughly speaking, each monopole has a position in space (three parameters) plus a phase (one parameter), making a total of $4|N|$ parameters; an overall phase can be removed by a gauge transformation, leaving $(4|N| - 1)$ parameters. In fact, it is often useful to retain the overall phase, and to work with the corresponding $4|N|$-dimensional manifold $\widetilde{\mathcal{M}}_N$. This manifold has a natural metric, which corresponds to the expression for the kinetic energy of the system. A point in $\widetilde{\mathcal{M}}_N$ represents an $N$-monopole configuration, and the slow-motion dynamics of $N$ monopoles corresponds to geodesics on $\widetilde{\mathcal{M}}_N$; this is the geodesic approximation of monopole dynamics.

The $N = 1$ monopole is spherically symmetric, and the corresponding fields take a simple form; for example, the Higgs field of a 1-monopole located at $r = 0$ is

$$\phi^a = \left[\frac{\coth(2r)}{r} - \frac{1}{2r^2}\right] x^a$$

For $N > 1$, the expressions tend to be less explicit; but monopole solutions can nevertheless be characterized in a fairly complete way. The Bogomol'nyi equations [7] are a dimensional reduction of the self-dual Yang–Mills equations in $\mathbf{R}^4$, and BPS monopoles correspond to holomorphic vector bundles over a certain two-dimensional complex manifold ("mini-twistor space"). This leads to various other characterizations of monopole solutions, for example, in terms of certain curves ("spectral curves") on mini-twistor space, and in terms of solutions of a set of ordinary differential equations called the Nahm equations. Having all these descriptions enables one to deduce much about the monopole moduli space, and to characterize many monopole solutions. In particular, there are explicit solutions of the Nahm equations involving elliptic functions, which correspond to monopoles with certain discrete symmetries, such as a 3-monopole with tetrahedral symmetry, and a 4-monopole with the appearance and symmetries of a cube.

## Yang–Mills Instantons

Consider gauge fields in four-dimensional Euclidean space $\mathbf{R}^4$, with gauge group $G$. For simplicity, in what follows, $G$ is taken to be SU(2); one can extend much of the structure to more general groups, for example, the simple Lie groups. Let $A_\mu$ and $F_{\mu\nu}$

denote the gauge potential and gauge field. The Yang–Mills action is

$$S = -\frac{1}{4}\int \mathrm{tr}\big(F_{\mu\nu}F_{\mu\nu}\big)\,\mathrm{d}^4x \qquad [8]$$

where we assume a boundary condition, at infinity in $\boldsymbol{R}^4$, such that this integral converges. The Euler–Lagrange equations which describe critical points of the functional $S$ are the Yang–Mills equations

$$D_\mu F_{\mu\nu} = 0 \qquad [9]$$

Finite-action Yang–Mills fields are called instantons. The Euclidean action [8] is used in the path-integral approach to quantum gauge field theory; therefore, instantons are crucial in understanding the path integral.

The dual of the field tensor $F_{\mu\nu}$ is

$$*F_{\mu\nu} = \tfrac{1}{2}\varepsilon_{\mu\nu\alpha\beta}F_{\alpha\beta}$$

The gauge field is self-dual if $*F_{\mu\nu} = F_{\mu\nu}$, and anti-self-dual if $*F_{\mu\nu} = -F_{\mu\nu}$. In view of the Bianchi identity $D_\mu * F_{\mu\nu} = 0$, any self-dual or anti-self-dual gauge field is automatically a solution of the Yang–Mills equations [9]. This fact also follows from the discussion below, where we see that self-dual instantons give local minima of the action.

The Yang–Mills action (and Yang–Mills equations) are conformally invariant; any finite-action solution of the Yang–Mills equations on $R^4$ extends smoothly to the conformal compactification $S^4$. Gauge fields on $S^4$, with gauge group SU(2), are classified topologically by an integer $N$, namely, the second Chern number

$$N = c_2 = -\frac{1}{8\pi^2}\int \mathrm{tr}\big(F_{\mu\nu} * F_{\mu\nu}\big)\,\mathrm{d}^4x \qquad [10]$$

From [8] and [10] a topological lower bound on the action is given as follows:

$$\begin{aligned} 0 &\leq -\int \mathrm{tr}\big(F_{\mu\nu} - *F_{\mu\nu}\big)\big(F_{\mu\nu} - *F_{\mu\nu}\big)\,\mathrm{d}^4x \\ &= 8S - 16\pi^2 N \end{aligned}$$

and so $S \geq 2\pi^2 N$, with equality if and only if the field is self-dual. If $N < 0$, we get $S \geq 2\pi^2|N|$, with equality if and only if $F$ is anti-self-dual. So the self-dual (or anti-self-dual) fields minimize the action in each topological class.

For the remainder of this section, we restrict to self-dual instantons with instanton number $N > 0$. The space (moduli space) of such instantons, with gauge equivalence factored out, is an $(8N-3)$-dimensional real manifold. In principle, all these gauge fields can be constructed using algebraic-geometry (twistor) methods: instantons correspond to holomorphic vector bundles over complex projective 3-space (twistor space). One large class of solutions which can be written out explicitly is as follows: for $N = 1$ and $N = 2$ it gives all instantons, while for $N \geq 3$ it gives a $(5N+4)$-dimensional subfamily of the full $(8N-3)$-dimensional solution space. The gauge potentials in this class have the form

$$A_\mu = \mathrm{i}\sigma_{\mu\nu}\partial_\nu \log \phi \qquad [11]$$

where the $\sigma_{\mu\nu}$ are constant matrices (antisymmetric in $\mu\nu$) defined in terms of the Pauli matrices $\sigma_a$ by

$$\begin{aligned} \sigma_{10} &= \sigma_{23} = \tfrac{1}{2}\sigma_1 \\ \sigma_{20} &= \sigma_{31} = \tfrac{1}{2}\sigma_2 \\ \sigma_{30} &= \sigma_{12} = \tfrac{1}{2}\sigma_3 \end{aligned}$$

The real-valued function $\phi = \phi(x^\mu)$ is a solution of the four-dimensional Laplace equation given by

$$\phi(x^\mu) = \sum_{k=0}^{N} \frac{\lambda_k}{(x^\mu - x_k^\mu)(x^\mu - x_k^\mu)}$$

where the $x_k^\mu$ are $N+1$ distinct points in $\boldsymbol{R}^4$, and the $\lambda_k$ are $N+1$ positive constants: a total of $5N+5$ parameters. It is clear from [11] that the overall scale of $\phi$ is irrelevant, leaving a $(5N+4)$-parameter family. For $N = 1$ and $N = 2$, symmetries reduce the parameter count further, to 5 and 13, respectively. Although $\phi$ has poles at the points $x = x_k$, the gauge potentials are smooth (possibly after a gauge transformation).

Finally, it is worth noting that (as one might expect) there is a gravitational analog of the gauge-theoretic structures described here. In other words, one has self-dual gravitational instantons – these are four-dimensional Riemannian spaces for which the conformal-curvature tensor (the Weyl tensor) is self-dual, and the Ricci tensor satisfies Einstein's equations $R_{\mu\nu} = \Lambda g_{\mu\nu}$. As before, such spaces can be constructed using a twistor-geometrical correspondence.

## Q-Balls

A $Q$-ball (or nontopological soliton) is a soliton which has a periodic time dependence in a degree of freedom which corresponds to a global symmetry. The simplest class of $Q$-ball systems involves a complex scalar field $\phi$, with an invariance under the constant phase transformation $\phi \mapsto \mathrm{e}^{\mathrm{i}\theta}\phi$; the $Q$-balls are soliton solutions of the form

$$\phi(t, \boldsymbol{x}) = \mathrm{e}^{\mathrm{i}\omega t}\psi(\boldsymbol{x}) \qquad [12]$$

where $\psi(\boldsymbol{x})$ is a complex scalar field depending only on the spatial variables $\boldsymbol{x}$. The best-known case is the 1-soliton solution

$$\phi(t,x) = a\sqrt{2}\exp(\mathrm{i}a^2 t)\mathrm{sech}(ax)$$

of the nonlinear Schrödinger equation $\mathrm{i}\phi_t + \phi_{xx} + \phi|\phi|^2 = 0$.

More generally, consider a system (in $n$ spatial dimensions) with Lagrangian

$$\mathcal{L} = \tfrac{1}{2}(\partial_\mu \phi)(\partial^\mu \phi) - U(|\phi|)$$

where $\phi(x^\mu)$ is a complex-valued field. Associated with the global phase symmetry is the conserved Noether charge $Q = \int \mathrm{Im}(\bar{\phi}\phi_t)\,\mathrm{d}^n x$. Minimizing the energy of a configuration subject to $Q$ being fixed implies that $\phi$ has the form [12]. Without loss of generality, we may take $\omega \geq 0$. Note that $Q = \omega I$, where $I = \int |\psi|^2\,\mathrm{d}^n x$. The energy of a configuration of the form [12] is $E = E_q + E_k + E_p$, where

$$E_q = \frac{1}{2}\int |\partial_j \psi|^2\,\mathrm{d}^n x$$

$$E_k = \tfrac{1}{2} I\omega^2 = \tfrac{1}{2} Q^2/I$$

$$E_p = \int U(|\psi|)\,\mathrm{d}^n x$$

Let us take $U(0) = 0 = U'(0)$, with the field satisfying the boundary condition $\psi \to 0$ as $r \to \infty$.

A stationary $Q$-lump is a critical point of the energy functional $E[\psi]$, subject to $Q$ having some fixed value. The usual (Derrick) scaling argument shows that any stationary $Q$-lump must satisfy

$$(2-n)E_q - nE_p + nE_k = 0 \qquad [13]$$

For simplicity, in what follows, let us take $n \geq 3$. Define $m > 0$ by $U''(0) = m^2$; then, near spatial infinity, the Euler–Lagrange equations give $\nabla^2\psi - (m^2 - \omega^2)\psi = 0$. So, in order to satisfy the boundary condition $\psi \to 0$ as $r \to \infty$, we need $\omega < m$.

It is clear from [13] that if $U \geq (1/2)m^2|\psi|^2$ everywhere, then there can be no solution. So $K = \min[2U(|\psi|)/|\psi|^2]$ has to satisfy $K < m^2$. Also, we have

$$E_p = \int U \geq \tfrac{1}{2}KI = (K/\omega^2)E_k > (K/\omega^2)E_p \qquad [14]$$

where the final inequality comes from [13]. As a consequence, we see that $\omega^2$ is restricted to the range

$$K < \omega^2 < m^2 \qquad [15]$$

An example which has been studied in some detail is $\mathrm{U}(f) = f^2[1 + (1-f^2)^2]$; here $m^2 = 4$ and $K = 2$, so the range of frequency for $Q$-balls in this system is $\sqrt{2} < \omega < 2$. The dynamics of $Q$-balls in systems such as these turns out to be quite complicated.

# Source Coding in Quantum Information Theory

**N Datta**, University of Cambridge, Cambridge, UK
**T C Dorlas**, Dublin Institute for Advanced Studies, Dublin, Republic of Ireland

## Introduction

Two key issues of classical and quantum information theory are storage and transmission of information. An information source produces some outputs (or signals) more frequently than others. Due to this redundancy, one can reduce the amount of space needed for its storage without compromising on its content. This data compression is done by a suitable encoding of the output of the source. In contrast, in the transmission of information through a channel, it is often advantageous to add redundancy to a message, in order to combat the effects of noise. This is done in the form of error-correcting codes. The amount of redundancy which needs to be added to the original message depends on how much noise is present in the channel (see, e.g., Nielson and Chuang (2000)). Hence, redundancy plays complementary roles in data compression and transmission of data through a noisy channel. In this review we focus only on data compression in quantum information theory.

In classical information theory, Shannon showed that there is a natural limit to the amount of compression that can be achieved. It is given by the Shannon entropy. The analogous concept in quantum information theory is the von Neumann entropy. Here, we review some of the main results of quantum data compression and the significance of the von Neumann entropy in this context.

The review is structured as follows. We first give a brief introduction to the Shannon entropy and classical data compression. This is followed by a discussion of quantum entropy and the idea behind quantum source coding. We elaborate on data compression schemes for three different classes of quantum sources, namely memoryless sources, ergodic sources, and sources modeled by Gibbs states of quantum spin systems. In the bulk of the review, we concentrate on source-dependent, fixed-length coding schemes. We conclude with a brief discussion of universal and variable-length coding. We would like to point out that this review article is by no means complete. Due to a restriction on its length, we had to leave out various important aspects and developments of quantum source coding.

## Classical Data Compression

### Entropy and Source Coding

A simple model of a classical information source consists of a sequence of discrete random variables $X_1, X_2, \ldots, X_n$, whose values represent the output of the source. Each random variable $X_i, 1 \le i \le n$, takes values $x_i$ from a finite set, the source alphabet $\mathcal{X}$. Hence, $\underline{X}^{(n)} := (X_1, \ldots, X_n)$ takes values $\underline{x}^{(n)} := (x_1, \ldots, x_n) \in \mathcal{X}^n$. We recall the definition of entropy (or information content) of a source.

If the discrete random variables $X_1, \ldots, X_n$ which take values from a finite alphabet $\mathcal{X}$ have joint probabilities

$$\mathbb{P}(X_1 = x_1, \ldots, X_n = x_n) = p_n(x_1, \ldots, x_n)$$

then the Shannon entropy of this source is defined by

$$\begin{aligned} H(X_1, \ldots, X_n) \\ = -\sum_{x_1 \in \mathcal{X}} \cdots \sum_{x_n \in \mathcal{X}} p_n(x_1, \ldots, x_n) \\ \times \log p_n(x_1, \ldots, x_n) \end{aligned} \qquad [1]$$

Here and in the following, the logarithm is taken to the base 2. This is because the fundamental unit of classical information is a "bit," which takes two values 0 and 1. Notice that $H(X_1, \ldots, X_n)$ in fact only depends on the (joint) probability mass function (p.m.f.) $p_n$ and can also be denoted as $H(p_n)$.

There are several other concepts of entropy, for example, relative entropy, conditional entropy, and mutual information. See, for example, Cover and Thomas (1991) and Nielson and Chuang (2000). It is easy to see that

1. $0 \le H(X_1, \ldots, X_n) \le n \log |\mathcal{X}|$, where $|\mathcal{X}|$ denotes the number of letters in the alphabet $\mathcal{X}$. Two other important properties are as follows:
2. $H(X_1, \ldots, X_n)$ is jointly concave in $X_1, \ldots, X_n$ and
3. $H(X_1, \ldots, X_n) \le H(X_1, \ldots, X_m) + H(X_{m+1}, \ldots, X_n)$ for $m < n$.

The latter property is called subadditivity.

In the next section, analogous quantities are introduced for quantum information and the corresponding properties are stated.

Suppose that the random variables $X_1, X_2, \ldots, X_n$ are independent and identically distributed (i.i.d.). Then the entropy of each random variable modeling the source is the same and can be denoted by $H(X)$. From the point of view of classical information theory, the Shannon entropy has an important operational definition. It quantifies the minimal

physical resources needed to store data from a classical information source and provides a limit to which data can be compressed reliably (i.e., in a manner in which the original data can be recovered later with a low probability of error). Shannon showed that the original data can be reliably obtained from the compressed version only if the rate of compression is greater than the Shannon entropy. This result is formulated in Shannon's noiseless channel coding theorem (Shannon 1918, Cover and Thomas 1991, Nielson and Chuang 2000) given later.

### The Asymptotic Equipartition Property

The main idea behind Shannon's noiseless channel coding theorem is to divide the possible values $x_1, x_2, \dots, x_n$ of random variables $X_1, \dots, X_n$ into two classes – one consisting of sequences which have a high probability of occurrence, known as "typical sequences," and the other consisting of sequences which occur rarely, known as "atypical sequences." The idea is that there are far fewer typical sequences than the total number of possible sequences, but they occur with high probability. The existence of typical sequences follows from the so-called "asymptotic equipartition property":

**Theorem 1** (AEP). *If $X_1, X_2, X_3, \dots$ are i.i.d. random variables with p.m.f. $p(x)$, then*

$$-\frac{1}{n}\log p_n(X_1, \dots, X_n) \xrightarrow{\mathbb{P}} H(X) \qquad [2]$$

*where $H(X)$ is the Shannon entropy for a single variable, and $p_n(X_1, \dots, X_n)$ denotes the random variable taking values $p_n(x_1, \dots, x_n) = \prod_{i=1}^{n} p(x_i)$ with probabilities $p_n(x_1, \dots, x_n)$.*

This theorem has been generalized to the case of sequences of dependent variables $(X_n)_{n\in\mathbb{Z}}$ which are ergodic for the shift transformation defined below. It is easiest to formulate this for an information stream which extends from $-\infty$ to $+\infty$:

**Definition** A sequence $(X_n)_{n\in\mathbb{Z}}$ is called "stationary" if for any $n_1 < n_2$ and any $x_{n_1}, \dots, x_{n_2} \in \mathcal{X}$,

$$\mathbb{P}(X_{n_1} = x_{n_1}, \dots, X_{n_2} = x_{n_2}) = \mathbb{P}(X_{n_1+1} = x_{n_1}, \dots, X_{n_2+1} = x_{n_2})$$

We define the shift transformation $\tau$ by

$$\tau\big((x_n)_{n\in\mathbb{Z}}\big) = (x'_n)_{n\in\mathbb{Z}}, \quad x'_n = x_{n-1} \qquad [3]$$

Then $(X_n)_{n\in\mathbb{Z}}$ is called "ergodic" if it is stationary and if every subset $A \subset \mathcal{X}^{\mathbb{Z}}$ such that $\tau(A) = A$ has probability 0 or 1, that is, $\mathbb{P}((X_n)_{n\in\mathbb{Z}} \in A) = 0$ or 1.

It is known that $(X_n)_{n\in\mathbb{Z}}$ is ergodic if and only if its probability distribution is extremal in the set of invariant probability measures. The generalization of Theorem 1 (McMillan 1953, Breiman 1957) now reads:

**Theorem 2** (Shannon–McMillan–Breiman theorem). *Suppose that the sequence $(X_n)_{n\in\mathbb{Z}}$ is ergodic. Then*

$$\lim_{n\to\infty}\left\{-\frac{1}{n}\log p_n(X_1, \dots, X_n)\right\} = h_{KS} \quad \text{with probability } 1 \qquad [4]$$

*where $h_{KS}$ is the Kolmogorov–Sinai entropy defined by*

$$h_{\mathrm{KS}} = \lim_{n\to\infty}\frac{1}{n}H(X_1, \dots, X_n) = \inf_n \frac{1}{n}H(X_1, \dots, X_n) \qquad [5]$$

**Remark.** It follows from the subadditivity property (3) above that the sequence $(1/n)H(p_n)$ is decreasing, and it is obviously bounded below by 0.

We now define the set of typical sequences (or more precisely, $\epsilon$-typical sequences) as follows:

**Definition** Let $X_1, \dots, X_n$ be i.i.d. random variables with p.m.f. $p(x)$. Given $\epsilon > 0$, $\epsilon$-typical set $T_\epsilon^{(n)}$ is the set of sequences $(x_1 \dots x_n)$ for which

$$2^{-n(H(X)+\epsilon)} \le p(x_1 \dots x_n) \le 2^{-n(H(X)-\epsilon)} \qquad [6]$$

In the case of an ergodic sequence, $H(X)$ is replaced by $h_{\mathrm{KS}}$ in [6].

Let $|T_\epsilon^{(n)}|$ denote the total number of typical sequences and $\mathbb{P}\{T_\epsilon^{(n)}\}$ denote the probability of the typical set. Then the following is an easy consequence of Theorem 1.

**Theorem 3** (Theorem of typical sequences). *For any $\delta > 0 \,\exists\, n_0(\delta) > 0$ such that $\forall n \ge n_0(\delta)$ the following hold:*

(i) $\mathbb{P}\{T_\epsilon^{(n)}\} > 1 - \delta$ *and*
(ii) $(1-\delta)2^{n(H(X)-\epsilon)} \le |T_\epsilon^{(n)}| \le 2^{n(H(X)+\epsilon)}$

### Shannon's Noiseless Channel Coding Theorem

Shannon's noiseless channel coding theorem is a simple application of the theorem of typical sequences and says that the optimal rate at which one can reliably compress data from an i.i.d. classical information source is given by the Shannon entropy $H(X)$ of the source.

A "compression scheme" $C^n$ of rate $R$ maps possible sequences $\underline{x} = (x_1, \dots, x_n)$ to a binary string of length $\lceil nR \rceil$: $C^n : \underline{x} \mapsto \underline{y} = (y_1, \dots, y_{\lceil nR \rceil})$, where $x_i \in \mathcal{X}$; $|\mathcal{X}| = d$ and $y_i \in \{0,1\}\,\forall\, 1 \le i \le \lceil nR \rceil$. The corresponding decompression scheme takes the $\lceil nR \rceil$

compressed bits and maps them back to a string of $n$ letters from the alphabet $\mathcal{X}$: $D^n : \underline{y} \in \{0,1\}^{\lceil nR \rceil} \mapsto \underline{x}' = (x'_1, \ldots, x'_n)$. A compression–decompression scheme is said to be "reliable" if the probability that $\underline{x}' \neq \underline{x}$ tends to 0 as $n \to \infty$. Shannon's noiseless channel coding theorem (Shannon 1918, Cover and Thomas 1991) now states

**Theorem 4** (Shannon). *Suppose that $\{X_i\}$ is an i.i.d. information source, with $X_i \sim p(x)$ and Shannon entropy $H(X)$. If $R > H(X)$ then there exists a reliable compression scheme of rate $R$ for the source. Conversely, any compression scheme with rate $R < H(X)$ is not reliable.*

**Proof** (sketch). Suppose $R > H(X)$. Choose $\epsilon > 0$ such that $H(X) + \epsilon < R$. Consider the set $T_\epsilon^{(n)}$ of typical sequences. The method of compression is then to examine the output of the source, to see if it belongs to $T_\epsilon^{(n)}$. If the output is a typical sequence, then we compress the data by simply storing an index for the particular sequence using $\lceil nR \rceil$ bits in the obvious way. If the input string is not typical, then we compress the string to some fixed $\lceil nR \rceil$ bit string, for example, $(00\ldots000)$. In this case, data compression effectively fails, but, in spite of this, the compression–decompression scheme succeeds with probability tending to 1 as $n \to \infty$, since by Theorem 3 the probability of atypical sequences can be made small by choosing $n$ large enough.

If $R < H(X)$, then any compression scheme of rate $R$ is not reliable. This also follows from Theorem 3 by the following argument. Let $\mathcal{S}(n)$ be a collection of sequences $\underline{x}^{(n)}$ of size $|\mathcal{S}(n)| \leq 2^{\lceil nR \rceil}$. Then the subset of atypical sequences in $\mathcal{S}(n)$ is highly improbable, whereas the corresponding subset of typical sequences has probability bounded by $2^{nR} 2^{-nH(X)} \to 0$ as $n \to \infty$. □

## Quantum Data Compression

### Quantum Sources and Entropy

In quantum information processing systems, information is stored in quantum states of physical systems. The most general description of a quantum state is provided by a density matrix.

A "density matrix" $\rho$ is a positive semidefinite operator on a Hilbert space $\mathcal{H}$, with $\mathrm{tr}\rho = 1$, and the expected value of an operator $A$ on $\mathcal{H}$ is given by

$$\phi(A) = \mathrm{tr}\,(\rho A) \qquad [7]$$

The functional $\phi$ on $\mathcal{M} = \mathcal{B}(\mathcal{H})$, the algebra of linear operators on $\mathcal{H}$, is positive (i.e., $\phi(A) \geq 0$, if $A \geq 0$) and maps the identity $\boldsymbol{I} \in \mathcal{M}$ to 1. Such a functional is also called a state. Conversely, given such a state on a finite-dimensional algebra $\mathcal{M}$, there exists a unique density matrix $\rho_\phi$ such that [7] holds, so the concepts can be used interchangeably. (This is not true in the infinite-dimensional case.)

The quantum analog of the Shannon entropy is called the von Neumann entropy. For any quantum state $\phi$ (or equivalently $\rho_\phi$), it is defined by

$$S(\phi) \equiv S(\rho_\phi) := -\mathrm{tr}\big(\rho_\phi \log \rho_\phi\big) \qquad [8]$$

Here we use log to denote $\log_2$ and define 0 log $0 \equiv 0$, as for the Shannon entropy. Let the density matrix $\rho_\phi$ have a spectral decomposition

$$\rho_\phi = \sum_{i=1}^{d} \lambda_i |\psi_i\rangle\langle\psi_i| \qquad [9]$$

Here $\{|\psi_i\rangle\}$ is the set of eigenvectors of $\rho_\phi$. They form an orthonormal basis of the Hilbert space $\mathcal{H}$. By the fact that $\rho_\phi$ is positive definite and has trace 1, the eigenvalues $\lambda_i$ of $\rho_\phi$ determine a probability distribution. When expressed in terms of the $\lambda_i$, the von Neumann entropy of $\rho$ reduces to the Shannon entropy corresponding to this probability distribution (henceforth, the subscript $\phi$ of $\rho_\phi$ will be omitted): $S(\rho) = H(\underline{\lambda})$, where $\underline{\lambda} = \{\lambda_1, \ldots, \lambda_d\}$.

The von Neumann entropy has properties analogous to $H(X_1, \ldots, X_n)$, in particular (Ohya and Petz 1993, Nielson and Chuang 2000)

1. $0 \leq S(\phi) \leq \log(\dim(\mathcal{H}))$;
2. $S(\phi)$ is concave in $\phi$; and
3. if $\phi$ is a state on $\mathcal{H} = \mathcal{H}_1 \otimes \mathcal{H}_2$ then $S(\phi) \leq S(\phi_1) + S(\phi_2)$ if $\phi_1$ and $\phi_2$ are the restrictions of $\phi$ to $\mathcal{H}_1 \otimes \boldsymbol{I}$ and $\boldsymbol{I} \otimes \mathcal{H}_2$ respectively.

A "quantum information source" in general is defined by a sequence of density matrices $\rho^{(n)}$ on Hilbert spaces $\mathcal{H}_n$ of increasing dimensions $N_n$ given by a decomposition

$$\rho^{(n)} = \sum_k p_k^{(n)} |\Psi_k^{(n)}\rangle\langle\Psi_k^{(n)}| \qquad [10]$$

where the states $|\Psi_k^{(n)}\rangle$ are interpreted as the signal states, and the numbers $p_k^{(n)} \geq 0$ with $\sum_k p_k^{(n)} = 1$, as their probabilities of occurrence. The vectors $|\Psi_k^{(n)}\rangle \in \mathcal{H}_n$ need not be mutually orthogonal.

### Compression–Decompression Scheme and Fidelity

To compress data from such a source one encodes each signal state $|\Psi_k^{(n)}\rangle$ by a state $\widetilde{\rho}_k^{(n)} \in \mathcal{B}(\widetilde{\mathcal{H}}_n)$ where $\dim \widetilde{\mathcal{H}}_n = d_c(n) < N_n$. Thus, a compression scheme is a map $\mathcal{C}^{(n)} : |\Psi_k^{(n)}\rangle\langle\Psi_k^{(n)}| \mapsto \widetilde{\rho}_k^{(n)} \in \mathcal{B}(\widetilde{\mathcal{H}}_n)$. The state $\widetilde{\rho}_k^{(n)}$ is referred to as the compressed state. A corresponding decompression scheme is a map $\mathcal{D}^{(n)}: \mathcal{B}(\widetilde{\mathcal{H}}_n) \mapsto \mathcal{B}(\mathcal{H}_n)$. Both $\mathcal{C}^{(n)}$ and $\mathcal{D}^{(n)}$ must be

completely positive maps. In particular, this implies that $\mathcal{D}^{(n)}$ must be of the form

$$\mathcal{D}^{(n)}(\rho) = \sum_i D_i \rho D_i^* \qquad [11]$$

for linear operators $D_i : \widetilde{\mathcal{H}}_n \mapsto \mathcal{H}_n$ such that $\sum_i D_i^* D_i = \boldsymbol{I}$ (see Nielson and Chuang 2000). Obviously, in order to achieve the maximum possible compression of Hilbert space dimensions per signal state, the goal must be to make the dimension $d_c(n)$ as small as possible, subject to the condition that the information carried in the signal states can be retrieved with high accuracy upon decompression.

The "rate of compression" is defined as

$$R_n := \frac{\log(\dim \widetilde{\mathcal{H}}_n)}{\log(\dim \mathcal{H}_n)} = \frac{\log d_c(n)}{\log N_n}$$

It is natural to consider the original Hilbert space $\mathcal{H}_n$ to be the $n$-qubit space. In this case $N_n = 2^n$ and hence $\log N_n = n$. As in the case of classical data compression, we are interested in finding the optimal limiting rate of data compression, which in this case is given by

$$R_\infty := \lim_{n \to \infty} \frac{\log d_c(n)}{n} \qquad [12]$$

Unlike classical signals, quantum signal states are not completely distinguishable. This is because they are, in general, not mutually orthogonal. As a result, perfectly reconstructing a quantum signal state from its compressed version is often an impossible task and therefore too stringent a requirement for the reliability of a compression–decompression scheme. Instead, a reasonable requirement is that a state can be reconstructed from the compressed version which is nearly indistinguishable from the original signal state. A measure of indistinguishability useful for this purpose is the average fidelity defined as follows:

$$F_n := \sum_k p_k^{(n)} \langle \Psi_k^{(n)} | \mathcal{D}^{(n)}(\widetilde{\rho}_k^{(n)}) | \Psi_k^{(n)} \rangle \qquad [13]$$

This fidelity satisfies $0 \le F_n \le 1$ and $F_n = 1$ if and only if $\mathcal{D}^{(n)}(\widetilde{\rho}_k^{(n)}) = |\Psi_k^{(n)}\rangle\langle\Psi_k^{(n)}|$ for all $k$. A compression–decompression scheme is said to be reliable if $F_n \to 1$ as $n \to \infty$.

The key idea behind data compression is the fact that some signal states have a higher probability of occurrence than others (these states playing a role analogous to the typical sequences of classical information theory). These signal states span a subspace of the original Hilbert space of the source and is referred to as the typical subspace.

### Schumacher's Theorem for Memoryless Quantum Sources

The notion of a typical subspace was first introduced in the context of quantum information theory by Schumacher (1995) in his seminal paper. He considered the simplest class of quantum information sources, namely quantum memoryless or i.i.d sources. For such a source the density matrix $\rho^{(n)}$, defined through [10], acts on a tensor product Hilbert space $\mathcal{H}_n = \mathcal{H}^{\otimes n}$ and is itself given by a tensor product

$$\rho^{(n)} = \pi^{\otimes n} \qquad [14]$$

Here $\mathcal{H}$ is a fixed Hilbert space (representing an elementary quantum subsystem) and $\pi$ is a density matrix acting on $\mathcal{H}$; for example, $\mathcal{H}$ can be a single qubit Hilbert space, in which case $\dim \mathcal{H} = 2, \mathcal{H}_n$ is the Hilbert space of $n$ qubits and $\pi$ is the density matrix of a single qubit. If the spectral decomposition of $\pi$ is given by

$$\pi = \sum_{i=1}^{\dim \mathcal{H}} q_i |\phi_i\rangle\langle\phi_i| \qquad [15]$$

then the eigenvalues and eigenvectors of $\rho^{(n)}$ are given by

$$\lambda_{\underline{k}}^{(n)} = q_{k_1} q_{k_2} \ldots q_{k_n} \qquad [16]$$

and

$$|\psi_{\underline{k}}^{(n)}\rangle = |\phi_{k_1}\rangle \otimes |\phi_{k_2}\rangle \otimes \cdots \otimes |\phi_{k_n}\rangle \qquad [17]$$

Thus, we can write the spectral decomposition of the density matrix $\rho^{(n)}$ of an i.i.d. source as

$$\rho^{(n)} = \sum_{\underline{k}} \lambda_{\underline{k}}^{(n)} |\psi_{\underline{k}}^{(n)}\rangle\langle\psi_{\underline{k}}^{(n)}| \qquad [18]$$

where the sum is over all possible sequences $\underline{k} = (k_1 \ldots k_n)$, with each $k_i$ taking $(\dim \mathcal{H})$ values. Hence, we see that the eigenvalues $\rho^{(n)}$ are labeled by a classical sequence of indices $\underline{k} = k_1 \ldots k_n$.

The von Neumann entropy of such a source is given by

$$S(\rho^{(n)}) \equiv S(\pi^{\otimes n}) = nS(\pi) = nH(X) \qquad [19]$$

where $X$ is the classical random variable with probability distribution $\{q_i\}$.

Let $T_\epsilon^{(n)}$ be the classical typical subset of indices $(k_1 \ldots k_n)$ for which

$$\left| -\frac{1}{n} \log(q_{k_1} \ldots q_{k_n}) - S(\pi) \right| \le \epsilon \qquad [20]$$

as in the theorem of typical sequences. Defining $\mathcal{T}_\epsilon^{(n)}$ as the space spanned by the eigenvectors $|\psi_{\underline{k}}^{(n)}\rangle$

with $\underline{k} \in T_\epsilon^{(n)}$ then immediately yields the quantum analog of the theorem of typical sequences – Theorem 4 given below. We refer to $\mathcal{T}_\epsilon^{(n)}$ as the typical subspace (or more precisely, the $\epsilon$–typical subspace).

**Theorem 4** (Typical subspace theorem). *Fix* $\epsilon > 0$. *Then for any* $\delta > 0 \, \exists \, n_0(\delta) > 0$ *such that* $\forall n \geq n_0(\delta)$ *and* $\rho^{(n)} = \pi^{\otimes n}$, *the following are true*:

(i) $\mathrm{Tr}(P_\epsilon^{(n)} \rho^{(n)}) > 1 - \delta$ *and*
(ii) $(1-\delta)2^{n(S(\pi)-\epsilon)} \leq \dim(\mathcal{T}_\epsilon^{(n)}) \leq 2^{n(S(\pi)+\epsilon)}$, *where* $P_\epsilon^{(n)}$ *is the orthogonal projection onto the subspace* $\mathcal{T}_\epsilon^{(n)}$.

Note that $\mathrm{tr}(P_\epsilon^{(n)} \rho^{(n)})$ gives the probability of the typical subspace. As $\mathrm{tr}(P_\epsilon^{(n)} \rho^{(n)})$ approaches unity for $n$ sufficiently large, $\mathcal{T}_\epsilon^{(n)}$ carries almost all the weight of $\rho^{(n)}$. Let $\mathcal{T}_\epsilon^{(n)\perp}$ denote the orthocomplement of the typical subspace, that is, for any pair of vectors $|\psi\rangle \in \mathcal{T}_\epsilon^{(n)}$ and $|\phi\rangle \in \mathcal{T}_\epsilon^{(n)\perp}$, $\langle\phi|\psi\rangle = 0$. It follows from the above theorem that the probability of a signal state belonging to $\mathcal{T}_\epsilon^{(n)\perp}$ can be made arbitrarily small for $n$ sufficiently large.

Let $P_\epsilon^{(n)}$ denote the orthogonal projection onto the typical subspace $\mathcal{T}_\epsilon^{(n)}$. The encoding (compression) of the signal states $|\Psi_k^{(n)}\rangle$ of [10], is done in the following manner. $\mathcal{C}^{(n)} : |\Psi_k^{(n)}\rangle \langle\Psi_k^{(n)}| \mapsto \tilde{\rho}_k^{(n)}$, where

$$\tilde{\rho}_k^{(n)} := \alpha_k^2 |\tilde{\Psi}_k^{(n)}\rangle\langle\tilde{\Psi}_k^{(n)}| + \beta_k^2 |\Phi_0\rangle\langle\Phi_0| \qquad [21]$$

Here

$$|\tilde{\Psi}_k^{(n)}\rangle := \frac{P_\epsilon^{(n)}|\Psi_k^{(n)}\rangle}{\|P_\epsilon^{(n)}|\Psi_k^{(n)}\rangle\|}$$
$$\alpha_k := \|P_\epsilon^{(n)}|\Psi_k^{(n)}\rangle\|, \quad \beta_k = \|(I - P_\epsilon^{(n)})|\Psi_k^{(n)}\rangle\| \qquad [22]$$

and $|\Phi_0\rangle$ is any fixed state in $\mathcal{T}_\epsilon^{(n)}$.

Obviously $\tilde{\rho}_k^{(n)} \in \mathcal{B}(\mathcal{T}_\epsilon^{(n)})$, and hence the typical subspace $\mathcal{T}_\epsilon^{(n)}$ plays the role of the compressed space. The decompression $\mathcal{D}^{(n)}(\tilde{\rho}_k^{(n)})$ is defined as the extension of $\tilde{\rho}_k^{(n)}$ on $\mathcal{T}_\epsilon^{(n)}$ to $\mathcal{H}_n$:

$$\mathcal{D}^{(n)}\left(\tilde{\rho}_{\underline{k}}^{(n)}\right) = \tilde{\rho}_{\underline{k}}^{(n)} \oplus 0$$

The fidelity of this compression–decompression scheme satisfies

$$\begin{aligned} F_n &= \sum_k p_k^{(n)} \langle\Psi_k^{(n)}|\tilde{\rho}_k^{(n)}|\Psi_k^{(n)}\rangle \\ &= \sum_k p_k^{(n)} \left[\alpha_k^2 |\langle\Psi_k^{(n)}|\tilde{\Psi}_k^{(n)}\rangle|^2 + \beta_k^2 |\langle\Psi_k^{(n)}|\Phi_0\rangle|^2\right] \\ &\geq \sum_k p_k^{(n)} \alpha_k^2 |\langle\Psi_k^{(n)}|\tilde{\Psi}_k^{(n)}\rangle|^2 = \sum_k p_k^{(n)} \alpha_k^4 \\ &\geq \sum_k p_k^{(n)} (2\alpha_k^2 - 1) = 2A_n - 1 \end{aligned} \qquad [23]$$

where $A_n = \mathrm{tr}(P_\epsilon^{(n)} \rho_n)$.

Using the typical subspace theorem, Schumacher (1995) proved the following analog of Shannon's noiseless channel coding theorem for memoryless quantum information sources:

**Theorem 5** (Schumacher's quantum coding theorem). *Let* $\{\rho_n, \mathcal{H}_n\}$ *be an i.i.d. quantum source*: $\rho_n = \pi^{\otimes n}$ *and* $\mathcal{H}_n = \mathcal{H}^{\otimes n}$. *If* $R > S(\pi)$, *then there exists a reliable compression scheme of rate R. If* $R < S(\pi)$, *then any compression scheme of rate R is not reliable.*

**Proof**

(i) $R > S(\pi)$. Choose $\epsilon > 0$ such that $R > S(\pi) + \epsilon$. For a given $\delta > 0$, choose the typical subspace as above and choose $n$ large enough so that (i) and (ii) in the typical subspace theorem hold. In particular, $A_n = \mathrm{tr}(P_\epsilon^{(n)}\rho_n) > 1 - \delta$. Thus, the fidelity tends to 1 as $n \to \infty$.

(ii) *Suppose* $R < S(\pi)$. Let the compression map be $\mathcal{C}^{(n)}$. We may assume that $\widetilde{\mathcal{H}}_n$ is a subspace of $\mathcal{H}_n$ with $\dim \widetilde{\mathcal{H}}_n = 2^{nR}$. We denote the projection onto $\widetilde{\mathcal{H}}_n$ as $\widetilde{P}_n$ and let $\tilde{\rho}_k^{(n)} = \mathcal{C}^{(n)}(|\Psi_k^{(n)}\rangle\langle\Psi_k^{(n)}|)$. Since $\tilde{\rho}_k^{(n)}$ is concentrated on $\widetilde{\mathcal{H}}_n$, we have $\tilde{\rho}_k^{(n)} \leq \widetilde{P}_n$ and hence $\mathcal{D}^{(n)}(\tilde{\rho}_k^{(n)}) \leq \mathcal{D}^{(n)}(\widetilde{P}_n)$, for any decompression map $\mathcal{D}^{(n)}$. Inserting into the definition of the fidelity, we then have

$$\begin{aligned} F &\leq \sum_k p_k^{(n)} \langle\Psi_k^{(n)}|\mathcal{D}^{(n)}(\widetilde{P}_n)|\Psi_k^{(n)}\rangle = \mathrm{tr}\left(\rho^{(n)}\mathcal{D}^{(n)}(\widetilde{P}_n)\right) \\ &\leq \sum_{\underline{k}\in T_\epsilon^{(n)}} \lambda_{\underline{k}}^{(n)} \langle\psi_{\underline{k}}^{(n)}|\mathcal{D}^{(n)}(\widetilde{P}_n)|\psi_{\underline{k}}^{(n)}\rangle + \sum_{\underline{k}\notin T_\epsilon^{(n)}} \lambda_{\underline{k}}^{(n)} \end{aligned} \qquad [24]$$

By the typical subspace theorem, the latter sum tends to 0 as $n \to \infty$, and in the sum over $\underline{k} \in T_\epsilon^{(n)}$ we have $\lambda_{\underline{k}}^{(n)} \leq 2^{-n(S(\pi)-\epsilon)}$. The first sum can therefore be bounded as follows:

$$\begin{aligned} &\sum_{\underline{k}\in T_\epsilon^{(n)}} \lambda_{\underline{k}}^{(n)} \langle\psi_{\underline{k}}^{(n)}|\mathcal{D}^{(n)}(\widetilde{P}_n)|\psi_{\underline{k}}^{(n)}\rangle \\ &\quad \leq 2^{-n(S(\pi)-\epsilon)} \sum_{\underline{k}} \langle\psi_{\underline{k}}^{(n)}|\mathcal{D}^{(n)}(\widetilde{P}_n)|\psi_{\underline{k}}^{(n)}\rangle \\ &\quad = 2^{-n(S(\pi)-\epsilon)} \mathrm{tr}\left(\mathcal{D}^{(n)}(\widetilde{P}_n)\right) \\ &\quad = 2^{-n(S(\pi)-\epsilon)} \mathrm{tr}\left(\sum_i D_i \widetilde{P}_n D_i^*\right) \\ &\quad = 2^{-n(S(\pi)-\epsilon)} 2^{nR} \end{aligned} \qquad [25]$$

by the cyclic property of the trace and the fact that $\sum_i D_i^* D_i = I$ and $\dim \widetilde{\mathcal{H}}_n = 2^{nR}$. □

Even for a quantum source with memory, reliable data compression is achieved by looking for a typical subspace $\mathcal{T}_\epsilon^{(n)}$ of the Hilbert space $\mathcal{H}_n$ for a given $\epsilon > 0$. In the following subsections, we discuss two different classes of such sources for which one

can find typical subspaces $\mathcal{T}_\epsilon^{(n)}$ such that the fidelity $F_n$ tends to 1 as $n \to \infty$.

## Ergodic Quantum Sources

A quantum generalization of classical ergodic sources is defined as follows. First consider the analog of an infinite sequence of random variables which is a state on the infinite tensor product of a finite-dimensional $*$-algebra $\mathcal{M}$. The latter is given by the norm closure of the increasing sequence of finite tensor products

$$\mathcal{M}_\infty = \overline{\bigcup_n \otimes_{k=-n}^n \mathcal{M}} \qquad [26]$$

A translation-invariant state $\phi_\infty$ on $\mathcal{M}_\infty$ is said to be ergodic if it cannot be decomposed as a (nontrivial) convex combination of other translation-invariant states. The analog of the Kolmogorov–Sinai entropy [5] for an ergodic state $\phi_\infty$ is called the mean entropy and is given by

$$S_M(\phi_\infty) = \lim_{n\to\infty} \frac{1}{n} S(\phi_n) = \inf_{n\in\mathbb{N}} \frac{1}{n} S(\phi_n) \qquad [27]$$

where $\phi_n$ is the restriction of $\phi_\infty$ to $\mathcal{M}_n := \mathcal{M}^{\otimes n}$. Following Hiai and Petz (1991), we define the following quantity for any state $\phi$ on an arbitrary finite-dimensional $*$-algebra $\mathcal{M}$ and a given $\delta > 0$:

$$\beta_\delta(\phi) = \inf\{\log \mathrm{tr}(q) : q \in \mathcal{M}, q^* = q, \\ q^2 = q, \phi(q) \geq 1 - \delta\} \qquad [28]$$

We also define a state $\phi_\infty$ on $\mathcal{M}_\infty$ to be completely ergodic if it is ergodic under transformations on $\mathcal{M}_\infty$, induced by $l$-fold shifts on $\mathbb{Z}$, for arbitrary $l \in \mathbb{N}$. The following theorem is due to Hiai and Petz (1991), who proved it in a slightly more general setting:

**Theorem 6** (Hiai and Petz). *Suppose that $\phi_\infty$ is a completely ergodic state on $\mathcal{M}_\infty$ and $d := \dim \mathcal{M} < \infty$, and set $\phi_n = \phi_\infty \restriction_{\mathcal{M}_n}$. Then, for any $\delta > 0$, the following hold*:

(i) $$\limsup_{n\to\infty} \frac{1}{n} \beta_\delta(\phi_n) \leq S_M(\phi_\infty) \qquad [29]$$

(ii) $$\liminf_{n\to\infty} \frac{1}{n} \beta_\delta(\phi_n) \geq S_M(\phi_\infty) - \delta \log d \qquad [30]$$

**Proof of (i)** Choose $r > S_M(\phi_\infty)$ and let $\epsilon < r - S_M(\phi_\infty)$ and $h = r - \epsilon$. By the definition of $S_M(\phi_\infty)$, there exists $l \in \mathbb{N}$ such that $S(\phi_l) < lh$. Let $\{|e_i\rangle\}_{i=1}^{ld}$ be an orthonormal set of eigenvectors of $\rho_{\phi_l}$, with corresponding eigenvalues $\lambda_i$, that is, let

$$\rho_{\phi_l} = \sum_{i=1}^{ld} \lambda_i p_i \qquad [31]$$

where $p_i = |e_i\rangle\langle e_i|$ is the projection onto $|e_i\rangle$, be the spectral decomposition for $\rho_{\phi_l}$. Denote the spectrum $\mathcal{X} = \{\lambda_i\}_{i=1}^{ld}$. For $n \in \mathbb{N}$, introduce the probability measures $\nu_n$ on $\mathcal{X}^n$ by

$$\nu_n(A) = \phi_{nl}(q_A) \qquad [32]$$

where, for any $A \subset \mathcal{X}^n$, the projection $q_A$ is defined by

$$q_A = \sum_{(\lambda_{i_1},\ldots,\lambda_{i_n})\in A} p_{i_1} \otimes \ldots \otimes p_{i_n} \qquad [33]$$

Similarly, we define $\nu_\infty$ on $\mathcal{X}^{\mathbb{Z}}$. The sequence of random variables $(X_n)_{n\in\mathbb{Z}}$ with distribution $\nu_\infty$ is then ergodic since $\phi_\infty$ is completely ergodic (and hence $l$-ergodic).

By the Shannon–McMillan–Breiman theorem (Theorem 2),

$$-\frac{1}{n} \log \nu_n(\{(x_1, \ldots, x_n)\}) \to h_{\mathrm{KS}} \qquad [34]$$

almost surely w.r.t. $\nu_\infty$, where $h_{\mathrm{KS}}$ is the Kolmogorov–Sinai entropy. The latter is given by $h_{\mathrm{KS}} = \lim_{n\to\infty} (1/n)H_n = \inf_{n\in\mathbb{N}} (1/n)H_n$, where

$$H_n = -\sum_{(x_1,\ldots,x_n)\in\mathcal{X}^n} \nu_n(\{(x_1, \ldots, x_n)\}) \\ \times \log \nu_n(\{(x_1, \ldots, x_n)\}) \qquad [35]$$

Notice in particular that

$$h_{\mathrm{KS}} \leq H_1 = S(\phi_l) < lh \qquad [36]$$

If let $T_\epsilon^{(n)}$ be the (typical) subset of $\mathcal{X}^n$ such that

$$-\frac{1}{n} \log \nu_n(\{(x_1, \ldots, x_n)\}) \in (h_{\mathrm{KS}} - \epsilon, h_{\mathrm{KS}} + \epsilon) \qquad [37]$$

for $(x_1, \ldots, x_n) \in T_\epsilon^{(n)}$ then we have $\nu_\infty(T_\epsilon^{(n)}) \geq 1 - \delta$ for $n$ large enough. Moreover, since $\nu_n(\{(x_1, \ldots, x_n)\}) \geq \mathrm{e}^{-n(h_{\mathrm{KS}}+\epsilon)}$ for all $(x_1, \ldots, x_n) \in T_\epsilon^{(n)}$, and the total measure is 1,

$$|T_\epsilon^{(n)}| \leq \mathrm{e}^{n(h_{\mathrm{KS}}+\epsilon)} \leq \mathrm{e}^{n(lh+\epsilon)} \qquad [38]$$

It follows that $\mathrm{tr}(q_{T_\epsilon^{(n)}}) \leq \mathrm{e}^{n(lh+\epsilon)}$ whereas $\phi_{nl}(q_{T_\epsilon^{(n)}}) = \nu_n(T_\epsilon^{(n)}) \geq 1 - \delta$ and we conclude that

$$\frac{1}{nl} \beta_\delta(\phi_{nl}) \leq \frac{n(lh + \epsilon)}{nl} < r \qquad [39]$$

from which [29] follows upon taking $n \to \infty$, since $r > S_M(\phi_\infty)$ was arbitrary. (Notice that $\beta_\delta(\phi_n)$ is decreasing in $n$ since $\mathcal{M}_n \subset \mathcal{M}_{n+1}$.) □

**Proof of (ii)** Given $\epsilon, \delta > 0$ and $n \in \mathbb{N}$, choose a projection $q_n$ with $\phi_n(q_n) \geq 1 - \delta$ and $\log \mathrm{tr}(q_n) < \beta_\delta(\phi_n) + \epsilon$. Since $S_M(\phi_\infty) = \inf (1/n) S(\phi_n)$ we have

$S_M(\phi_\infty) \leq (1/n)S(\phi_n)$. We now use the following lemma:

**Lemma 7** *If $\phi$ is a state on a finite-dimensional $*$-algebra $\mathcal{M}$, and $q \in \mathcal{M}$ is a projection, then*

$$S(\phi) \leq H(p) + \phi(q)\log \mathrm{tr}(q) + (1-\phi(q))\log \mathrm{tr}(1-q) \qquad [40]$$

*where $H(p) = -p\log p - (1-p)\log(1-p)$ (the binary entropy) with $p = \phi(q)$.*

**Proof** First notice that if $[\rho_\phi, q] = 0$ then the result [40] follows from the simple inequality:

$$-\sum_{i=1}^{m} \tilde{\lambda}_i \log \tilde{\lambda}_i \leq \log m \quad \text{if} \quad \sum_{i=1}^{m} \tilde{\lambda}_i = 1 \qquad [41]$$

Indeed, diagonalizing $\rho_\phi$, the eigenvalues $\lambda_i$ divide into two subsets with corresponding eigenvectors belonging to the range of $q$, respectively, its complement. Considering the first set, we have, if $m = \dim(\mathrm{Ran}(q))$, and taking $\tilde{\lambda}_i = \lambda_i/(\sum_{i=1}^m \lambda_i)$ in [41],

$$-\sum_{i=1}^{m} \lambda_i \log \lambda_i \leq -\left(\sum_{i=1}^{m} \lambda_i\right) \log\left(\frac{1}{m}\sum_{i=1}^{m} \lambda_i\right) = -\mathrm{tr}(q\rho_\phi)\left[\log \mathrm{tr}(q\rho_\phi) - \log \mathrm{tr}(q)\right]$$

Adding the analogous inequality for the part of the spectrum corresponding to $1-q$, we obtain [40].

In the general case, that is, if $[\rho_\phi, q] \neq 0$, define the unitary $u = 2q - 1$ and the state

$$\phi'(x) = \tfrac{1}{2}[\phi(x) + \phi(uxu)] \qquad [42]$$

Then $[\rho_{\phi'}, q] = 0$ and by concavity of $S(\phi)$ and the result for the previous case

$$H(X) + \phi(q) \log \mathrm{tr}(q) + (1-\phi(q)) \log \mathrm{tr}(1-q) \geq S(\phi') \geq S(\phi) \qquad [43]$$

since $\phi'(q) = \phi(q)$. □

Continuing with the proof of (ii), we conclude that

$$S(\phi_n) \leq H(p) + \phi_n(q_n)\log \mathrm{tr}(q_n) + (1-\phi(q_n))\log \mathrm{tr}(1-q_n) \leq 1 + \beta_\delta(\phi_n) + \epsilon + \delta n \log d$$

Dividing by $n$ and taking the limit we obtain (30). □

It follows from this theorem that we can define a typical subspace in the same way as in Schumacher's theorem. Indeed, given $\delta > 0$ and $\epsilon > 0$, we have that for $n$ large enough, there exists a subspace $\mathcal{T}_\epsilon^{(n)}$ equal to the range of a projection $q_n$ such that $\phi_n(q_n) > 1 - \delta$ and $\mathrm{e}^{n(S_M(\phi_\infty) - \delta\log d - \epsilon)} < \dim(\mathcal{T}_\epsilon^{(n)}) = \mathrm{tr}(q_n) < \mathrm{e}^{n(S_M(\phi_\infty)+\epsilon)}$. The proof of the quantum analog of the Shannon–McMillan theorem is then similar to that of Schumacher's theorem (Petz and Mosonyi 2001, Bjelaković *et al.* 2004):

**Theorem 8** *Let $\phi_\infty$ be a completely ergodic stationary state on the infinite tensor product algebra $\mathcal{M}_\infty$. If $R > S_M(\phi_\infty)$, then for any decomposition of the form*

$$\rho^{(n)} = \sum p_k^{(n)} |\Psi_k^{(n)}\rangle\langle\Psi_k^{(n)}| \qquad [44]$$

*there exists a reliable quantum code of rate $R$. Conversely, if $R < S_M(\phi_\infty)$ then any quantum compression–decompression scheme of rate $R$ is not reliable.*

**Remarks** Theorem 6 also holds for higher-dimensional information streams, with essentially the same proof. (The existence of the mean entropy is more complicated in that case.) The condition of complete ergodicity in this theorem is unnecessary. Indeed, Bjelaković *et al.* (2004) showed that the result remains valid (also in more than one dimensions) if the state $\phi_\infty$ of the source is simply ergodic. They achieved this by decomposing a general ergodic state into a finite number of $l$-ergodic states, and then applying the above strategy to each. It should also be mentioned that a weaker version of Theorem 6 was proved by King and Lesniewski (1998). They considered the entropy of an associated classical source, but did not show that this classical entropy can be optimized to approximate the von Neumann entropy. This had in fact already been proved by Hiai and Petz (1991). The relevance of the latter work for quantum information theory was finally pointed out by Mosonyi and Petz (2001).

## Source Coding for Quantum Spin Systems

In this section we consider a class of quantum sources modeled by Gibbs states of a finite strongly interacting quantum spin system in $\Lambda \subset \mathbb{Z}^d$ with $d \geq 2$. Due to the interaction between spins, the density matrix of the source is not given by a tensor product of the density matrices of the individual spins and hence the quantum information source is non-i.i.d. We consider the density matrix to be written in the standard Gibbsian form:

$$\rho^{\omega,\Lambda} = \frac{\mathrm{e}^{-\beta H_\Lambda^\omega}}{\Xi^{\omega,\Lambda}} \qquad [45]$$

where $\beta > 0$ is the inverse temperature. Here $\omega$ denotes the boundary condition, that is, the configuration of the spins in $\Lambda^c = \mathbb{Z}^d \setminus \Lambda$, and $H_\Lambda^\omega$ is the Hamiltonian acting on the spin system in $\Lambda$ under this boundary condition. (see Datta and Suhov (2002)

for precise definitions of these quantities). The denominator on the right-hand side of [45] is the partition function.

Note that any faithful density matrix can be written in the form [45] for some self-adjoint operator $H_\Lambda^\omega$ with discrete spectrum, such that $e^{-\beta H_\Lambda^\omega}$ is trace class. However, we consider $H_\Lambda^\omega$ to be a small quantum perturbation of a classical Hamiltonian and require it to satisfy certain hypotheses (see Datta and Suhov (2002)). In particular, we assume that $H_\Lambda = H_{0\Lambda} + \lambda V_\Lambda$, where (1) $H_{0\Lambda}$ is a classical, finite-range, translation-invariant Hamiltonian with a finite number of periodic ground states, and the excitations of these ground states have an energy proportional to the size of their boundaries (Peierls condition); (2) $\lambda V_\Lambda$ is a translation-invariant, exponentially decaying, quantum perturbation, $\lambda$ being the perturbation parameter. These hypotheses ensure that the quantum Pirogov–Sinai theory of phase transitions in lattice systems (see, e.g., Datta *et al.* (1996)) applies.

The power of quantum Pirogov–Sinai theory is such that, in proving reliable data compression for such sources, we do not need to invoke the concept of ergodicity.

Using the concavity of the von Neumann entropy $S(\rho^{\omega,\Lambda})$, one can prove that the von Neumann entropy rate (or mean entropy) of the source

$$h := \lim_{\Lambda \nearrow \mathbb{Z}^d} \frac{S(\rho^{\omega,\Lambda})}{|\Lambda|}$$

exists. For a general van Hove sequence, this follows from the strong subadditivity of the von Neumann entropy (see, e.g., Ohya and Petz (1993)).

Let $\rho^{\omega,\Lambda}$ have a spectral decomposition

$$\rho^{\omega,\Lambda} = \sum_j \lambda_j |\psi_j\rangle\langle\psi_j|$$

where the eigenvalues $\lambda_j, 1 \le j \le 2^{|\Lambda|}$, and the corresponding eigenstates $|\psi_j\rangle$, depend on $\omega$ and $\Lambda$. Let $\mathcal{P}^{\omega,\Lambda}$ denote the probability distribution $\{\lambda_j\}$ and consider a random variable $K^{\omega,\Lambda}$ which takes a value $\lambda_j$ with probability $\lambda_j$:

$$K^{\omega,\Lambda}(\psi_j) = \lambda_j; \quad \mathcal{P}^{\omega,\Lambda}(K^{\omega,\Lambda} = \lambda_j) = \lambda_j$$

The data compression limit is related to asymptotical properties of the random variables $K^{\omega,\Lambda}$ as $\Lambda \nearrow \mathbb{Z}^d$. As in the case of i.i.d. sources, we prove the reliability of data compression by first proving the existence of a typical subspace. The latter follows from Theorem 9 below. The proof of this crucial theorem relies on results of quantum Pirogov–Sinai theory (Datta *et al.* 1996).

**Theorem 9** *Under the above assumptions, for $\beta$ large and $\lambda$ small enough, for all $\epsilon > 0$*

$$\lim_{\Lambda \nearrow \mathbb{Z}^d} \mathcal{P}^{\omega,\Lambda}\left(\left|\frac{-1}{|\Lambda|}\log K^{\omega,\Lambda} - h\right| \le \epsilon\right) = \lim_{\Lambda \nearrow \mathbb{Z}^d} \sum_j \lambda_j \chi_{\{|-|\Lambda|^{-1}\log\lambda_j - h| \le \epsilon\}} = 1 \qquad [46]$$

*where $\chi_{\{\ldots\}}$ denotes an indicator function.*

Theorem 9 is essentially a law of large numbers for random variables ($-\log K^{\omega,\Lambda}$). The statement of the theorem can be alternatively expressed as follows. For any $\epsilon > 0$,

$$\lim_{\Lambda \nearrow \mathbb{Z}^d} \mathcal{P}^{\omega,\Lambda}\left(2^{-|\Lambda|(h+\epsilon)} \le K^{\omega,\Lambda} \le 2^{-|\Lambda|(h-\epsilon)}\right) = 1 \qquad [47]$$

Thus, we can define a typical subspace $\mathcal{T}_\epsilon^{\omega,\Lambda}$ by

$$\mathcal{T}_\epsilon^{\omega,\Lambda} := \text{span}\,\{|\psi_j\rangle : 2^{-|\Lambda|(h+\epsilon)} \le \lambda_j \le 2^{-|\Lambda|(h-\epsilon)}\} \qquad [48]$$

It clearly satisfies the analogs of (i) and (ii) of the typical subspace theorem, which implies as before that a compression scheme of rate $R$ is reliable if and only if $R > h$.

## Universal and Variable Length Data Compression

Thus far we discussed source-dependent data compression for various classes of quantum sources. In each case data compression relied on the identification of the typical subspace of the source, which in turn required a knowledge of its density matrix. In classical information theory, there exists a generalization of the theorem of typical sequences due to Csiszár and Körner (1981) where the typical set is universal, in that it is typical for every possible probability distribution with a given entropy. This result was used by Jozsa *et al.* (1998) to construct a universal compression scheme for quantum i.i.d sources with a given von Neumann entropy $S$ using a counting argument for symmetric subspaces. This was generalized to ergodic sources by Kaltchenko and Yang (2003) along the lines of Theorem 6. Hayashi and Matsumoto (2002) supplemented the work of Jozsa *et al.* (1998) with an estimation of the eigenvalues of the source (using the measurement smearing technique) to show that a reliable compression scheme exists for any quantum i.i.d source, independent of the value of its von Neumann entropy $S$, the limiting rate of compression being given by $S$. If one admits variable length coding, the Lempel–Ziv algorithm gives a completely universal compression scheme, independent of the value of the entropy, in the classical case (Cover and Thomas 1991). This algorithm was generalized to the quantum case for i.i.d sources by Jozsa and Presnell (2003), and to

sources modeled by Gibbs states of free bosons or fermions on a lattice by Johnson and Suhov (2002).

Another important question is the efficiency of the various coding schemes. The above-mentioned schemes for quantum i.i.d. sources are not efficient, in the sense that they have no polynomial time implementation. Recently, it was shown by Bennett *et al.* (2004) that an efficient, universal compression scheme for i.i.d sources can be constructed by employing quantum state tomography.

# Spacetime Topology, Causal Structure and Singularities

**R Penrose**, University of Oxford, Oxford, UK

## The Value of Topological Reasoning in General Relativity

Solving the equations of Einstein's general relativity (*see* General Relativity: Overview) can be an exceedingly complicated business; it is commonly found necessary to resort to numerical solutions involving very complex computer codes (*see* Computational Methods in General Relativity: The Theory). The essential content of the basic equations of the theory itself is, however, something that can be phrased in simple geometrical terms, using only basic concepts of differential geometry (*see* General Relativity: Overview). By virtue of this, it is sometimes the case, in general relativity, that geometrical arguments of various kinds – including purely topological ones (i.e., arguments depending only upon the properties of continuity or smoothness) – can be used to great effect to obtain results that are not readily accessible by standard procedures of differential equation theory or by direct numerical calculation.

One particularly significant family of situations where this kind of argument has a key role to play is in the important issue of the singularities that arise in many solutions of the Einstein equations, in which spacetime curvatures may be expected to diverge to infinity. These are exemplified, particularly, by two important classes of solutions of the

Einstein field equations in which singularities arise. In the first instance, we have cosmological models, which tend to exhibit the presence of an initial singularity referred to as the "Big Bang," as was first noted in the standard Friedmann models (which are solutions of the Einstein equations with simple matter sources; *see* Cosmology: Mathematical Aspects). Secondly, we find a final singularity (for local observers) at the endpoint of gravitational collapse to a black hole (where in the relevant region, outside the collapsing matter, Einstein's vacuum equations are normally taken to hold). In either case, there are canonical exact models, in which considerable symmetry is assumed, and where the models indeed become singular at places where the spacetime curvature diverges to infinity. For many years (prior to 1965), there had been much debate as to whether these singularities were an inevitable feature of the general physical situation under consideration, or whether the presence of singularities might be an artifact of the assumed high symmetry. The use of topological-type arguments has established that, in general terms, the occurrence of a singularity is not merely an artifact of symmetry, and cannot generally be removed by the introduction of small (finite) perturbations.

Let us first consider the standard picture, put forward in 1939 by Oppenheimer and Snyder (OS), of the gravitational collapse of an over-massive star to a black hole; see Figure 1 (and *see* Stationary Black Holes). This assumes exact spherical symmetry. The region external to the matter is described by the well-known Schwarzschild solution of the Einstein vacuum equations, appropriately extended to inside the "Schwarzschild radius" $r = 2mG/c^2$ ($G$ being Newton's gravitational constant and $c$, the speed of light, and where $m$ is the total mass of the collapsing material; from now, for convenience, we choose units so that $G = c = 1$). In Figure 1, this internal extension is conveniently expressed using Eddington–Finkelstein coordinates $(r, v, \theta, \phi)$ (see Eddington (1924) and Finkelstein (1958)), where $v = t + r + 2m \log(r - 2m)$, the metric form being

$$ds^2 = (1 - 2m/r)dv^2 - 2dvdr - r^2(d\theta^2 + \sin^2\theta d\phi^2)$$

(The signature convention $+---$ is being adopted here; *see* General Relativity: Overview.) We find that, in this model, there is a singularity (at $r = 0$) at the future endpoint of each world line of collapsing matter. Moreover, no future-timelike line starting inside the horizon can avoid reaching the singularity when we try to extend it, as a timelike curve,

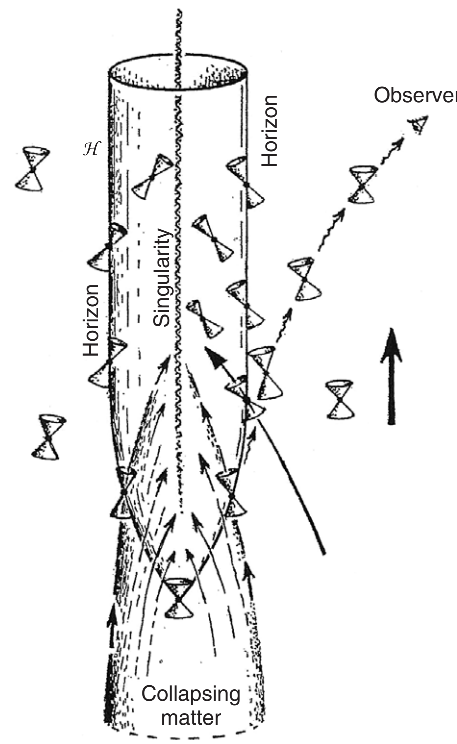

**Figure 1** Spacetime diagram of collapse to a black hole. (One spatial dimension is suppressed.) Matter collapses inwards, through the 3-surface that becomes the (absolute) event horizon. No matter or information can escape the hole once it has been formed. The null cones are tangent to the horizon and allow matter or signals to pass inwards but not outwards. An external observer cannot see inside the hole, but only the matter – vastly dimmed and redshifted – just before it enters the hole. (Reproduced with permission from Penrose R. (2004) *The Road to Reality: a Complete Guide to the Laws of the Universe*. London: Jonathan Cape.)

indefinitely into the future, where the "horizon" is the three-dimensional region obtained by rotating, over the $(\theta, \phi)$ 2-sphere, the null (lightlike) line which is $r = 2m$ outside the matter region and which is the extension of this line, as a null line, into the past until it meets the axis. It is easy to see that any observer's world line within this horizon is indeed trapped in this sense.

The question naturally arises: how representative is this model? Here, the singularity occurs at the center ($r = 0$), the place where all the matter is directed, and where it all reaches without rebounding. So it may be regarded as unsurprising that the density becomes infinite there. Now, let us suppose that the collapsing material is not exactly spherically symmetrical. Even if it is only slightly (though finitely) perturbed away from this symmetrical situation, having slight (but finite) transverse motions, the collapsing matter is now not all directed exactly towards the center, as it is in the OS model. One might imagine that the singularity

could now be avoided, the different portions of matter just “missing” each other and then being finally flung out again, after some complicated motions, where the density and spacetime curvatures might well become large but presumably still finite. To follow such an irregular collapse in full detail would present a very difficult task, and one would have to carry it out by numerical means. As yet, despite enormous advances in computational technique, a fully effective simulation of such a “generic” collapse is still not in hand. In any case, it is hard to make a convincing case as to whether or not a singularity arises, because as soon as metric or curvature quantities begin to diverge, the computation becomes fundamentally unreliable and simply “gives up.” So we cannot really tell whether the failure is due to some genuine divergence or whether it is an artifact. It is thus fortunate that other mathematical techniques are available. Indeed, by use of a differential–topological–causal argument, we find that such perturbations do not help, at least so long as they are small enough not to alter the general character of the collapse, which we find has an “unstoppable” character, so long as a certain criterion is satisfied its early stages.

## Trapped Surfaces

But how are we to characterize the collapse as “unstoppable,” where no symmetries are to be assumed, and the simple picture illustrated in Figure 1 cannot be appealed to? A convenient characterization is the presence of what is called a “trapped surface.” This notion generalizes a key feature of the $0 < r < 2m$ region inside the horizon of the vacuum (Eddington–Finkelstein) picture of Figure 1. To understand what this feature is, consider fixing a point $s$ in the vacuum region of the $(v, r)$-plane of Figure 1. We must, of course, bear in mind that, because this plane is to be “rotated” about the central vertical axis ($r = 0$) by letting $\theta$ and $\phi$ vary as coordinates on a 2-sphere $S^2$, the point $s$ actually describes a closed 2-surface $\mathtt{S}$ (coordinatized by $\theta$ and $\phi$) with topology $S^2$ (so $\mathtt{S}$ is intrinsically an ordinary 2-sphere). We shall be concerned with the region $I^+(\mathtt{S})$, which is the (chronological) “future” of $\mathtt{S}$, that is, the locus of points $q$ for which a timelike curve exists having a future endpoint at $q$ and a past endpoint on $\mathtt{S}$. We shall also be interested, particularly, in the boundary $\partial I^+(\mathtt{S})$ of $I^+(\mathtt{S})$. This boundary is described, in Figure 1, by the pair of null curves $v = \text{const.}$ and $2r + 4m \log(r - 2m) = \text{const.}$, proceeding into the future from $s$ (and rotated in $\theta$ and $\phi$). The region $I^+(\mathtt{S})$ itself is represented by that part of Figure 1 which lies between these null curves.

We observe that, in this symmetrical case ($s$ being chosen in the vacuum region), a characterization of $s$ as being “trapped,” in the sense that it lies in a region that is within the horizon, is that the future tangents to these null curves both point “inwards,” in the sense of decreasing $r$. Since $r$ is the metric radius of the $S^2$ of rotation, so that the element of surface area of this sphere is proportional to $r^2$, it follows that the surface area of the boundary $\partial I^+(\mathtt{S})$ reduces, on both branches, as we move away from $\mathtt{S}$ into the future. The three-dimensional region $\partial I^+(\mathtt{S})$ consists of two null surfaces joined along $\mathtt{S}$, in the sense that their Lorentzian normals are null 4-vectors. For each fixed value of $\theta$ and $\phi$, this normal is a tangent to one or other of the two null curves of Figure 1, starting at $s$. For a trapped $s$, these normals point in the direction of decreasing $r$, and it follows that the divergence of these normals is negative (so $\rho > 0$ in what follows below).

In the general case, it is this property of negativity of the divergence, at $\mathtt{S}$, of both sets of Lorentzian normals (i.e., of null tangents to $\partial I^+(\mathtt{S})$), that characterizes $\mathtt{S}$ as a trapped surface, where in the general case we must also prescribe $\mathtt{S}$ to be compact and spacelike. But now there are to be no assumptions of symmetry whatever. Such a characterization is stable against small, but finite, perturbations of the location of $\mathtt{S}$, within the spacetime manifold $\mathtt{M}$, and also against small, but finite, perturbations of $\mathtt{M}$ itself.

We can think of a trapped surface in more direct physical/geometrical terms. Imagine a flash of light emitted all over some spacelike compact spherical surface such as $\mathtt{S}$, but now in ordinary flat spacetime, where for simplicity we suppose that $\mathtt{S}$ is situated in some spacelike (flat) 3-hypersurface $\mathtt{H}$, of constant time $t = 0$. There will be one component to the flash proceeding outwards and another proceeding inwards. Provided that $\mathtt{S}$ is convex, the outgoing flash will represent an initial increase of the surface area at every point of $\mathtt{S}$ and the ingoing flash, an initial decrease. In four-dimensional spacetime terms, we express this as positivity of the divergence of the outward null normal and the negativity of the divergence of the inward one. The characteristic feature of a trapped surface is that whereas the ingoing flash will still have an initially reducing surface area, the “outgoing” flash now has the curious property that its surface area is also initially decreasing, this holding at every point of $\mathtt{S}$.

Locally, this is not particularly strange. For a surface wiggling in and out, we are quite likely to find portions of ingoing flash with increasing area,

and portions of outgoing flash with decreasing area. An extreme case in Minkowski spacetime has S as the intersection of two past light cones. All the null normals to S point along the generators of these past cones, and therefore all converge into the future. Such a surface S (indeed spacelike) looks "trapped" everywhere locally, but fails to count as trapped, not being compact. Since there is nothing causally extreme about Minkowski space, it is appropriate not to count such surfaces as "trapped." What *is* the peculiar about a trapped surface is that both ingoing and outgoing flashes are initially decreasing in area, over the entire compact S. (N. B. Hawking and Ellis (1973) adopt a slightly different terminology; the term "trapped," used here, refers to their "closed trapped.")

## The Null Raychaudhuri Equation

What do we deduce from the existence of a trapped surface? A glance at **Figure 1** gives us some indication of the trouble. As we trace $\partial I^{+}(S)$ into the future, we find that its cross-sectional area continues to decrease, until becoming zero at the central singularity. This last feature need not reflect closely what happens in more general cases, with no spherical symmetry. But the reduction in surface area is a general property. This is the first point to appreciate in a theorem (Penrose 1965, 1968, Hawking and Ellis 1973) which indicates the profoundly disturbing physical implications of the existence of a trapped surface in physically realistic gravitational collapse, according to Einstein's general relativity. The surface-area reduction arises from a result known as "Raychaudhuri's equation," in the case of null rays – where we refer to this as the "Sachs" equations. We come to this next.

Although many different notations are used to express the needed quantities, we can here conveniently employ the spin-coefficient formalism, as described elsewhere in this Encyclopedia (*see* Spinors and Spin Coefficients).

Suppose that we have a congruence (smooth three-parameter family) of rays (null geodesics) in four-dimensional spacetime. Let $\ell^a$ be a real future-null vector, tangent to a null geodesic $\gamma$ of the congruence, and let $m^b$ be complex-null, also defined along $\gamma$, where its real and imginary parts are unit vectors spanning a 2-surface element orthogonal to $\ell^a$ at each point of $\gamma$, so we have

$$\ell_a \ell^a = 0,\ \ell_a m^a = 0,$$
$$m_a m^a = 0,\ \bar{m}_a m^a = -1,$$
$$\ell^a = \bar{\ell}^a$$

where it is assumed that each of $\ell^a, m^a$ is parallel-propagated along $\gamma$:

$$\ell^a \nabla_a \ell^b = 0, \qquad \ell^a \nabla_a m^b = 0$$

($\nabla_a$ denoting covariant derivative). The spin-coefficient quantities

$$\rho = m^a \bar{m}^b \nabla_a \ell_b \qquad \text{and} \qquad \sigma = m^a m^b \nabla_a \ell_b$$

are of importance. Here, the real part of $\rho$ measures the convergence of the congruence and the imaginary part defines its rotation; $\sigma$ measures its shear, where the argument of $\sigma$ defines the direction (perpendicular to $\gamma$) of the axis of shear, and whose strength is defined by $|\sigma|$ (see Penrose and Rindler (1986) for a graphic description of these quantities). Defining propagation derivative along $\gamma$ by

$$\mathrm{D} = \ell^a \nabla_a$$

we can write the Sachs equations as

$$\mathrm{D}\rho = \rho^2 + \bar{\sigma}\sigma + \Phi$$
$$\mathrm{D}\sigma = 2\rho\sigma + \Psi$$

where $\Phi = -(1/2)R_{ab}\ell^a\ell^b$ and $\Psi = C_{abcd}\ell^a m^b \ell^c m^d$, conventions for the Ricci tensor $R_{ab}$ and the Weyl tensor $C_{abcd}$ being those of General Relativity: Overview (and of Penrose and Rindler (1984)). We note that it is the real Ricci component $\Phi$ which governs the propagation of the divergence and the complex Weyl component $\Psi$ which governs the propagation of shear, though there are some non-linear terms. The quantity $\Phi$ is normally taken non-negative, since it measures the energy flux across $\gamma$ (with, in fact $\Phi = 4\pi G T_{ab}\ell^a\ell^b$, where $T_{ab}$ is the energy tensor). The condition that $\Phi \geq 0$ at all points of spacetime and for all null directions $\ell^a$, is called the "weak energy condition." (Again there is a minor discrepancy with Hawking and Ellis (1973) who adopt a somewhat stronger "weak energy condition," which is the above but where $\ell^a$ is also allowed to be future-timelike. Unfortunately, with this terminology, their "weak energy condition" is not strictly weaker than their "strong energy condition.")

It will now be assumed that $\rho$ is real:

$$\rho = \bar{\rho}$$

which is always the case for propagation along the generators of a null hypersurface. The weak energy condition then has an important implication for us. We find that if $A$ is an element of 2-surface area within the plane spanned by the real and imaginary parts of $m^a$, then (this area element being propagated by D along the lines $\gamma$)

$$\mathrm{D}A^{1/2} = -\rho A^{1/2}$$

As a consequence, assuming $\Phi \geq 0$,

$$\mathrm{D}^2 A^{1/2} = -(\bar{\sigma}\sigma + \Phi)A^{1/2} \leq 0$$

This tells us that once the divergence $(-\rho)$ becomes negative, then the area element must reduce to zero sometime in the future along $\gamma$, assuming that $\gamma$ is future-null-complete in the sense that it extends to indefinitely large values of an affine parameter $u$ defined along it, where an affine parameter associated with the parallel-propagated $\ell^a$ satisfies

$$\ell^a \nabla_a u = 1$$

Such a place where the cross-sectional area pinches down to zero is a singularity of the congruence or null hypersurface, referred to as a "caustic." (There are also terminological confusions arising from different authors defining the term "caustic" in slightly different ways. The terminology used here is slightly discrepant from that of Arnol'd (1992) (Chapter 3).)

From this property, it follows that if we have a trapped surface $\mathtt{S}$, then every generator of $\partial I^+(\mathtt{S})$, if extended indefinitely into the future, must eventually encounter a caustic. This, so far, tells us nothing about actual singularities in the spacetime $\mathtt{M}$; even Minkowski space contains many null hypersurfaces with multitudes of caustic points. However, caustics do tell us something significant about sets like $\partial I^+(\mathtt{S})$, which are the boundaries of future sets, and we come to this shortly.

## Causality Properties

First, consider the basic causal relations. If $a$ an $b$ are two points of $\mathtt{M}$, then if there is a nontrivial future-timelike curve in $\mathtt{M}$ from $a$ to $b$ we say that $a$ "chronologically" precedes $b$ and write

$$a \ll b$$

(so it would be possible for some observer's world line to encounter first $a$ and then $b$). If there is a future-null curve in $\mathtt{M}$ from $a$ to $b$ (trivial or otherwise), we say that $a$ "causally" precedes $b$ and write

$$a \prec b$$

(so it would be possible for a signal to get from $a$ to $b$). We have the following elementary properties (see Penrose (1972)):

$$\begin{gathered} a \prec a \\ \text{if } a \ll b \text{ then } a \prec b \\ \text{if } a \ll b \text{ and } b \ll c \text{ then } a \ll c \\ \text{if } a \ll b \text{ and } b \prec c \text{ then } a \ll c \\ \text{if } a \prec b \text{ and } b \ll c \text{ then } a \ll c \\ \text{if } a \prec b \text{ and } b \prec c \text{ then } a \prec c \end{gathered}$$

We generalize the definition of $I^+(\mathtt{S})$, above, to an arbitrary subset $\mathtt{Q}$ in $\mathtt{M}$, obtaining the *chronological future* $I^+(\mathtt{Q})$ and *past* $I^-(\mathtt{Q})$ of $\mathtt{Q}$ in $\mathtt{M}$ by

$$\begin{aligned} I^+(\mathtt{Q}) &= \{q | p \ll q \text{ for some } p \in \mathtt{Q}\} \\ I^-(\mathtt{Q}) &= \{q | q \ll p \text{ for some } p \in \mathtt{Q}\} \end{aligned}$$

The notation $\{q|$ some property of $q\}$ denotes the set of $q$'s with the stated property and the *causal future* $J^+(\mathtt{Q})$ and past $J^-(\mathtt{Q})$ of $\mathtt{Q}$ in $\mathtt{M}$ by

$$\begin{aligned} J^+(\mathtt{Q}) &= \{q | p \prec q \text{ for some } p \in \mathtt{Q}\} \\ J^-(\mathtt{Q}) &= \{q | q \prec p \text{ for some } p \in \mathtt{Q}\} \end{aligned}$$

The $I^{\pm}(\mathtt{Q})$ are always open sets, but the $J^{\pm}(\mathtt{Q})$ are not always closed (though they are for any closed set $\mathtt{Q}$ in Minkowski space). Thus, the sets $I^{\pm}(\mathtt{Q})$ have a more uniform character than the $J^{\pm}(\mathtt{Q})$, and it is simpler to concentrate, here, on the $I^{\pm}(\mathtt{Q})$ sets.

The boundary $\partial I^+(\mathtt{Q})$ of $I^+(\mathtt{Q})$ has an elegant characterization:

$$\partial I^+(\mathtt{Q}) = \{q | I^+(q) \subseteq \partial I^+(\mathtt{Q}), \text{but } q \notin I^+(\mathtt{Q})\}$$

and the corresponding statement holds for $\partial I^-(\mathtt{Q})$. Boundaries of futures also have a relatively simple structure, as is exhibited in the following result (for which there is also a version with past and future interchanged):

**Lemma** *Let $\mathtt{Q} \subseteq \mathtt{M}$ be closed, and $p \in \partial I^+(\mathtt{Q}) - \mathtt{Q}$, then there exists a null geodesic on $\partial I^+(\mathtt{Q})$ with future endpoint at $p$ and which either extends along $\partial I^+(\mathtt{Q})$ indefinitely into the past, or until it reaches a point of $\mathtt{Q}$. It can only extend into the future along $\partial I^+(\mathtt{Q})$ if $p$ is not a caustic point of $\partial I^+(\mathtt{Q})$.*

Beyond a caustic point, the null geodesic would enter into the interior of $I^+(\mathtt{Q})$, but this also happens (more commonly) when crossing another region of null hypersurface on $\partial I^+(\mathtt{Q})$.

We wish to apply this to $\partial I^+(\mathtt{S})$, for a trapped surface $\mathtt{S}$, but we first need a further assumption that $\mathtt{S}$ lies in the interior of the (future) domain of dependence $D^+(\mathtt{H})$ of some spacelike hypersurface $\mathtt{H}$. This region is defined as the totality of points $q$ for which every timelike curve with future endpoint $q$ can be extended into the past until it meets $\mathtt{H}$. One can consider domains of dependence for regions $\mathtt{H}$ other than smooth spacelike surfaces, but it is usual to assume, more generally, that $\mathtt{H}$ is a closed achronal set, where "achronal" means that $\mathtt{H}$ contains no pair of points $a$, $b$ for which $a \ll b$. We find that every point $q$ in the interior int$D^+(\mathtt{H})$ of $D^+(\mathtt{H})$ has the further property that all null curves into the past from $q$ will also eventually meet $\mathtt{H}$ if extended sufficiently. The physical significance of $D^+(\mathtt{H})$ is that, for fields with locally Lorentz-invariant and deterministic evolution equations, the (appropriate) initial data on $\mathtt{H}$ will fix the fields throughout $D^+(\mathtt{H})$ (and also

throughout the similarly defined past domain of dependence $D^{-}(\mathtt{H})$). We find that points in the future Cauchy horizon $H^{+}(\mathtt{H})$, which is the future boundary of $D^{+}(\mathtt{H})$ defined by

$$H^{+}(\mathtt{H}) = D^{+}(\mathtt{H}) - I^{-}(D^{+}(\mathtt{H})),$$

has properties similar to the boundary of a past set, in accordance with the above lemma, and also for the past Cauchy horizon $H^{-}(\mathtt{H})$, defined correspondingly.

## Singularity Theorems and Related Questions

Now, applying our lemma to $\partial I^{+}(\mathtt{S})$, for a trapped surface $\mathtt{S} \subseteq \mathrm{int}D^{+}(\mathtt{H})$, we find that every one of its points lies on a null-geodesic segment $\gamma$ on $\partial I^{+}(\mathtt{S})$, with past endpoint on $\mathtt{S}$ (for if $\gamma$ did not terminate at $\mathtt{S}$ it would have to reach $\mathtt{H}$, which is impossible). Assuming future-null completeness and weak energy ($\Phi \geq 0$), we conclude that if extended far enough into the future, the family of such null geodesics $\gamma$ must encounter a caustic, and therefore they must leave $\partial I^{+}(\mathtt{S})$ and enter $I^{+}(\mathtt{S})$. We finally conclude that $\partial I^{+}(\mathtt{S})$ must be a compact topological 3-manifold. Using basic theorems, we construct an everywhere timelike vector field in $\mathrm{int}D^{+}(\mathtt{H})$ which provides a (1–1) continuous map from the compact $\partial I^{+}(\mathtt{S})$ to $\mathtt{H}$, yielding a contradiction if $\mathtt{H}$ is noncompact, thereby establishing the following (Penrose 1965, 1968):

**Theorem** *The requirement that there be a trapped surface which, together with its closed future, lies in the interior of the domain of dependence of a noncompact spacelike hypersurface, is incompatible with future null completeness and the weak energy condition.*

We notice that this “singularity theorem” gives no indication of the nature of the failure of future null completeness in a spatially open spacetime subject to weak positivity of energy and containing a trapped surface. The natural assumption is that in an actual physical situation of such gravitational collapse, the failure of completeness would arise at places where curvatures mount to such extreme values that classical general relativity breaks down, and must be replaced by the appropriate “quantum geometry” (*see* Quantum Geometry and its Applications, etc.). Hawking (1965) showed how this theorem (in time-reversed form) could also be applied on a cosmological scale to provide a strong argument that the Big-Bang singularity of the standard cosmologies is correspondingly stable. He subsequently introduced techniques from “Morse theory” which could be applied to timelike rather than just null geodesics and, using arguments applied to Cauchy horizons, was able to remove assumptions concerning domains of dependence (e.g., Hawking (1967)). A later theorem (Hawking and Penrose 1970) encompassed most of the earlier ones and had, as one of its implications, that virtually all spatially closed universe models, satisfying a reasonable energy condition and without closed timelike curves, would have to be singular, in this sense of “incompleteness,” but again the topological-type arguments used give little indication of the nature or location of the singularities.

Another issue that is not addressed by these arguments is whether the singularities arising from gravitational collapse are inevitably “hidden,” as in **Figure 1**, by the presence of a horizon – a conjecture referred to as “cosmic censorship” (see Penrose (1969, 1998)). Without this assumption, one cannot deduce that gravitational collapse, in which a trapped surface forms, will lead to a black hole, or to the alternative which would be a “naked singularity.” There are many results in the literature having a bearing on this issue, but it still remains open.

A related issue is that of strong cosmic censorship which has to do with the question of whether singularities might be observable to local observers. Roughly speaking, a naked singularity would be one which is “timelike,” whereas the singularities in black holes might in general be expected to be spacelike (or future-null), and in the Big Bang, spacelike (or past-null). There are ways of characterizing these distinctions purely causally, in terms of past sets or future sets (sets $\mathtt{Q}$ for which $\mathtt{Q} = I^{-}(\mathtt{Q})$ or $\mathtt{Q} = I^{+}(\mathtt{Q})$); see Penrose (1998). If (strong) cosmic censorship is valid, so there are no timelike singularities, the remaining singularities would be cleanly divided into past-type and future-type. In the observed universe, there appears to be a vast difference between the structure of the two, which is intimately connected with the second law of thermodynamics, there appearing to be an enormous constraint on the Weyl curvature (*see* General Relativity: Overview) in the initial singularities but not in the final ones.

Despite the likelihood of singularities arising in their time evolution, it is possible to set up initial data for the Einstein vacuum equations for a wide variety of complicated spatial topologies (*see* Einstein Equations: Initial Value Formulation). On the observational side, however, there seems to be little evidence for anything other than Euclidean spatial topology in our actual universe (which includes black holes). Speculation on the nature of spacetime at the tiniest scales, however, where quantum gravity might be relevant, often involves non-Euclidean topology, however. It may be noted that an early theorem of Geroch established that the constraints of classical Lorentzian geometry do not permit the spatial topology to change without violations of causality (closed timelike curves).

# Spectral Sequences

**P Selick**, University of Toronto, Toronto, ON, Canada

## Introduction

Spectral sequences are a tool for collecting and distilling the information contained in an infinite number of long exact sequences. Their most common use is the calculation of homology by filtering the object under study and using a spectral sequence to pass from knowledge of the homology of the filtration quotients to that of the object itself. This article will discuss the construction of spectral sequences and the notion of convergence including conditions sufficient to guarantee convergence. Some sample applications of spectral sequences are given.

A differential on an abelian group $G$ is a self-map $d: G \to G$ such that $d^2 = 0$. A morphism of differential groups is a map $f: G \to G'$ such that $d'f = fd$. The condition $d^2 = 0$ guarantees that $\operatorname{Im} d \subset \operatorname{Ker} d$, so to the differential group $(G, d)$ we can associate its homology, $H(G, d) := \operatorname{Ker} d / \operatorname{Im} d$. Often $G$ has extra structure and we require $d$ to satisfy some compatibility condition in order that $H(G, d)$ should also have this structure. For example, a differential graded Lie algebra $(L, d)$ requires a differential $d$ *which satisfies the condition* $d[x, y] = [dx, y] + (-1)^{|x|}[x, dy]$. *While, for simplicity, throughout this article we will always assume that* $G$ is an abelian group, the concepts are readily extended to the case where $G$ is an object of some abelian category and generalizations to nonabelian situations have also been studied.

An important example of extra structure is the case where $G = \bigoplus_{n=-\infty}^{\infty} G_n$ is a graded abelian group. The appropriate compatibility condition for a differential graded group is that $d$ should be homogeneous of degree –1. That is, $d(G_n) \subset G_{n-1}$. In many contexts it is more natural to use superscripts and regard $d$ as having degree +1; the two concepts are equivalent via the reindexing convention $G^n := G_{-n}$. Another important example is that

where $G$ forms a graded algebra, meaning that it has a multiplication $G_n \otimes G_k \to G_{n+k}$. To form a differential graded algebra, in addition to having degree –1, $d$ is required to satisfy the Leibniz rule $d(xy) = d(x)y + -(1)^{|x|}xd(y)$ (where $|x|$ denotes the degree of $x$) familiar from the differentiation of differential forms.

In many cases, $G$ itself is not the main object of interest, but is a relatively large and complicated object, $G = G(X)$, formed by applying some functor $G$ to the object $X$ being studied. For example, $X$ might be some manifold and $G$ could be the set of all differential forms on $X$ with the exterior derivative as $d$. The presumption is that $H(G(X))$ carries the information we want about $X$ in a much simpler form than the whole of $G(X)$.

A *spectral sequence* (Leray 1946) is defined simply as a sequence $((E^r, d^r))_{r=n_0, n_0+1, \ldots,}$ of differential abelian groups such that $E^{r+1} = H(E^r, d^r)$. By reindexing, we could always arrange that $n_0 = 1$, but sometimes it is more natural to begin with some other integer. If all terms $(E^r, d^r)$ of the spectral sequence have the appropriate additional structure, we might refer, for example, to a spectral sequence of Lie algebras. If there exists $N$ such that $E^r = E^N$ for all $r \geq N$ (equivalently $d^r = 0$ for all $r \geq N$), the spectral sequence is said to "collapse" at $E^N$.

The definition of spectral sequence is so broad that we can say almost nothing of interest about them without putting on some additional conditions. We will begin by considering the most common type of spectral sequence, historically the one that formed the motivating example: the spectral sequence of a filtered chain complex.

## Filtered Objects

To study a complicated object $X$, it often helps to filter $X$ and study it one filtration at a time. A filtration $\mathcal{F}_X$ of a group $X$ is a nested collection of subgroups

$$\mathcal{F}_X := \ldots F_nX \subset F_{n+1}X \subset \cdots \subset X \quad -\infty < n < \infty$$

A morphism $f : \mathcal{F}_X \to \mathcal{F}_Y$ of filtered groups is a homomorphism $f : X \to Y$ such that $f(F_n(X)) \subset F_n(Y)$. The groups $F_nX/F_{n-1}X$ are called the "filtration quotients" and their direct sum $\mathrm{Gr}(\mathcal{F}_X) := \bigoplus_n F_nX/F_{n-1}X$ is called the *associated graded group* of the filtered group $\mathcal{F}_X$. In cases where $X$ has additional structure, we might define special types of filtrations satisfying some compatibility conditions so that $\mathrm{Gr}(\mathcal{F}_X)$ inherits the additional structure. For example, an *algebra filtration* of an algebra $X$ is defined as one for which $(F_nX)(F_kX) \subset F_{n+k}X$.

Since our plan is to study $X$ by computing $\mathrm{Gr}(\mathcal{F}_X)$, the first question we need to consider is what conditions we need to place on our filtration so that $\mathrm{Gr}(\mathcal{F}_X)$ retains enough information to recover $X$. Our experience from the "5-lemma" suggests that the appropriate way to phrase the requirement is to ask for conditions on the filtrations which are sufficient to conclude that $f : X \to Y$ is an isomorphism whenever $f : \mathcal{F}_X \to \mathcal{F}_Y$ is a morphism of filtered groups for which the induced $\mathrm{Gr}(f) : \mathrm{Gr}(X) \to \mathrm{Gr}(Y)$ is an isomorphism.

It is clear that $\mathrm{Gr}\mathcal{F}_X$ can tell us nothing about $X - (\cup X_n)$ so we require that $X = \cup X_n$. Similarly we need that $\cap X_n = 0$. However, the latter condition is insufficient as can be seen from the following example.

**Example 1** Let $X := \bigoplus_{k=1}^{\infty} \mathbb{Z}$ and $Y := \prod_{k=1}^{\infty} \mathbb{Z}$. Set

$$F_nX := \begin{cases} X & \text{if } n \geq 0 \\ \bigoplus_{k=-n}^{\infty} \mathbb{Z} & \text{if } n < 0 \end{cases}$$

$$F_nY := \begin{cases} Y & \text{if } n \geq 0 \\ \prod_{k=-n}^{\infty} \mathbb{Z} & \text{if } n < 0 \end{cases}$$

and let $f : X \to Y$ be the inclusion. Then $\mathrm{Gr}(f)$ is an isomorphism but $f$ is not.

To phrase the appropriate condition we need the concept of algebraic limits. Given a sequence of objects $\{X_n\}_{n \in \mathbb{Z}}$ and morphisms $f_n : X_n \to X_{n+1}$ in some category, the "direct limit" or "colimit" of the sequence, written $\varinjlim_n F_nX$, is an object $X$ together with morphisms $g_n : X_n \to X$ satisfying $g_{n+1} \circ f_n = g_n$, having the universal property that given any object $X'$ together with maps $g'_n : X_n \to X'$ satisfying $g'_{n+1} \circ f_n = g'_n$, there exists a unique morphism $h : X \to X'$ such that $g'_n = h \circ g_n$ for all $n$. By the usual categorical argument the object $X$, if it exists, is unique up to isomorphism. The dual concept, "inverse limit" or simply "limit" of the sequence, written $\varprojlim_n F_nX$, is obtained by reversing the directions of the morphisms. For intuition, we note that these notions share, with the notion of limits of sequences in calculus, the properties that changing the terms $X_n$ only for $n < N$ does not affect $\varinjlim_n F_nX$, and if the sequence stabilizes at $N$ (i.e., the morphisms $f_n$ are isomorphisms for all $n \geq N$), then $\varinjlim_n F_nX \cong X_N$. Similarly $\varprojlim_n F_nX$ depends only upon behavior of the sequence as $n \to -\infty$. Limits over partially ordered sets other than $\mathbb{Z}$ can also be taken but we shall not need them in this article. Although limits need not exist in general, in the category of abelian groups, both the direct and inverse limit exist for any sequence and are given explicitly by the following constructions. $\varinjlim_n F_nX = \bigoplus X_n/\sim$ where, letting $i_k : X_k \to \bigoplus X_n$ be the

canonical inclusion, the equivalence relation is generated by $i_n(x) \sim i_{n+1}f(x)$ for $x \in X_n$. $\varprojlim_n F_n X = \{(x_n) \in \Pi X_n \mid f_n(x_n) = x_{n+1}\, \forall n\}$.

The condition needed is that our filtrations should be *bicomplete*, defined as follows. $\mathcal{F}_X$ is called "cocomplete" if the canonical map $X \to \varinjlim_n F_n X$ is an isomorphism and $\mathcal{F}_X$ is called "complete" if $X \to \varprojlim_n X/F_n X$ is an isomorphism. $\mathcal{F}_X$ is called bicomplete if it is both complete and cocomplete. Note that $\mathcal{F}_X$ cocomplete is equivalent to $\cup F_n X = X$ but $\mathcal{F}_X$ complete is stronger than $\cap F_n X = 0$.

**Theorem 1** (Comparison theorem). *Let $\mathcal{F}_X$ be bicomplete and let $\mathcal{F}_Y$ be cocomplete with $\cap F_n Y = 0$. Suppose that $f : \mathcal{F}_X \to \mathcal{F}_Y$ is a morphism such that* $\mathrm{Gr}(f) : \mathrm{Gr}(X) \to \mathrm{Gr}(Y)$ *is an isomorphism. Then $f : X \to Y$ is an isomorphism.*

## Filtered Chain Complexes

A *chain complex* $(C, d)$ of abelian groups consists of abelian groups $C_n$ for $n \in \mathbb{Z}$ together with homomorphisms $d_n : C_n \to C_{n-1}$ such that $d_n \circ d_{n+1} = 0$ for all $n$. To the chain complex $(C, d)$ we can associate the differential (abelian) group $(C_*, d) := \bigoplus_{n=-\infty}^{\infty} C_n$ with $d|_{C_n}$ induced by $d_n$. We often write simply $C$ if the differential is understood. The dual notion in which $d$ has degree +1 is called a *cochain complex* and the concepts are equivalent through our convention $C^n := C_{-n}$.

**Theorem 2** (Homology commutes with direct limits). $H(\varinjlim_n C_n) = \varinjlim_n H(C_n)$.

As we shall see later, failure of homology to commute with inverse limits is a source of great complication in working with spectral sequences.

Let $\mathcal{F}_C$ be a filtered chain complex. In many applications, our goal is to compute $H_*(C)$ from a knowledge of $H_*(F_n C/F_{n-1}C)$ for all $n$. The overall plan, which is not guaranteed to be successful in general, would be:

1. use the given filtration on $C$ to define a filtration on $H_*(C)$,
2. use our knowledge of $H_*(\mathrm{Gr}\, C)$ to compute $\mathrm{Gr}\, H_*(C)$,
3. reconstruct $H_*(C)$ from $\mathrm{Gr}\, H_*(C)$.

To begin, set $F_n(H_*C) := \mathrm{Im}(s_n)_*$, where $s_n : F_n(C) \to C$ is the inclusion (chain) map from the filtration. The spectral sequence which we will define for this situation can be regarded as a method of keeping track of the information contained in the infinite collection of long exact homology sequences coming from the short exact sequences $0 \to F_{n-1}C \to F_n C \to F_n C/F_{n-1}C \to 0$. When working with a long exact sequence, knowledge of two of every three terms gives a handle on computing the remaining terms but does not, in general, completely determine those terms, which explains intuitively why we have some reason to hope that a spectral sequence might be useful and also why it is not guaranteed to solve our problem.

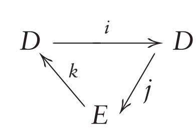
Before proceeding with our motivating example, we digress to discuss spectral sequences formed from *exact couples*.

## Exact Couples

In this section, we will define exact couples, show how to associate a spectral sequence to an exact couple, and discuss some properties of spectral sequences coming from exact couples. As we shall see, a filtered chain complex gives rise to an exact couple and we will examine this spectral sequence in greater detail.

Exact couples were invented by Massey and many books use them as a convenient method of constructing spectral sequences. Other books bypass discussion of exact couples and define the spectral sequence coming from a filtered chain complex directly.

**Definition 1** An "exact couple" consists of a triangle



containing abelian groups $D$, $E$, and together with homomorphisms $i$, $j$, $k$ such that the diagram is exact at each vertex.

In the following, to avoid conflicting notation considering the many superscripts and subscripts which will be needed, we use the convention that an $n$-fold composition will be written $f^{\circ n}$ rather than the usual $f^n$.

Given an exact couple, set $d := jk : E \to E$. By exactness, $kj = 0$, so $d^{\circ 2} = jkjk = 0$ and therefore $(E, d)$ forms a differential group. To the exact couple we can associate another exact couple, called its derived couple, as follows. Set $D' := \mathrm{Im}\, i \subset D$ and $E' := H(E, d)$. Define $i' := i|_D$ and let $j' : D' \to E'$ be given by $j'(iy) := \overline{j(y)}$, where $\overline{x}$ denotes the equivalence class of $x$. The map $k' : E' \to D'$ is defined by $k'(\overline{z}) := kz$. One checks that the maps $j'$ and $k'$ are well defined and that $(D', E', i', j', k')$ forms an exact couple. Therefore, from our original exact couple, we can inductively form a sequence of exact couples $(D^r, E^r, i^r, j^r, k^r)_{r=1}^{\infty}$ with $D^1 := D, E^1 := E, D^r := (D^{r-1})'$

and $E^r := (E^{r-1})'$. This gives a spectral sequence $(E^r, d^r)_{r=1}^{\infty}$ with $d^r = j^r k^r$.

To the filtered chain complex $\mathcal{F}_C$, we can associate an exact couple as follows. Set $D := \bigoplus_{p,q} D_{p,q}$ where $D_{p,q} = H_{p+q}(F_p C)$ and $E := \bigoplus_{p,q} E_{p,q}$ where $E_{p,q} = H_{p+q}(F_p C/F_{p-1}C)$. The long exact homology sequences coming from the sequences $0 \to F_{p-1}C \xrightarrow{a} F_p C \xrightarrow{b} F_p C/F_{p-1}C \to 0$ give rise, for each $p$ and $q$, to maps $a_* : D_{p-1,q+1} \to D_{p,q}, b_* : D_{p,q} \to E_{p,q}$, and $\partial : E_{p,q} \to D_{p-1,q}$. Define $i : D \to D$ to be the map whose restriction to $D_{p-1,q+1}$ is the composition of $a_*$ with the canonical inclusion $D_{p,q} \to D$. Similarly, define $j : D \to E$ and $k : E \to D$ to be the maps whose restrictions to each summand are the compositions of $b_*$ and $\partial$ with the inclusions. The indexing scheme for the bigradations is motivated by the fact that in many applications it causes all of the nonzero terms to appear in the first quadrant, so it is the most common choice, although one sometimes sees other conventions.

There is actually a second exact couple we could associate to $\mathcal{F}_C$, which yields the same spectral sequence: use the same $E$ as above but replace $D$ by $\bigoplus D_{p,q}$ with $D_{p,q} = H_{p+q+1}(C/F_p C)$, and define $i$, $j$, and $k$ in a manner similar to that above.

When dealing with cohomology rather than homology, the usual starting point would be a system of inclusions of cochain complexes $\cdots F^{n+1}C \subset F^n C \subset F^{n-1} \subset \cdots \subset C$. This can be reduced to the previous case by replacing the cochain complex $C$ by a chain complex $C_*$ using the convention $C_p := C^{-p}$ and filtering the result by $F_n C_* := F^{-n}C$. The usual practice, equivalent to the above followed by a rotation of 180°, is to leave the original indices and instead reverse the arrows in the exact couple. In this case, it is customary to write $D_r^{p,q}$ and $E_r^{p,q}$ for the terms in the exact couple and spectral sequence.

In applications, it is often the case that $E^1$ is known and that our goal includes computing $D^1$. The example of the filtered chain complex with the assumption that we know $H_*(F_p C/F_{p-1}C)$ for all $p$ is fairly typical.

Since each $D^r$ is contained in $D^{r-1}$ and each $E^r$ is a subquotient of $E^{r-1}$, the terms of these exact couples get smaller as we progress. To get properties of the spectral sequence, we need to examine this process and, in particular, analyze that which remains in the spectral sequence as we let $r$ go to infinity.

For $x \in E$, if $dx = 0$ then $\bar{x}$ belongs to $E^2$ and so $d^2(\bar{x})$ is defined. In the following, we shall usually simplify the notation by writing simply $x$ in place of $\bar{x}$ and writing $d^r x = 0$ to mean "$d^r x$ is defined and equals 0."

If $dx = 0, \ldots, d^{r-1}x = 0$, then $x$ represents an element of $E^r$ and $d^r x$ is defined. Set $Z^r := \{x \in E \mid d^m x = 0 \, \forall m \leq r\}$. Then $E^{r+1} \cong Z^r/\sim$ where $x \sim y$ if there exists $z \in E$ such that for some $t \leq r$ we have $d^m z = 0$ for $m < t$ (thus $d^t z$ is defined) and $d^t z = x - y$. With this as motivation, we set $Z^\infty := \cap_r Z^r = \{x \in E \mid d^m x = 0 \ \forall m\}$ (known as the "infinite cycles") and define $E^\infty := Z^\infty/\sim$ where $x \sim y$ if there exists $z \in E$ such that for some $t$ we have $d^m z = 0$ for $m < t$ and $d^t z = x - y$.

Notice that $D^{r+1} = \mathrm{Im} i^{\circ r} \cong D/\mathrm{Ker}\, i^{\circ r}$. There is no analog of this statement for $r = \infty$. Instead we have separate concepts so we set $D^\infty := D/\cup_r \mathrm{Ker}\, i^{\circ r}$ and ${}^\infty D := \cap_r \mathrm{Im} i^{\circ r}$. The analog of the $r$th-derived exact couple when $r = \infty$ is the following exact sequence.

**Theorem 3** *There are maps induced by $i$, $j$, and $k$ producing an exact sequence*

$$0 \to D^\infty \xrightarrow{i^\infty} D^\infty \xrightarrow{j^\infty} E^\infty \xrightarrow{{}^\infty k} {}^\infty D \xrightarrow{{}^\infty i} {}^\infty D$$

The fact that we were able to add the 0 term to the left of this sequence but not the right can be traced to the fact that $\varinjlim$ preserves exactness but $\varprojlim$ does not.

In our motivating example, the terms of the initial exact couple came with a bigrading $D = \bigoplus D_{p,q}$ and $E = \bigoplus E_{p,q}$ and writing $|f|$ for the bidegree of a morphism $f$ we had: $|i| = (1, -1); |j| = (0, 0); |k| = (-1, 0); d = (-1, 0)$. It follows that $|i^r| = (1, -1); |j^r| = (-r+1, r-1); |k^r| = (-1, 0); |d^r| = (-r, r-1)$ which is considered the standard bigrading for a bigraded exact couple. Similarly, the standard bigrading for a bigraded spectral sequence is one such that $|d^r| = (-r, r-1)$.

We observed earlier that terms of an exact couple and its corresponding spectral sequence get smaller as $r \to \infty$ as each is a subquotient of its predecessor. Note that the bigrading is such that this applies to each pair of coordinates individually (e.g., $E_{p,q}^{r+1}$ is a subquotient of $E_{p,q}^r$) and so in particular if the $p$, $q$-position ever becomes 0 that position remains 0 forevermore.

## Convergence of Graded Spectral Sequences

As noted earlier, the definition of spectral sequence is so broad that we need to put some conditions on our spectral sequences to make them useful as a computational tool. From now on, we will restrict attention to spectral sequences arising from exact couples in which $D = \bigoplus D_p$ and $E = \bigoplus E_p$ are graded with $i|_{D_p} \subset D_{p+1}, j|_{D_p} \subset E_p$, and $k|_{E_p} \subset D_{p-1}$. All the spectral sequences which have been studied

to date satisfy this condition and in fact most also have a second gradation as in the case of our motivating example. To see how to proceed, we examine that case more closely.

For a filtered chain complex $\mathcal{F}_C$ with structure maps $s_p : F_pC \to C$ we defined $F_p(H_*(C)) = \operatorname{Im} s_{p*}$. If $x = i^{\circ(r-1)}y$ belongs to

$$D^r_{p,q} = \operatorname{Im} i^{\circ(r-1)} : H_{p+q}(F_{p-r+1}C) \to H_{p+q}(F_pC)$$

then $(s_p)_*x = (s_p)_* i^{\circ(r-1)}y = (s_{p+1})_* i^{\circ r}y = (s_{p+1})_* ix$. Therefore, we have a commutative diagram

$$\begin{array}{ccc} D^r_{p,q} & \longrightarrow & F_p(H_{p+q}(C)) \\ \downarrow i & & \downarrow \\ D^{r+1}_{p+1,q-1} & \longrightarrow & F_{p+1}(H_{p+q}(C)) \end{array}$$

yielding a map

$$D^{r+1}_{p+1,q-1}/D^r_{p,q} \to F_{p+1}\big(H_{p+q}(C)\big)/F_p\big(H_{p+q}(C)\big) = \operatorname{Gr}_{p+1}(H_{p+q})C$$

Letting $r$ go to infinity, we get an induced map $\phi : D^\infty / i^\infty(D^\infty) \to \operatorname{Gr}(H(C))$.

**Theorem 4** *If $\mathcal{F}_H(C)$ is cocomplete then*

(i) $D^\infty = F_n(H(C))$;
(ii) $\phi : D^\infty / i^\infty(D^\infty) \to \operatorname{Gr}(H(C))$ *is an isomorphism*;
(iii) *There is an exact sequence* $0 \to \operatorname{Gr}(H(C)) \xrightarrow{i^\infty} E^\infty \xrightarrow{\infty k} {}^\infty D \xrightarrow{\infty i} {}^\infty D$.

We say that the spectral sequence $(E^r)$ "abuts" to $\mathcal{F}_L$ if there is an isomorphism $\operatorname{Gr}L \to E^\infty$. Here we mean an isomorphism of graded abelian groups, which makes sense since under our assumptions $E^r$ inherits a grading from $E^1$ for each $r$. If in addition the filtration on $L$ is cocomplete, we say that $(E^r)$ "weakly converges" to $\mathcal{F}_L$ and if it is bicomplete we say that $(E^r)$ "converges" (or *strongly converges*) to $\mathcal{F}_L$. The notation $(E^r) \Rightarrow \mathcal{F}_L$ (or simply $(E^r) \Rightarrow L$ when the filtration on $L$ is either understood or unimportant) is often used in connection with convergence but there is no universal agreement as to which of the three concepts (abuts, weakly converges, or converges) it refers to! In this article, we will also use the expression $(E^r)$ "quasiconverges" to $\mathcal{F}_L$ to mean that the spectral sequence weakly converges to $\mathcal{F}_L$ with $\cap_n F_n L = 0$. (Note: the terminology quasiconverges is nonstandard although the concept has appeared in the literature, sometimes under the name *converges*.)

While it would be overstating things to claim that convergence of the spectral sequence shows that $E^\infty$ determines $H(C)$, it is clear that convergence is what we need in order to expect that $E^\infty$ contains enough information to possibly reconstruct $H(C)$. The sense in which this is true is stated more precisely in the following theorem.

**Theorem 5** (Spectral sequence comparison theorem). *Let $f = (f^r) : (E^r) \to \tilde{E}^r$ be a morphism of spectral sequences.*

(i) *If $f : E^N \to \tilde{E}^N$ is an isomorphism for some $N$, then $f^r$ is an isomorphism for all $r \geq N$ (including $r = \infty$).*
(ii) *Suppose in addition that $(E^r)$ converges to $\mathcal{F}_X$ and $(\tilde{E}^r)$ quasiconverges to $\mathcal{F}_{\tilde{X}}$. Let $\phi : \mathcal{F}_X \to \mathcal{F}_{\tilde{X}}$ be a morphism of filtered abelian groups which is compatible with $f$. (i.e., there exist isomorphisms $\eta : \operatorname{Gr} X \cong E^\infty$ and $\tilde{\eta} : \operatorname{Gr} \tilde{X} \cong \tilde{E}^\infty$ such that $f^\infty \circ \eta = \tilde{\eta} \circ \operatorname{Gr}(f)$). Then $f : X \to \tilde{X}$ is an isomorphism.*

Within the constraints provided by Theorem 5, a spectral sequence might have many limits. A typical calculation of some group $Y$ by means of spectral sequences might proceed as an application of Theorem 5 along the lines of the following plan.

1. Subgroups $F_nY$ forming a filtration of $Y$ are defined, although usually not computable at this point. The subgroups are chosen in a manner that seems natural bearing in mind that to be useful it will be necessary to show convergence properties.
2. Directly or by means of an exact couple, a spectral sequence is defined in a manner that seems to be related to the filtration.
3. Some early term of the spectral sequence (usually $E^1$ or $E^2$) is calculated explicitly and the differentials $d^r$ are calculated successively resulting in a computation of $E^\infty$.
4. With the aid of the knowledge of $E^\infty$, a conjecture $Y = G$ is formulated for some $G$.
5. A suitable filtration on G and a map of filtrations $\mathcal{F}_G \to \mathcal{F}_Y$ or $\mathcal{F}_Y \to \mathcal{F}_G$ are defined.
6. The spectral sequence arising from $\mathcal{F}_G$ is demonstrated to converge to $G$.
7. The original spectral sequence is demonstrated to converge to $Y$ and Theorem 5 is applied.

The hardest steps are usually (3) and (7). For step (3), in most cases the calculations require knowledge which cannot be obtained from the spectral sequence itself, although the spectral sequence machinery plays its role in distilling the information and pointing the way to exactly what needs to be calculated. Steps (4)–(6) are frequently very easy, and often not stated explicitly, with "by construction of $G$" being the most common justification of (6). We now discuss the types of considerations involved in step (7).

Convergence of a spectral sequence to a desired $L$ can be difficult to verify in general partly because

the conditions are stated in terms of some filtration (usually understood only in a theoretical sense) on an initially unknown $L$ rather than in terms of properties of the spectral sequence itself or an exact couple from which it arose. Theorems 2 and 4(ii) give us the following extremely important special case in which we can conclude convergence to $H(C)$ of the spectral sequence for $\mathcal{F}_C$ based on conditions that are often easily checked.

**Theorem 6** *If $\mathcal{F}_C$ is a filtered chain complex such that $\mathcal{F}_C$ is cocomplete and there exists M such that $H(F_nC)=0$ for $n<M$, then the spectral sequence for $\mathcal{F}_C$ converges to $H(C)$.*

Although the second hypothesis, which implies that ${}^{\infty}D=0$, is very strong it handles the large numbers of commonly used filtrations which are 0 in negative degrees.

Under the conditions of Theorem 6, inserting the bigradings into Theorem 4 gives a short exact sequence $0\to D^{\infty}_{p-1,q+1}\to D^{\infty}_{p,q}\to E^{\infty}_{p,q}\to 0$ with $D^{\infty}_{p,q}\cong F_p(H_{p+q}(X))$; equivalently

$$F_k(H_n(C))/F_{k-1}(H_n(C))\cong E^{\infty}_{k,n-k}$$

Thus, the only $E^{\infty}$-terms relevant to the computation to $H_n(C)$ are those on the diagonal $p+q=n$. In the important case of a first quadrant spectral sequence ($E^r_{p,q}=0$ if $p<0$ or $q<0$), the number of nonzero terms on any diagonal is finite so the $E^{\infty}$-terms on the diagonal $p+q=n$ give a finite composition series for each $H_n(C)$.

Here is an elementary example of an application of a spectral sequence.

**Example 2** Let $S_*(\,)$ denote the singular chain complex, let $H_*(\,):=H_*(S_*(\,))$ denote singular homology, and let $H^{\text{cell}}_*(\,)$ denote cellular homology. Let $X$ be a CW-complex with $n$-skeleton $X^{(n)}$. The inclusions $S_*(X^{(n)})\to S_*(X)$ yield a filtration on $S_*(X)$. In the associated spectral sequence,

$$E^1_{p,q}=H_{p+q}\left(X^{(p)}/X^{(p-1)}\right)\cong\begin{cases}\text{free abelian group on the } p\text{-cells of } X & \text{if } q=0\\ 0 & \text{if } q\neq 0\end{cases}$$

The differential

$$d^1_{p,0}\,:\,H_p\left(X^{(p)}/X^{(p-1)}\right)\to H_{p-1}\left(X^{(p-1)}/X^{(p-2)}\right)$$

is the definition of the differential in cellular homology. Therefore,

$$E^2_{p,q}=\begin{cases}H^{\text{cell}}(X) & \text{if } q=0\\ 0 & \text{if } q\neq 0\end{cases}$$

Looking at the bidegrees, the domain or range of $d^2_{p,q}$ is zero for each $p$ and $q$ so $d^2=0$, and similarly $d^r=0$ for all $r>2$. Therefore, the spectral sequence collapses with $E^2=E^{\infty}$. The spectral sequence converges to $H_*(X)$ so the terms on the diagonal $p+q=n$ form a composition series for $H_n(X)$. Since the $(n,0)$ term is the only nonzero term on this diagonal, $H_n(X)\cong H^{\text{cell}}_n(X)$. That is, "cellular homology equals singular homology."

Returning to the general situation, set $L_{\infty}:=\varinjlim_n D_n$ and $L_{-\infty}:=\varprojlim_n D_n$. Filter $L_{\infty}$ by $F_nL_{\infty}:=\operatorname{Im}(D_n\to L_{\infty})$ and filter $L_{-\infty}$ by $F_nL_{-\infty}:=\operatorname{Ker}(L_{-\infty}\to D_n)$. It follows from the definitions that $F_nL_{\infty}=D^{\infty}_n$ and so $D^{\infty}_n/i^{\infty}(D^{\infty}_{n-1})=\operatorname{Gr}_nL_{\infty}$. At the other end, the canonical map $L_{-\infty}\to D_n$ lifts to ${}^{\infty}D_n$ yielding an injection $L_{-\infty}/F_nL_{-\infty}\to {}^{\infty}D_n$. Therefore, for each $n$ there is an injection $\operatorname{Gr}_nL_{-\infty}\to K_n$ where $K_n=\operatorname{Ker}({}^{\infty}D_{n-1}\to {}^{\infty}D_n)$. In general, the map $L_{-\infty}\to {}^{\infty}D_n$ need not be surjective (an element could be in the image of $i^{\circ r}$ for each finite $r$ without being part of a consistent infinite sequence), although it is surjective in the special case when ${}^{\infty}D_s\to {}^{\infty}D_{s+1}$ is surjective for each $s$. In the latter case we get $\operatorname{Gr}L_{-\infty}\cong K$. As we will see in the next section, the exact sequence of Theorem 3 extends to the right (Theorem 8) giving $\varprojlim^1_r Z^r=0$ as a sufficient condition that ${}^{\infty}D_s\to {}^{\infty}D_{s+1}$ be surjective for each $s$, where $\varprojlim^1$ is described in that section and $(Z^r)$ refers to the system of inclusions $\cdots\subset Z^{r+1}\subset Z^r\subset Z^{r-1}\subset\cdots$. Thus, $\varprojlim^1_r Z^r=0$ is a sufficient condition for $\operatorname{Gr}L_{-\infty}\cong K$.

Taking into account the short exact sequence $0\to D^{\infty}/i^{\infty}(D^{\infty})\to E^{\infty}\to K\to 0$ coming from Theorem 3, the preceding discussion yields two obvious candidates for a suitable $\mathcal{F}_L$: $\mathcal{F}_{L_{\infty}}$ or $\mathcal{F}_{L_{-\infty}}$. In theory there are other possibilities, but in practice one of these two cases usually occurs. We examine them individually and see what additional conditions are required for convergence.

*Case* I: *Conditions for convergence to $\mathcal{F}_{L_{\infty}}$* It is easily checked from the definitions that $\varinjlim_n D^{\infty}_n=\varinjlim_n D_n$ so $\mathcal{F}_{L_{\infty}}$ is always cocomplete. Therefore, besides $\operatorname{Gr}L_{\infty}\cong E^{\infty}$ (equivalently, $K=0$), it is required to verify that $\mathcal{F}_{L_{\infty}}$ is complete. As we will see in the next section, the completeness condition can be restated as $\cap D_n=0$ and $\varprojlim^1_n D_n=0$. According to the preceding discussion, under the assumption that $L_{-\infty}=\cap D^n=0$, which we need anyway as part of the requirement that $\mathcal{F}_{L_{\infty}}$ be complete, $\varprojlim^1_r Z_rX=0$ is sufficient to show $K=0$.

*Case* II: *Conditions for convergence to $\mathcal{F}_{L_{-\infty}}$* Any inverse limit is complete in its canonical filtration, so $\mathcal{F}_{L_{-\infty}}$ is always complete and the issues are whether $\operatorname{Gr}L_{-\infty}\cong E^{\infty}$ and whether $\mathcal{F}_{L_{-\infty}}$ is cocomplete. $\mathcal{F}_{L_{-\infty}}$ is cocomplete if and only if every element of

$L_{-\infty}$ lies in $\mathrm{Ker}(L_{-\infty} \to D_n)$ for some $n$, for which a sufficient condition is that $L_\infty = 0$ or equivalently $E^\infty \cong K$. Therefore, if the reason for the isomorphism $\mathrm{Gr}\, L_{-\infty} \cong E^\infty$ is that the maps $E^\infty \twoheadrightarrow K$ and $\mathrm{Gr}\, L_{-\infty} \rightarrowtail K$ are isomorphisms, then the rest of the convergence conditions are automatic. In particular, to deduce convergence to $\mathcal{F}_{L_{-\infty}}$ it suffices to know that $L_\infty = 0$ and $\varprojlim_r{}^1 Z_r = 0$.

## Derived Functors

The left and right derived functors $L_nT, R^nT$ of a functor $T$ provide a measure of the amount by which the functor deviates from preserving exactness.

The category $\mathcal{I}nv$ of inverse systems indexed over $\mathbb{Z}$ (i.e., the category whose objects are diagrams of abelian groups $\cdots \to A_{n-1} \to A_n \to A_{n+1} \to \cdots$) forms an abelian category in which a sequence of morphisms $A' \to A \to A''$ is exact if and only if the sequence $A_n{}' \to A_n \to A_n{}''$ of abelian groups is exact for each $n$. The functor of interest to us is $\varprojlim : \mathcal{I}nv \to \mathcal{AB}$ where $\mathcal{AB}$ denotes the category of abelian groups.

Let $T : \underline{\underline{A}} \to \underline{\underline{B}}$ be an additive functor between abelian categories. Suppose that $X$ in $\mathrm{Obj}\, \underline{\underline{A}}$ has an injective resolution $I_X$. The definition of additive functor implies that $T$ takes zero morphisms to zero morphisms, so $TI_X$ forms a cochain complex in $\underline{\underline{B}}$. The *right derived functors* of $T$ are defined by $(R^nT)(X) := H^n(TI_X)$. The result is independent of the choice of injective resolution (assuming one exists) and satisfies:

1. If $T$ is "left exact" (meaning that $T$ preserves monomorphisms), then $R^0T(X) = T(X)$;
2. If $T$ preserves exactness, then $(R^nT)(X) = 0$ for $n > 0$.

**Theorem 7** *Let $0 \to X' \to X \to X'' \to 0$ be a short exact sequence in $\underline{\underline{A}}$. Suppose $T$ is left exact and that all the objects have injective resolutions. Then there is a (long) exact sequence*

$$0 \to T(X') \to T(X) \to T(X'') \to (R^1T)(X') \to \cdots$$
$$\to (R^{n-1}T)(X'') \to (R^nT)(X') \to (R^nT)(X) \to$$
$$(R^nT)(X'') \to \cdots$$

Similarly, the *left derived functors* of $T$ are defined by using projective resolutions and have similar properties with respect to the obvious duality.

The functor $\varprojlim_n$ is left exact and in the category $\mathcal{I}nv$ every object has an injective resolution. Therefore $\varprojlim_n{}^q$ is defined and $\varprojlim_n{}^0 X_n = \varprojlim_n X_n$, where $\varprojlim_n{}^q$ denotes the derived functor $R^q(\varprojlim_n)$. It turns out that $\varprojlim_n{}^q$ is 0 for $q > 1$, but we are particularly interested in $\varprojlim_n{}^1$.

Let $(X_n)$ be an inverse system with structure maps $i_{n-1} : X_{n-1} \to X_n$. An explicit construction for $\varprojlim_n{}^1 X_n$ is as follows. Define $\phi : \prod_n X_n \to \prod_n X_n$ by letting $\phi(x_n)$ be the sequence whose $n$th component is $(x_n - i_{n-1}x_{n-1})$. Then $\varprojlim_n{}^1 X_n \cong \mathrm{Coker}\,\phi$. Observe that $\mathrm{Ker}\,\phi \cong \varprojlim_n X_n$ according to the explicit formula for $\varprojlim_n X_n$ given earlier.

Recall that we defined ${}^\infty D = \cap_r \mathrm{Im}\, i^{\circ r} \cong \varprojlim_r D^r$. The exact sequence of Theorem 3 can be extended to give:

**Theorem 8** *There is an exact sequence*

$$0 \to D^\infty \xrightarrow{i} D^\infty \xrightarrow{j} E^\infty \xrightarrow{k} {}^\infty D \xrightarrow{i} {}^\infty D$$
$$\xrightarrow{j} \varprojlim_r{}^1 Z^r \xrightarrow{k} \varprojlim_r{}^1 D^r \xrightarrow{i} \varprojlim_r{}^1 D^r \to 0$$

It is clear from the explicit construction that if the system $(X_n)$ stabilizes with $X_n = G$ for all sufficiently small $n$, then $\varprojlim_n X = G$ and $\varprojlim_n{}^1 X = 0$. If the spectral sequence collapses at any stage then the system $(Z^r)$ stabilizes at that point, and so for a spectral sequence which collapses, the condition $\varprojlim_r{}^1 Z^r = 0$, which arose in the discussion of convergence in the previous section, is automatic.

Let $\mathcal{F}_X$ be a filtered abelian group. Applying Theorem 7 to the short exact sequence $0 \to F_nX \to X \to X/F_nX \to 0$ of inverse systems gives an exact sequence

$$0 \to \varprojlim_n F_nX \to \varprojlim_n X \to \varprojlim_n X/F_n$$
$$\to \varprojlim_n{}^1 F_nX \to \varprojlim_n{}^1 X$$

Since $\varprojlim_n X = X$ and $\varprojlim_n{}^1 X = 0$, we get

**Theorem 9** *$\mathcal{F}_X$ is complete if and only if $\varprojlim_n F_nX = 0$ and $\varprojlim_n{}^1 F_nX = 0$.*

When working with $\varprojlim_n{}^1$ the following sufficient condition for its vanishing, known as the Mittag–Leffler condition, is often useful.

**Theorem 10** *Suppose $A$ is an inverse system in which for each $n$ there exists $k(n) \le n$ such that $\mathrm{Im}(A_i \to A_n)$ equals $\mathrm{Im}(A_{k(n)} \to A_n)$ for all $i \le k(n)$. Then $\varprojlim_n{}^1 A = 0$.*

Of course, this will not be (directly) useful in establishing $\varprojlim_n{}^1 F_nX = 0$ since the structure maps in that system are all monomorphisms.

## Some Examples of Standard Spectral Sequences and Their Use

To this point we have considered the general theory of spectral sequences. The properties of the spectral sequences arising in many specific situations have

been well studied. Usually the spectral sequence would be defined either directly, through an exact couple, or by giving some filtration on a chain complex. This defines the $E^1$-term. Typically, a theorem would then be proved giving some formula for the resulting $E^2$-term. In many cases, conditions under which the spectral sequence converges may also be well known.

In this section, we shall take a brief look at the Serre spectral sequence, Atiyah–Hirzebruch spectral sequence, spectral sequence of a double complex, Grothendieck spectral sequence, change of ring spectral sequence, and Eilenberg–Moore spectral sequence, and carry out a few sample calculations.

### Serre Spectral Sequence

Let $F \to X \xrightarrow{\pi} B$ be a fiber bundle (or more generally a fibration) in which the base $B$ is a CW-complex. Define a filtration on the total space by $F_nX := \pi^{-1}B^{(n)}$. This yields a filtration on $H_*(X)$ by setting $F_nH_*(X) := \mathrm{Im}(H_*(F_nX) \to H_*(X))$. The spectral sequence coming from the exact couple in which $D^1_{p,q} := H_{p+q}(F_pX)$ and $E^1_{p,q} := H_{p+q}(F_pX, F_{p-1}X)$ is called the "Serre spectral sequence" of the fibration. Theorems from topology guarantee that this filtration is cocomplete and that $E^1_{p,q} = 0$ if either $p < 0$ or $q < 0$. Therefore, the Serre spectral sequence is always a first quadrant spectral sequence converging to $H_*(X)$.

**Theorem 11** (Serre). *In the Serre spectral sequence of the fibration $F \to E \to B$ there is an isomorphism $E^2_{p,q} \cong H_p(B; {}^tH_q(F))$.*

Here ${}^tH_*(F)$ denotes a "twisted" or "local" coefficient system in which the differential is modified to take into account the action, coming from the fibration, of the fundamental groupoid of the base $B$ on the fiber $F$. In the special case where $B$ is simply connected and $\mathrm{Tor}(H_*(B), H_*(F)) = 0$, the "universal coefficient theorem" says that the $E^2$-term reduces to $E^2_{p,q} \cong H_p(B) \otimes H_q(F)$.

The Serre spectral sequence for cohomology, $E_2^{p,q} \cong H^p(B; {}^tH^q(F)) \Rightarrow H^{p+q}(X)$, has the advantage that it is a spectral sequence of algebras which greatly simplifies calculation of the differentials $d_r$ which are restricted by the requirement that they satisfy the Leibniz rule with respect to the cup product on $H^*(B)$ and $H^*(F)$, and which also allows the computation of the cup product on $H^*(X)$. Since it is a first quadrant spectral sequence, convergence is not an issue.

Frequently in applications of the Serre spectral sequence, instead of using the spectral sequence to calculate $H_*(X)$ from knowledge of $H_*(F)$ and $H_*(B)$ it is instead $H_*(X)$ and one of the other two homologies which is known, and one is working backwards from the spectral sequence to find the homology of the third space.

**Example 3** The universal $S^1$-bundle is the bundle $S^1 \to S^\infty \to \mathbb{C}P^\infty$ where $S^\infty$ is contractible. We will calculate $H^*(\mathbb{C}P^\infty)$ from the Serre spectral sequence of this bundle, taking $H^*(S^1)$ and $H^*(S^\infty)$ as known. We also take as known that $\mathbb{C}P^\infty$ is path connected, so $H^0(\mathbb{C}P^\infty) \cong \mathbb{Z}$.

$$E_2^{p,q} \cong H^p(\mathbb{C}P^\infty) \otimes H^q(S^1) \cong \begin{cases} H^p(\mathbb{C}P^\infty) & \text{if } q = 0 \text{ or } 1 \\ 0 & \text{otherwise} \end{cases}$$

$E_\infty$-terms on the diagonal $p + q = n$ form a composition series for $H^n(S^\infty)$ which is zero for $n \neq 0$. Therefore $E_\infty^{p,q} = 0$ unless $p = 0$ and $q = 0$, with $E_\infty^{0,0} \cong \mathbb{Z}$. Because all nonzero terms lie in the first quadrant, the bidegrees of the differentials show that $d_r(E_2^{1,0}) = 0$ for all $r \geq 2$, so $0 = E_\infty^{1,0} = E_2^{1,0} = H^1(\mathbb{C}P^\infty)$. Since $E_2^{1,q} \cong E_2^{1,0} \otimes E_2^{0,q}$, it follows that $E_2^{1,q} = 0$ for all $q$. Taking into the account the known zero terms, the bidegrees of the differentials show that $E_3^{0,1} \cong \mathrm{Ker}(d_2 : E_2^{0,1} \to E_2^{2,0})$ and $E_\infty^{0,1} = E_3^{0,1}$. Similarly, $E_\infty^{2,0} = E_3^{2,0} \cong \mathrm{Coker}(d_2 : E_2^{0,1} \to E_2^{2,0})$. Therefore, the vanishing of these $E_\infty$-terms shows that $d_2 : E_2^{0,1} \cong E_2^{2,0}$ and in particular $H^2(\mathbb{C}P^\infty) \cong E_2^{0,1} = H^1(S^1) \cong \mathbb{Z}$. It follows that $E_2^{2,q} \cong \mathbb{Z} \otimes E_2^{0,q} \cong E_2^{0,q}$ for all $q$. With the aid of the fact that we showed $E_2^{1,1} = 0$, we can repeat the argument used to show $E_2^{1,q} = 0$ for all $q$ to conclude that $E_2^{3,q} = 0$ for all $q$. Repeating the procedure, we inductively find that $E_2^{p,q} \cong E_2^{p-2,q}$ for all $p > 0$ and all $q$ and in particular

$$H^n(\mathbb{C}P^\infty) \cong \begin{cases} \mathbb{Z} & \text{if } n \text{ is even} \\ 0 & \text{if } n \text{ is odd} \end{cases}$$

The cup products in $H^*(\mathbb{C}P^\infty)$ can also be determined by taking advantage of the fact that the spectral sequence is a spectral sequence of algebras. Let $a \in E_2^{2,0} \cong \mathbb{Z}$ be a generator and set $x := d_2 a$. By the preceding calculation, $d_2$ is an isomorphism so $x$ is a generator of $H^2(\mathbb{C}P^\infty)$. Therefore, $x \otimes a$ is a generator of $E_2^{2,2}$ and the isomorphism $d_2$ gives that $d_2(x \otimes a)$ is a generator of $H^4(\mathbb{C}P^\infty)$. However, $d_2(x \otimes a) = d_2(x \otimes 1)(1 \otimes a) = 0 \otimes 1 + (-1)^2(x \otimes 1)d_2 a = x^2 \otimes 1$ and thus, $x^2$ is a generator of $H^4(\mathbb{C}P^\infty)$. Inductively, it follows that $x^n$ is a generator of $H^{2n}(\mathbb{C}P^\infty)$ for all $n$ and so $H^*(\mathbb{C}P^\infty) \cong \mathbb{Z}[x]$.

When working backwards from the Serre or other first quadrant spectral sequences in which $E^2_{p,q} \cong E^2_{p,0} \otimes E^2_{0,q}$ the following analog of the comparison theorem (Theorem 5) is often useful.

**Theorem 12** (Zeeman comparison theorem). *Let $E$ and $E'$ be first quadrant spectral sequences such that $E^2_{p,q} = E^2_{p,0} \otimes E^2_{0,q}$ and $E'^2_{p,q} = E'^2_{p,0} \otimes E'^2_{0,q}$. Let $f : E \to E'$ be a homomorphism of spectral sequences such that $f^2_{p,q} = f^2_{p,0} \otimes f^2_{0,q}$. Suppose that $f^\infty_{p,q} : E^\infty_{p,q} \to E'^\infty_{p,q}$ is an isomorphism for all $p$ and $q$. Then the following are equivalent*:

(i) $f^2_{p,0} : E^2_{p,0} \to E'^2_{p,0}$ *is an isomorphism for* $p \le n-1$;
(ii) $f^2_{0,q} : E^2_{0,q} \to E'^2_{0,q}$ *is an isomorphism for* $q \le n$.

There is a version of the Serre spectral sequence for generalized homology theories coming from the exact couple obtained by applying the generalized homology theory to the Serre filtration of $X$.

**Theorem 13** (Serre spectral sequence for generalized homology). *Let $F \to X \to B$ be a fibration and let $Y$ be an* (*unreduced*) *homology theory satisfying the Milnor wedge axiom. Then there is a* (*right half-plane*) *spectral sequence with $E^2_{p,q} \cong H_p(B; {}^tY_q(F))$ converging to $Y_{p+q}(X)$.*

Cocompleteness of the filtration follows from the properties of generalized homology theories satisfying the wedge axiom (Milnor 1962), and the rest of the convergence conditions are trivial since the filtration is 0 in negative degrees. Here, unlike the Serre spectral sequence for ordinary homology, the existence of terms in the fourth quadrant opens the possibility for composition series of infinite length, although in the case where $B$ is a finite-dimensional complex all the nonzero terms of the spectral sequence will live in the strip between $p=0$ and $p=\dim B$ and so the filtrations will be finite.

The special case of the fibration $* \to X \to X$ yields what is known as the "Atiyah–Hirzebruch spectral sequence".

**Theorem 14** (Atiyah–Hirzebruch spectral sequence). *Let $X$ be a CW-complex and let $Y$ be an* (*unreduced*) *homology theory satisfying the Milnor wedge axiom. Then there is a* (*right half-plane*) *spectral sequence with $E^2_{p,q} \cong H_p(X; Y_q(*))$ converging to $Y_{p+q}(X)$.*

In the cohomology Serre spectral sequence for generalized cohomology (including the cohomology Atiyah–Hirzebruch spectral sequence), convergence of the spectral sequence to $Y^*(X)$ is not guaranteed. Convergence to $\varprojlim_n Y^*(F_nX)$, should that occur, would be of the type discussed in case II in the section "Convergence of graded spectral sequences". Since $X_n = \emptyset$ for $n < 0$, the system defining $L_\infty$ stabilizes to 0. Therefore, $L_\infty = 0$ and, by the discussion in that section, $\varprojlim_r{}^1 Z_rX = 0$ becomes a sufficient condition for convergence to $\varprojlim_n Y^*(F_nX)$. However since the real object of study is usually $Y^*(X)$, the spectral sequence is most useful when one is also able to show $\varprojlim_n{}^1 Y^*(F_nX) = 0$ in which case the Milnor exact sequence (Milnor 1962)

$$\begin{aligned} 0 \to \varprojlim_n{}^1 Y^*(F_nX) \to Y^*(X) \\ \to \varprojlim_n Y^*(F_nX) \to 0 \end{aligned}$$

gives $Y^*(X) \cong \varprojlim_n Y^*(F_nX)$.

If $Y^*(\,)$ has cup products then the spectral sequence has the extra structure of a spectral sequence of $Y^*(*)$-algebras. In the case where $B$ is finite dimensional, all convergence problems disappear since the spectral sequence lives in a strip and the filtrations are finite.

**Example 4** Let $K^*(\,)$ be complex $K$-theory. Since $K^*(*) \cong \mathbb{Z}[z, z^{-1}]$ with $|z| = 2$, in the Atiyah–Hirzebruch spectral sequence for $K^*(\mathbb{C}P^n)$ we have

$$E_2^{p,q} = \begin{cases} \mathbb{Z} & \text{if } q \text{ is even and } p \text{ is even with } 0 \le p \le 2n \\ 0 & \text{otherwise} \end{cases}$$

Because $\mathbb{C}P^n$ is a finite complex, the spectral sequence converges to $K^*(\mathbb{C}P^n)$. Since all the nonzero terms have even total degree and all the differentials have total degree $+1$, the spectral sequence collapses at $E_2$ and we conclude that $K^q(\mathbb{C}P^n) = 0$ if $q$ is odd and that it has a composition series consisting of $(n+1)$ copies of $\mathbb{Z}$ when $q$ is even. Since $\mathbb{Z}$ is a free abelian group, this uniquely identifies the group structure of $K^{\text{even}}(\mathbb{C}P^n)$ as $\mathbb{Z}^{n+1}$. To find the ring structure we can make use of the fact that this is a spectral sequence of $K^*(*)$-algebras. The result is $K^*(\mathbb{C}P^n) \cong K^*(*)[x]/(x^{n+1})$, where $|x| = 2$.

In the Atiyah–Hirzebruch spectral sequence for $K^*(\mathbb{C}P^\infty)$ again all the terms have even total degree so the spectral sequence collapses at $E_2$. We noted earlier that collapse of the spectral sequence implies that $\varprojlim_r{}^1 Z_rX = 0$ and so the spectral sequence convergences to $\varprojlim_n K^*(\mathbb{C}P^n)$, where we used $F_{2n}\mathbb{C}P^\infty = \mathbb{C}P^n$. Since our preceding calculation shows that $K^*(\mathbb{C}P^n) \to K^*(\mathbb{C}P^{n-1})$ is onto, Mittag–Leffler (Theorem 10) implies that $\varprojlim_n{}^1 K^*(\mathbb{C}P^n) = 0$. Therefore, the spectral sequence converges to $K^*(\mathbb{C}P^\infty)$ and we find that $K^*(\mathbb{C}P^\infty) \cong \varprojlim_n K^*(\mathbb{C}P^n)$, which is isomorphic to the power series ring $K^*(*)[[x]]$, where $|x| = 2$.

In topology one might be interested in the Atiyah–Hirzebruch spectral sequence in the case where $X$ is a spectrum rather than a space (a spectrum being a generalization in which cells in negative degrees are allowed including the possibility that the dimensions

of the cells are not bounded below). In such cases, the spectral sequence is no longer constrained to lie in the right half-plane and convergence criteria are not well understood for either the homology or cohomology version.

### Spectral Sequence of a Double Complex

A double complex is a chain complex of chain complexes. That is, it is a bigraded abelian group $C_{p,q}$ together with two differentials $d' : C_{p,q} \to C_{p-1,q}$ and $d'' : C_{p,q} \to C_{p,q-1}$ satisfying $d' \circ d' = 0, d'' \circ d'' = 0$, and $d'd'' = d''d'$. Given a double complex C its total complex Tot C is defined by $(\text{Tot}\, C)_n := \bigoplus_{p+q=n} C_{p,q}$ with differential defined by $d|_{C_{p,q}} := d' + (-1)^p d'' : C_{p,q} \to C_{p-1,q} \oplus C_{p,q-1} \subset \text{Tot}_{n-1} C$.

There are two natural filtrations, $\mathcal{F}'_{\text{TotC}}$ and $\mathcal{F}''_{\text{Tot C}}$, on Tot C given by

$$\left(F'_p(\text{TotC})\right)_n = \bigoplus_{\substack{s+t=n \\ s \leq p}} C_{s,t}$$

$$\left(F''_p(\text{TotC})\right)_n = \bigoplus_{\substack{s+t=n \\ t \leq p}} C_{s,t}$$

yielding two spectral sequences abutting to $H_*(\text{TotC})$. In the first $E'^2_{p,q} = H_p(H_q(C_{*,*}))$ and in the other $E''^2_{p,q} = H_q(H_p(C_{*,*}))$. Convergence of these spectral sequences is not guaranteed, although the first will always converge if there exists $N$ such that $C_{p,q} = 0$ for $p < N$ and the second will converge if there exists $N$ such that $C_{p,q} = 0$ for $q < N$. From the double complex $C$ one could instead form the product total complex $(\text{Tot}^\pi C)_n := \prod_{p+q=n} C_{p,q}$ and proceed in a similar manner to construct the same spectral sequences with different convergence problems. In the important special case of a first quadrant double complex both spectral sequences converge and information is often obtained by playing one off against the other.

**Example 5** Let $M$ and $N$ be $R$-modules. Let $\text{Tor}'^R_*(M,N)$ and $\text{Tor}''^R_*(M,N)$ be the derived functors of $(_) \otimes N$ and $M \otimes (_)$, respectively. Let $P_*$ and $Q_*$ be projective resolutions of $M$ and $N$ respectively. Define a first quadrant double complex by $C_{p,q} := P_p \otimes Q_q$. Since $P_p$ is projective,

$$H_q(C_{p,*}) = P_p \otimes H_q(C_{p,*}) = \begin{cases} 0 & \text{if } q \neq 0 \\ N & \text{if } q = 0 \end{cases}$$

and so in the first spectral sequence of the double complex,

$$E'^2_{p,q} = \begin{cases} 0 & \text{if } q \neq 0 \\ \text{Tor}'^R_p(M,N) & \text{if } q = 0 \end{cases}$$

Therefore, the spectral sequence collapses to give $H_n(\text{Tot}\ C) \cong \text{Tor}'^R_n(M,N)$. Similarly, the second spectral sequence shows that $H_n(\text{Tot}\, C) \cong \text{Tor}''^R_n(M,N)$. Thus, $\text{Tor}^R_*(M,N)$ can be computed equally well from a projective resolution of either variable.

The technique of using a double complex in which one spectral sequence yields the homology the total complex to which both converge can be used to prove.

**Theorem 15** (Grothendieck spectral sequence). *Let $\underline{\underline{C}} \xrightarrow{F} \underline{\underline{B}} \xrightarrow{G} \underline{\underline{A}}$ be a composition of additive functors, where $\underline{\underline{C}}$, $\underline{\underline{B}}$, and $\underline{\underline{A}}$ are abelian categories. Assume that all objects in $\underline{\underline{C}}$ and $\underline{\underline{B}}$ have projective resolutions. Suppose that F takes projectives to projectives. Then for all objects C of $\underline{\underline{C}}$ there exists a (first quadrant) spectral sequence with $E^2_{p,q} = (L_p G)((L_q F)(C))$ converging to $(L_{p+q}(GF))(C)$.*

Naturally, there is a corresponding version for right derived functors.

An application of the Grothendieck spectral sequence is the following "change of rings spectral sequence." Let $f : R \to S$ be a ring homomorphism, let $M$ be a right $S$-module and let $N$ be a left $R$-module. Let $F(A) = S \otimes_R A$ and $G(B) = M \otimes_S B$, and note that $GF(A) = M \otimes_R A$. Applying the Grothendieck spectral sequence to the composition (left $R$-modules $\xrightarrow{F}$ left $S$-modules $\xrightarrow{G}$ abelian groups) yields a convergent spectral sequence $E^2_{p,q} \cong \text{Tor}^S_p(M, \text{Tor}^R_q(S,N)) \Rightarrow \text{Tor}^R_{p+q}(M,N)$.

### Eilenberg–Moore Spectral Sequence

For a topological group $G$, Milnor showed how to construct a universal $G$-bundle $G \to EG \to BG$ in which $EG$ is the infinite join $G^{*\infty}$ with diagonal $G$-action. There is a natural filtration $F_n BG := G^{*(n+1)}/G$ on $BG$ and therefore an induced filtration on the base of any principal $G$-bundle. This filtration yields a spectral sequence including as a special case a tool for calculating $H_*(BG)$ from knowledge of $H_*(G)$.

**Theorem 16** *Let $G \to X \to B$ be a principal $G$-bundle and let $H_*(\,)$ denote homology with coefficients in a field. Then there is a first quadrant spectral sequence with $E^2_{p,q} = \text{Tor}^{H_*(G)}_{pq}(H_*(X), H_*(*))$ converging to $H_{p+q}(BG)$.*

Here the group structure makes $H_*(G)$ into an algebra and $\text{Tor}^A_{pq}(M,N)$ denotes degree $q$ of the graded object formed as the $p$th-derived functor of the tensor product of the graded modules $M$ and $N$ over the graded ring $A$.

There is also a version (Eilenberg and Moore 1962) which, like the Serre spectral sequence, is suitable for computing $H^*(G)$ from $H^*(BG)$.

**Theorem 17** *Let*

$$\begin{array}{ccc} W & \longrightarrow & Y \\ \downarrow & & \downarrow \pi \\ X & \xrightarrow{f} & B \end{array}$$

*be a pullback square in which $\pi$ is a fibration and $X$ and $B$ are simply connected. Suppose that $H^*(X), H^*(Y)$, and $H^*(B)$ are flat $R$-modules of finite type, where $H^*(\,)$ denotes cohomology with coefficients in the Noetherian ring $R$. Then there is a (second quadrant) spectral sequence with $E_2^{p,q} \cong \mathrm{Tor}_{pq}^{H^*(B)}(H^*(X), H^*(Y))$ converging to $H^{p+q}(W)$.*

The cohomological version of the Eilenberg–Moore spectral sequence, stated above, contains the more familiar Tor for modules over an algebra. For the homological version, one must dualize these notions appropriately to define the cotensor product of comodules over a coalgebra, and its derived functors Cotor.

Provided the action of the fundamental group of $B$ is sufficiently nice there are extensions of the Eilenberg–Moore spectral sequence to the case where $B$ is not simply connected, although they do not always converge, and extensions to generalized (co)homology theories have also been studied.

# Spectral Theory of Linear Operators

**M Schechter**, University of California at Irvine, Irvine, CA, USA

## Introduction

We begin with the study of linear operators on normed vector spaces (for definitions, see, e.g., Schechter (2002) or the appendix at the end of this article). If the scalars are complex numbers, we shall call the space complex. If the scalars are real, we shall call it real.

Let $X, Y$ be normed vector spaces. A mapping $A$ which assigns to each element $x$ of a set $D(A) \subset X$ a unique element $y \in Y$ is called an operator (or transformation). The set $D(A)$ on which $A$ acts is called the domain of $A$. The operator $A$ is called linear if

1. $D(A)$ is a subspace of $X$, and
2. $A(\alpha_1 x_1 + \alpha_2 x_2) = \alpha_1 A x_1 + \alpha_2 A x_2$

for all scalars $\alpha_1, \alpha_2$ and all elements $x_1, x_2 \in D(A)$.

To begin, we shall only consider operators $A$ with $D(A) = X$.

An operator $A$ is called bounded if there is a constant $M$ such that

$$\|Ax\| \le M\|x\|, \quad x \in X \qquad [1]$$

The norm of such an operator is defined by

$$\|A\| = \sup_{x \neq 0} \frac{\|Ax\|}{\|x\|} \qquad [2]$$

It is the smallest $M$ which works in [1]. An operator $A$ is called continuous at a point $x \in X$ if $x_n \to x$ in $X$ implies $Ax_n \to Ax$ in $Y$. A bounded linear operator is continuous at each point. For if $x_n \to x$ in $X$, then

$$\|Ax_n - Ax\| \le \|A\| \cdot \|x_n - x\| \to 0$$

We also have

**Theorem 1** *If a linear operator $A$ is continuous at one point $x_0 \in X$, then it is bounded, and hence continuous at every point.*

We let $B(X, Y)$ be the set of bounded linear operators from $X$ to $Y$. Under the norm [2], one easily checks that $B(X, Y)$ is a normed vector space.

### The Adjoint Operator

An assignment $F$ of a number to each element $x$ of a vector space is called a functional and denoted by $F(x)$. If it satisfies

$$F(\alpha_1 x_1 + \alpha_2 x_2) = \alpha_1 F(x_1) + \alpha_2 F(x_2) \qquad [3]$$

for $\alpha_1, \alpha_2$ scalars, it is called linear. It is called bounded if

$$|F(x)| \le M\|x\|, \quad x \in X \qquad [4]$$

If $F$ is a bounded linear functional on a normed vector space $X$, the norm of $F$ is defined by

$$\|F\| = \sup_{x \in X,\, x \neq 0} \frac{|F(x)|}{\|x\|} \qquad [5]$$

It is equal to the smallest number $M$ satisfying [4].

For any normed vector space $X$, let $X'$ denote the set of bounded linear functionals on $X$. If $f, g \in X'$, we say that $f = g$ if

$$f(x) = g(x) \text{ for all } x \in X$$

The "zero" functional is the one assigning zero to all $x \in X$. We define $h = f + g$ by

$$h(x) = f(x) + g(x), \quad x \in X$$

and $g = \alpha f$ by

$$g(x) = \alpha f(x), \quad x \in X$$

Under these definitions, $X'$ becomes a vector space. The expression

$$\|f\| = \sup_{x \neq 0} \frac{|f(x)|}{\|x\|}, \quad f \in X' \qquad [6]$$

is easily seen to be a norm. Thus, $X'$ is a normed vector space. It is therefore natural to ask when $X'$ will be complete. A rather surprising answer is given by

**Theorem 2** *$X'$ is a Banach space whether or not $X$ is.*

(For the definition of a Banach space, see, e.g., Schechter (2002) or the appendix at the end of this article.)

Suppose $X, Y$ are normed vector spaces and $A \in B(X, Y)$. For each $y' \in Y'$, the expression $y'(Ax)$ assigns a scalar to each $x \in X$. Thus, it is a functional $F(x)$. Clearly $F$ is linear. It is also bounded since

$$|F(x)| = |y'(Ax)| \le \|y'\| \cdot \|Ax\| \le \|y'\| \cdot \|A\| \cdot \|x\|$$

Thus, there is an $x' \in X'$ such that

$$y'(Ax) = x'(x), \quad x \in X \qquad [7]$$

This functional $x'$ is unique. Thus, to each $y' \in Y'$ we have assigned a unique $x' \in X'$. We designate this assignment by $A'$ and note that it is a linear operator from $Y'$ to $X'$. Thus, [7] can be written in the form

$$y'(Ax) = A'y'(x) \qquad [8]$$

The operator $A'$ is called the adjoint (or conjugate) of $A$. We note

**Theorem 3** *$A' \in B(Y', X')$, and $\|A'\| = \|A\|$.*

The adjoint has the following easily verified properties:

$$(A + B)' = A' + B' \qquad [9]$$

$$(\alpha A)' = \alpha A' \qquad [10]$$

$$(AB)' = B'A' \qquad [11]$$

Why should we consider adjoints? One reason is as follows. Many problems in mathematics and its applications can be put in the form: given normed vector spaces $X, Y$ and an operator $A \in B(X, Y)$, one wishes to solve

$$Ax = y \qquad [12]$$

The set of all $y$ for which one can solve [12] is called the "range" of $A$ and is denoted by $R(A)$. The set of all $x$ for which $Ax = 0$ is called the "null space" of $A$ and is denoted by $N(A)$. Since $A$ is linear, it is easily checked that $N(A)$ and $R(A)$ are subspaces of $X$ and $Y$,

respectively (for definitions, see, e.g., Schechter (2002) or the appendix at the end of this article). The dimension of $N(A)$ is denoted by $\alpha(A)$.

If $y \in R(A)$, there is an $x \in X$ satisfying [12]. For any $y' \in Y'$ we have

$$y'(Ax) = y'(y)$$

Taking adjoints we get

$$A'y'(x) = y'(y)$$

If $y' \in N(A')$, this gives $y'(y) = 0$. Thus, a necessary condition that $y \in R(A)$ is that $y'(y) = 0$ for all $y' \in N(A')$. Obviously, it would be of great interest to know when this condition is also sufficient.

## The Spectrum and Resolvent Sets

From this point henceforth we shall assume that $X = Y$. We can then speak of the identity operator $I$ defined by

$$Ix = x, \quad x \in X$$

For a scalar $\lambda$, the operator $\lambda I$ is given by

$$\lambda Ix = \lambda x, \quad x \in X$$

We shall denote the operator $\lambda I$ by $\lambda$.

We shall denote the space $B(X, X)$ by $B(X)$. For any operator $A \in B(X)$, a scalar $\lambda$ for which $\alpha(A - \lambda) \neq 0$ is called an eigenvalue of $A$. Any element $x \neq 0$ of $X$ such that $(A - \lambda)x = 0$ is called an eigenvector (or eigenelement). The points $\lambda$ for which $(A - \lambda)$ has a bounded inverse in $B(X)$ comprise the resolvent set $\rho(A)$ of $A$ (for definitions, see, e.g., Schechter (2002) or the appendix at the end of this article). If $X$ is a Banach space, it is the set of those $\lambda$ such that $\alpha(A - \lambda) = 0$ and $R(A - \lambda) = X$. The spectrum $\sigma(A)$ of $A$ consists of all scalars not in $\rho(A)$. The set of eigenvalues of $A$ is sometimes called the point spectrum of $A$ and is denoted by $P\sigma(A)$.

We note that

**Theorem 4** *For $A$ in $B(X)$, $\sigma(A') = \sigma(A)$.*

We are now going to examine the sets $\rho(A)$ and $\sigma(A)$ for arbitrary $A \in B(X)$.

**Theorem 5** *$\rho(A)$ is an open set and hence $\sigma(A)$ is a closed set.*

Does every operator $A \in B(X)$ have points in its resolvent set? Yes. In fact, we have

**Theorem 6** *For $A$ in $B(X)$, set*

$$r_\sigma(A) = \inf_n \|A^n\|^{1/n} \qquad [13]$$

*Then $\rho(A)$ contains all scalars $\lambda$ such that $|\lambda| > r_\sigma(A)$.*

Let $p(t)$ be a polynomial of the form

$$p(t) = \sum_0^n a_k t^k$$

Then for any operator $A \in B(X)$, we define the operator

$$p(A) = \sum_0^n a_k A^k$$

where we take $A^0 = I$. We have

**Theorem 7** *If $\lambda \in \sigma(A)$, then $p(\lambda) \in \sigma(p(A))$ for any polynomial $p(t)$.*

Proof Since $\lambda$ is a root of $p(t) - p(\lambda)$, we have

$$p(t) - p(\lambda) = (t - \lambda)q(t)$$

where $q(t)$ is a polynomial with real coefficients. Hence,

$$p(A) - p(\lambda) = (A - \lambda)q(A) = q(A)(A - \lambda) \qquad [14]$$

Now, if $p(\lambda)$ is in $\rho(p(A))$, then [14] shows that $\alpha(A - \lambda) = 0$ and $R(A - \lambda) = X$. This means that $\lambda \in \rho(A)$, and the theorem is proved. □

A symbolic way of writing Theorem 7 is

$$p(\sigma(A)) \subset \sigma(p(A)) \qquad [15]$$

Note that, in general, there may be points in $\sigma(p(A))$ which may not be of the form $p(\lambda)$ for some $\lambda \in \sigma(A)$. As an example, consider the operator on $\mathbb{R}^2$ given by

$$A(\alpha_1, \alpha_2) = (-\alpha_2, \alpha_1)$$

$A$ has no spectrum; $A - \lambda$ is invertible for all real $\lambda$. However, $A^2$ has –1 as an eigenvalue. What is the reason for this? It is simply that our scalars are real. Consequently, imaginary numbers cannot be considered as eigenvalues. We shall see later that in order to obtain a more complete theory, we shall have to consider complex Banach spaces. Another question is whether every operator $A \in B(X)$ has points in its spectrum. For complex Banach spaces, the answer is yes.

## The Spectral Mapping Theorem

Suppose we want to solve an equation of the form

$$p(A)x = y, \quad x, \ y \in X \qquad [16]$$

where $p(t)$ is a polynomial and $A \in B(X)$. If 0 is not in the spectrum of $p(A)$, then $p(A)$ has an inverse in $B(X)$ and, hence, [16] can be solved for all $y \in X$. So a natural question to ask is: what is the spectrum of $p(A)$? By Theorem 7 we see that it contains $p(\sigma(A))$,

but by the remark at the end of the preceding section it can contain other points. If it were true that

$$p(\sigma(A)) = \sigma(p(A)) \qquad [17]$$

then we could say that [16] can be solved uniquely for all $y \in X$ if and only if $p(\lambda) \neq 0$ for all $\lambda \in \sigma(A)$.

For a complex Banach space we have

**Theorem 8** *If X is a complex Banach space, then* $\mu \in \sigma(p(A))$ *if and only if* $\mu = p(\lambda)$ *for some* $\lambda \in \sigma(A)$, *that is, if [17] holds.*

Proof We have proved it in one direction already (Theorem 7). To prove it in the other, let $\gamma_1, \ldots, \gamma_n$ be the (complex) roots of $p(t) - \mu$. For a complex Banach space they are all scalars. Thus,

$$p(A) - \mu = c(A - \gamma_1) \cdots (A - \gamma_n), \quad c \neq 0$$

Now suppose that all of the $\gamma_j$ are in $\rho(A)$. Then each $A - \gamma_j$ has an inverse in $B(X)$. Hence, the same is true for $p(A) - \mu$. In other words, $\mu \in \rho(p(A))$. Thus, if $\mu \in \sigma(p(A))$, then at least one of the $\gamma_j$ must be in $\sigma(A)$, say $\gamma_k$. Hence, $\mu = p(\gamma_k)$, where $\gamma_k \in \sigma(A)$. This completes the proof. □

Theorem 8 is called the "spectral mapping theorem" for polynomials. As mentioned before, it has the useful consequence:

**Corollary 1** *If X is a complex Banach space, then eqn [16] has a unique solution for every y in X if and only if* $p(\lambda) \neq 0$ *for all* $\lambda \in \sigma(A)$.

## Operational Calculus

Other things can be done in a complex Banach space that cannot be done in a real Banach space. For instance, we can get a formula for $p(A)^{-1}$ when it exists. To obtain this formula, we first note

**Theorem 9** *If X is a complex Banach space, then* $(z - A)^{-1}$ *is a complex analytic function of z for* $z \in \rho(A)$.

By this, we mean that in a neighborhood of each $z_0 \in \rho(A)$, the operator $(z - A)^{-1}$ can be expanded in a "Taylor series," which converges in norm to $(z - A)^{-1}$, just like analytic functions of a complex variable.

Now, by Theorem 6, $\rho(A)$ contains the set $|z| > \|A\|$. We can expand $(z - A)^{-1}$ in powers of $z^{-1}$ on this set. In fact, we have

**Lemma 1** *If* $|z| > \limsup \|A^n\|^{1/n}$, *then*

$$(z - A)^{-1} = \sum_1^\infty z^{-n} A^{n-1} \qquad [18]$$

*where the convergence is in the norm of* $B(X)$.

Let $C$ be any circle with center at the origin and radius greater than, say, $\|A\|$. Then, by Lemma 1,

$$\oint_C z^n (z - A)^{-1} dz = \sum_{k=1}^\infty A^{k-1} \oint_C z^{n-k} dz = 2\pi i A^n \qquad [19]$$

or

$$A^n = \frac{1}{2\pi i} \oint_C z^n (z - A)^{-1} dz \qquad [20]$$

where the line integral is taken in the right direction.

Note that the line integrals are defined in the same way as is done in the theory of functions of a complex variable. The existence of the integrals and their independence of path (so long as the integrands remain analytic) are proved in the same way. Since $(z - A)^{-1}$ is analytic on $\rho(A)$, we have

**Theorem 10** *Let C be any closed curve containing* $\sigma(A)$ *in its interior. Then [20] holds.*

As a direct consequence of this, we have

**Theorem 11** $r_\sigma(A) = \max_{\lambda \in \sigma(A)} |\lambda|$ *and* $\|A^n\|^{1/n} \to r_\sigma(A)$ *as* $n \to \infty$.

We can now put Lemma 1 in the following form:

**Theorem 12** *If* $|z| > r_\sigma(A)$, *then [18] holds with convergence in* $B(X)$.

Now let $b$ be any number greater than $r_\sigma(A)$, and let $f(z)$ be a complex-valued function that is analytic in $|z| < b$. Thus,

$$f(z) = \sum_0^\infty a_k z^k, \quad |z| < b \qquad [21]$$

We can define $f(A)$ as follows: the operators

$$\sum_0^n a_k A^k$$

converge in norm, since

$$\sum_0^\infty |a_k| \cdot \|A^k\| < \infty$$

This last statement follows from the fact that if $c$ is any number satisfying $r_\sigma(A) < c < b$, then

$$\|A^k\|^{1/k} \leq c$$

for $k$ sufficiently large, and the series

$$\sum_0^\infty |a_k| c^k$$

is convergent. We define $f(A)$ to be

$$\sum_{0}^{\infty} a_k A^k \qquad [22]$$

By Theorem 10, this gives

$$\begin{aligned} f(A) &= \frac{1}{2\pi i} \sum_{0}^{\infty} a_k \oint_C z^k (z - A)^{-1} \, dz \\ &= \frac{1}{2\pi i} \oint_C \sum_{0}^{\infty} a_k z^k (z - A)^{-1} \, dz \\ &= \frac{1}{2\pi i} \oint_C f(z)(z - A)^{-1} \, dz \end{aligned} \qquad [23]$$

where $C$ is any circle about the origin with radius greater than $r_\sigma(A)$ and less than $b$.

We can now give the formula that we promised. Suppose $f(z)$ does not vanish for $|z| < b$. Set $g(z) = 1/f(z)$. Then $g(z)$ is analytic in $|z| < b$, and hence $g(A)$ is defined. Moreover,

$$\begin{aligned} f(A)g(A) &= \frac{1}{2\pi i} \oint_C f(z)g(z)(z - A)^{-1} \, dz \\ &= \frac{1}{2\pi i} \oint_C (z - A)^{-1} \, dz = I \end{aligned}$$

Since $f(A)$ and $g(A)$ clearly commute, we see that $f(A)^{-1}$ exists and equals $g(A)$. Hence,

$$f(A)^{-1} = \frac{1}{2\pi i} \oint_C \frac{1}{f(z)} (z - A)^{-1} \, dz \qquad [24]$$

In particular, if

$$g(z) = 1/f(z) = \sum_{0}^{\infty} c_k z^k, \quad |z| < b$$

then

$$f(A)^{-1} = \sum_{0}^{\infty} c_k A^k \qquad [25]$$

Now, suppose $f(z)$ is analytic in an open set $\Omega$ containing $\sigma(A)$, but not analytic in a disk of radius greater than $r_\sigma(A)$. In this case, we cannot say that the series [22] converges in norm to an operator in $B(X)$. However, we can still define $f(A)$ in the following way: there exists an open set $\omega$ whose closure $\bar{\omega} \subset \Omega$ and whose boundary $\partial\omega$ consists of a finite number of simple closed curves that do not intersect, and such that $\sigma(A) \subset \omega$. (That such a set always exists is left as an exercise; see, e.g., Schechter (2002).) We now define $f(A)$ by

$$f(A) = \frac{1}{2\pi i} \oint_{\partial\omega} f(z)(z - A)^{-1} \, dz \qquad [26]$$

where the line integrals are to be taken in the proper directions. It is easily checked that $f(A) \in B(X)$ and is independent of the choice of the set $\omega$. By [23], this definition agrees with the one given above for the case when $\Omega$ contains a disk of radius greater than $r_\sigma(A)$. Note that if $\Omega$ is not connected, $f(z)$ need not be the same function on different components of $\Omega$.

Now suppose $f(z)$ does not vanish on $\sigma(A)$. Then we can choose $\omega$ so that $f(z)$ does not vanish on $\bar{\omega}$ (this is also an exercise). Thus, $g(z) = 1/f(z)$ is analytic on an open set containing $\bar{\omega}$ so that $g(A)$ is defined. Since $f(z)g(z) = 1$, one would expect that $f(A)g(A) = g(A)f(A) = I$, in which case, it would follow that $f(A)^{-1}$ exists and is equal to $g(A)$. This follows from

**Lemma 2** *If $f(z)$ and $g(z)$ are analytic in an open set $\Omega$ containing $\sigma(A)$ and*

$$h(z) = f(z)g(z)$$

*then $h(A) = f(A)g(A)$.*

Therefore, it follows that we have

**Theorem 13** *If $A$ is in $B(X)$ and $f(z)$ is a function analytic in an open set $\Omega$ containing $\sigma(A)$ such that $f(z) \neq 0$ on $\sigma(A)$, then $f(A)^{-1}$ exists and is given by*

$$f(A)^{-1} = \frac{1}{2\pi i} \oint_{\partial\omega} \frac{1}{f(z)} (z - A)^{-1} \, dz$$

*where $\omega$ is any open set such that*

(i) $\sigma(A) \subset \omega$, $\bar{\omega} \subset \Omega$,
(ii) *$\partial\omega$ consists of a finite number of simple closed curves, and*
(iii) *$f(z) \neq 0$ on $\bar{\omega}$.*

Now that we have defined $f(A)$ for functions analytic in a neighborhood of $\sigma(A)$, we can show that the spectral mapping theorem holds for such functions as well (see Theorem 8). We have

**Theorem 14** *If $f(z)$ is analytic in a neighborhood of $\sigma(A)$, then*

$$\sigma(f(A)) = f(\sigma(A)) \qquad [27]$$

*that is, $\mu \in \sigma(f(A))$ if and only if $\mu = f(\lambda)$ for some $\lambda \in \sigma(A)$.*

## Complexification

What we have just done is valid for complex Banach spaces. Suppose, however, we are dealing with a real Banach space. What can be said then?

Let $X$ be a real Banach space. Consider the set $Z$ of all ordered pairs $\langle x, y\rangle$ of elements of $X$. We set

$$\langle x_1, y_1\rangle + \langle x_2, y_2\rangle = \langle x_1 + x_2,\ y_1 + y_2\rangle$$
$$(\alpha + \mathrm{i}\beta)\langle x, y\rangle = \langle(\alpha x - \beta y), (\beta x + \alpha y)\rangle$$
$$\alpha, \beta \in \mathbb{R}$$

With these definitions, one checks easily that $Z$ is a complex vector space. The set of elements of $Z$ of the form $\langle x, 0\rangle$ can be identified with $X$. We would like to introduce a norm on $Z$ that would make $Z$ into a Banach space and satisfy

$$\|\langle x, 0\rangle\| = \|x\|, \quad x \in X$$

An obvious suggestion is

$$(\|x\|^2 + \|y\|^2)^{1/2}$$

However, it is soon discovered that this is not a norm on $Z$ (why?). We have to be more careful. One that works is given by

$$\|\langle x, y\rangle\| = \max_{\alpha^2+\beta^2=1} (\|\alpha x - \beta y\|^2 + \|\beta x + \alpha y\|^2)^{1/2}$$

With this norm, $Z$ becomes a complex Banach space having the desired properties.

Now let $A$ be an operator in $B(X)$. We define an operator $\hat{A}$ in $B(Z)$ by

$$\hat{A}\langle x, y\rangle = \langle Ax, Ay\rangle$$

Then

$$\begin{aligned}
&\|\hat{A}\langle x, y\rangle\| \\
&\quad = \max_{\alpha^2+\beta^2=1} (\|\alpha Ax - \beta Ay\|^2 + \|\beta Ax + \alpha Ay\|^2)^{1/2} \\
&\quad = \max_{\alpha^2+\beta^2=1} (\|A(\alpha x - \beta y)\|^2 + \|A(\beta x + \alpha y)\|^2)^{1/2} \\
&\quad \le \|A\| \cdot \|\langle x, y\rangle\|
\end{aligned}$$

Thus,

$$\|\hat{A}\| \le \|A\|$$

But,

$$\|\hat{A}\| \ge \sup_{x \neq 0} \frac{\|\langle Ax, 0\rangle\|}{\|\langle x, 0\rangle\|} = \|A\|$$

Hence,

$$\|\hat{A}\| = \|A\|$$

If $\lambda$ is real, then

$$(\hat{A} - \lambda)\langle x, y\rangle = \langle(A - \lambda)x, (A - \lambda)y\rangle$$

This shows that $\lambda \in \rho(\hat{A})$ if and only if $\lambda \in \rho(A)$. Similarly, if $p(t)$ is a polynomial with real coefficients, then

$$p(\hat{A})\langle x, y\rangle = \langle p(A)x, p(A)y\rangle$$

showing that $p(\hat{A})$ has an inverse in $B(Z)$ if and only if $p(A)$ has an inverse in $B(X)$. Hence, we have

**Theorem 15** *Equation [16] has a unique solution for each $y$ in $X$ if and only if $p(\lambda) \neq 0$ for all $\lambda \in \sigma(\hat{A})$.*

In the example given earlier, the operator $\hat{A}$ has eigenvalues i and –i. Hence, –1 is in the spectrum of $\hat{A}^2$ and also in that of $A^2$. Thus, the equation

$$(A^2 + 1)x = y$$

cannot be solved uniquely for all $y$.

## Compact Operators

Let $X$, $Y$ be normed vector spaces. A linear operator $K$ from $X$ to $Y$ is called compact (or completely continuous) if $D(K) = X$ and for every sequence $\{x_n\} \subset X$ such that $\|x_n\| \le C$, the sequence $\{Kx_n\}$ has a subsequence which converges in $Y$. The set of all compact operators from $X$ to $Y$ is denoted by $K(X, Y)$.

A compact operator is bounded. Otherwise, there would be a sequence $\{x_n\}$ such that $\|x_n\| \le C$, while $\|Kx_n\| \to \infty$. Then $\{Kx_n\}$ could not have a convergent subsequence. The sum of two compact operators is compact, and the same is true of the product of a scalar and a compact operator. Hence, $K(X, Y)$ is a subspace of $B(X, Y)$.

If $A \in B(X, Y)$ and $K \in K(Y, Z)$, then $KA \in K(X, Z)$. Similarly, if $L \in K(X, Y)$ and $B \in B(Y, Z)$, then $BL \in K(X, Z)$.

Suppose $K \in B(X, Y)$, and there is a sequence $\{F_n\}$ of compact operators such that

$$\|K - F_n\| \longrightarrow 0 \text{ as } n \longrightarrow \infty \qquad [28]$$

We claim that if $Y$ is a Banach space, then $K$ is compact.

**Theorem 16** *Let $X$ be a normed vector space and $Y$ a Banach space. If $L$ is in $B(X, Y)$ and there is a sequence $\{K_n\} \subset K(X, Y)$ such that*

$$\|L - K_n\| \longrightarrow 0 \text{ as } n \longrightarrow 0$$

*then $L$ is in $K(X, Y)$.*

**Theorem 17** *Let $X$ be a Banach space and let $K$ be an operator in $K(X)$. Set $A = I - K$. Then, $R(A)$ is closed in $X$ and $\dim N(A) = \dim N(A')$ is finite.*

*In particular, either* $R(A) = X$ *and* $N(A) = \{0\}$, *or* $R(A) \neq X$ *and* $N(A) \neq \{0\}$.

The last statement of Theorem 17 is known as the "Fredholm alternative."

Let $X, Y$ be Banach spaces. An operator $A \in B(X, Y)$ is said to be a Fredholm operator from $X$ to $Y$ if

1. $\alpha(A) = \dim N(A)$ is finite,
2. $R(A)$ is closed in $Y$, and
3. $\beta(A) = \dim N(A')$ is finite.

The set of Fredholm operators from $X$ to $Y$ is denoted by $\Phi(X, Y)$. If $X = Y$ and $K \in K(X)$, then, clearly, $I - K$ is a Fredholm operator. The index of a Fredholm operator is defined as

$$i(A) = \alpha(A) - \beta(A) \qquad [29]$$

For $K \in K(X)$, we have shown that $i(I - K) = 0$ (Theorem 17).

**Theorem 18** *Let* $X$, $Y$ *be normed vector spaces, and assume that* $K$ *is in* $K(X, Y)$. *Then* $K'$ *is in* $K(Y', X')$.

Let $X$ be a Banach space, and suppose $K \in K(X)$. If $\lambda$ is a nonzero scalar, then

$$\lambda I - K = \lambda(I - \lambda^{-1}K) \in \Phi(X) \qquad [30]$$

For an arbitrary operator $A \in B(X)$, the set of all scalars $\lambda$ for which $\lambda I - A \in \Phi(X)$ is called the $\Phi$-set of $A$ and is denoted by $\Phi_A$. Thus, [30] gives

**Theorem 19** *If* $X$ *is a Banach space and* $K$ *is in* $K(X)$, *then* $\Phi_K$ *contains all scalars* $\lambda \neq 0$.

**Theorem 20** *Under the hypothesis of Theorem 19*, $\alpha(K - \lambda) = 0$ *except for, at most, a denumerable set* $S$ *of values of* $\lambda$. *The set* $S$ *depends on* $K$ *and has 0 as its only possible limit point. Moreover, if* $\lambda \neq 0$ *and* $\lambda \notin S$, *then* $\alpha(K - \lambda) = 0, R(K - \lambda) = X$ *and* $K - \lambda$ *has an inverse in* $B(X)$.

## Unbounded Operators

In many applications, one runs into unbounded operators instead of bounded ones. This is particularly true in the case of differential equations. For instance, consider the operator $\mathrm{d}/\mathrm{d}t$ on $C[0, 1]$ with domain consisting of continuously differentiable functions. It is clearly unbounded. In fact, the sequence $x_n(t) = t^n$ satisfies $\|x_n\| = 1, \|\mathrm{d}x_n/\mathrm{d}t\| = n \to \infty$ as $n \to \infty$. It would, therefore, be useful if some of the results that we have stated for bounded operators would also hold for unbounded ones. We shall see that, indeed, many of them do. Unless otherwise specified, $X, Y, Z$, and $W$ will denote Banach spaces in this article.

Let $X$, $Y$ be normed vector spaces, and let $A$ be a linear operator from $X$ to $Y$. We now officially lift our restriction that $D(A) = X$. However, if $A \in B(X, Y)$, it is still to be assumed that $D(A) = X$.

The operator $A$ is called closed if whenever $\{x_n\} \subset D(A)$ is a sequence satisfying

$$x_n \longrightarrow x \text{ in } X, \qquad Ax_n \longrightarrow y \text{ in } Y \qquad [31]$$

then $x \in D(A)$ and $Ax = y$. Clearly, all operators in $B(X, Y)$ are closed.

To define $A'$ for an unbounded operator, we follow the definition for bounded operators, and exercise a bit of care. We want

$$A'y'(x) = y'(Ax), \quad x \in D(A) \qquad [32]$$

Thus, we say that $y' \in D(A')$ if there is an $x' \in X'$ such that

$$x'(x) = y'(Ax), \quad x \in D(A) \qquad [33]$$

Then we define $A'y'$ to be $x'$. In order that this definition make sense, we need $x'$ to be unique, that is, that $x'(x) = 0$ for all $x \in D(A)$ should imply that $x' = 0$. This is true if and only if $D(A)$ is dense in $X$. To summarize, we can define $A'$ for any linear operator from $X$ to $Y$ provided $D(A)$ is dense in $X$. We take $D(A')$ to be the set of those $y' \in Y'$ for which there is an $x' \in X'$ satisfying [33]. This $x'$ is unique, and we set $A'y' = x'$. Note that if

$$|y'(Ax)| \leq C\|x\|, \quad x \in D(A)$$

then a simple application of the Hahn–Banach theorem (see e.g., Schechter (2002) or the appendix) shows that $y' \in D(A')$.

We define unbounded Fredholm operators in the following way: let $X$, $Y$ be Banach spaces. Then the set $\Phi(X, Y)$ of Fredholm operators from $X$ to $Y$ consists of linear operators from $X$ to $Y$ such that

1. $D(A)$ is dense in $X$,
2. $A$ is closed,
3. $\alpha(A) = \dim N(A) < \infty$,
4. $R(A)$ is closed in $Y$, and
5. $\beta(A) = \dim N(A') < \infty$.

## The Essential Spectrum

Let $A$ be a linear operator on a normed vector space $X$. We say that $\lambda \in \rho(A)$ if $R(A - \lambda)$ is dense in $X$ and there is a $T \in B(X)$ such that

$$\begin{aligned} T(A - \lambda) &= I \text{ on } D(A) \\ (A - \lambda)T &= I \text{ on } R(A - \lambda) \end{aligned} \qquad [34]$$

Otherwise, $\lambda \in \sigma(A)$. As before, $\rho(A)$ and $\sigma(A)$ are called the resolvent set and spectrum of $A$, respectively. To show the relationship of this definition to the one given before, we note the following.

**Lemma 3** *If $X$ is a Banach space and $A$ is closed, then $\lambda \in \rho(A)$ if and only if*

$$\alpha(A - \lambda) = 0, \qquad R(A - \lambda) = X \qquad [35]$$

Throughout the remainder of this section, we shall assume that $X$ is a Banach space, and that $A$ is a densely defined, closed linear operator on $X$. We ask the following question: what points of $\sigma(A)$ can be removed from the spectrum by the addition of a compact operator to $A$? The answer to this question is closely related to the set $\Phi_A$. We define this to be the set of all scalars $\lambda$ such that $A - \lambda \in \Phi(X)$. We have

**Theorem 21** *The set $\Phi_A$ is open, and $i(A - \lambda)$ is constant on each of its components.*

We also have

**Theorem 22** *$\Phi_{A+K} = \Phi_A$ for all $K$ which are $A$-compact, and $i(A + K - \lambda) = i(A - \lambda)$ for all $\lambda \in \Phi_A$.*

Set

$$\sigma_e(A) = \bigcap_{K \in K(X)} \sigma(A + K)$$

We call $\sigma_e(A)$ the essential spectrum of $A$ (there are other definitions). It consists of those points of $\sigma(A)$ which cannot be removed from the spectrum by the addition of a compact operator to $A$. We now characterize $\sigma_e(A)$.

**Theorem 23** *$\lambda \notin \sigma_e(A)$ if and only if $\lambda \in \Phi_A$ and $i(A - \lambda) = 0$.*

## Normal Operators

A sequence of elements $\{\varphi_n\}$ in a Hilbert space is called orthonormal if

$$(\varphi_m, \varphi_n) = \begin{cases} 0, & m \neq n \\ 1, & m = n \end{cases} \qquad [36]$$

(for definitions, see, e.g., Schechter (2002) or the appendix at the end of this article).

Let $\{\varphi_n\}$ be an orthonormal sequence (finite or infinite) in a Hilbert space $H$. Let $\{\lambda_k\}$ be a sequence (of the same length) of scalars satisfying

$$|\lambda_k| \leq C$$

Then for each element $f \in H$, the series

$$\sum \lambda_k (f, \varphi_k) \varphi_k$$

converges in $H$. Define the operator $A$ on $H$ by

$$Af = \sum \lambda_k (f, \varphi_k) \varphi_k \qquad [37]$$

Clearly, $A$ is a linear operator. It is also bounded, since

$$\|Af\|^2 = \sum |\lambda_k|^2 |(f, \varphi_k)|^2 \leq C^2 \|f\|^2 \qquad [38]$$

by Bessel's inequality

$$\sum_1^\infty (f, \varphi_k)^2 \leq \|f\|^2 \qquad [39]$$

For convenience, let us assume that each $\lambda_k \neq 0$ (just remove those $\varphi_k$ corresponding to the $\lambda_k$ that vanish). In this case, $N(A)$ consists of precisely those $f \in H$ which are orthogonal to all of the $\varphi_k$. Clearly, such $f$ are in $N(A)$. Conversely, if $f \in N(A)$, then

$$0 = (Af, \varphi_k) = \lambda_k (f, \varphi_k)$$

Hence, $(f, \varphi_k) = 0$ for each $k$. Moreover, each $\lambda_k$ is an eigenvalue of $A$ with $\varphi_k$ the corresponding eigenvector. This follows immediately from [37]. Since $\sigma(A)$ is closed, it also contains the limit points of the $\lambda_k$.

Next, we shall see that if $\lambda \neq 0$ is not a limit point of the $\lambda_k$, then $\lambda \in \rho(A)$. To show this, we solve

$$(\lambda - A)u = f \qquad [40]$$

for any $f \in H$. Any solution of [40] satisfies

$$\lambda u = f + Au = f + \sum \lambda_k (u, \varphi_k) \varphi_k \qquad [41]$$

Hence,

$$\lambda (u, \varphi_k) = (f, \varphi_k) + \lambda_k (u, \varphi_k)$$

or

$$(u, \varphi_k) = \frac{(f, \varphi_k)}{\lambda - \lambda_k} \qquad [42]$$

Substituting back in [41], we obtain

$$\lambda u = f + \sum \frac{\lambda_k (f, \varphi_k) \varphi_k}{\lambda - \lambda_k} \qquad [43]$$

Since $\lambda$ is not a limit point of the $\lambda_k$, there is a $\delta > 0$ such that

$$|\lambda - \lambda_k| \geq \delta, \quad k = 1, 2, \ldots$$

Hence, the series in [43] converges for each $f \in H$. It is an easy exercise to verify that [43] is indeed a solution of [40]. To see that $(\lambda - A)^{-1}$ is bounded, note that

$$|\lambda| \cdot \|u\| \leq \|f\| + C\|f\|/\delta \qquad [44]$$

(cf. [38]). Thus, we have proved

**Lemma 4** *If the operator A is given by [37], then* $\sigma(A)$ *consists of the points* $\lambda_k$*, their limit points and possibly* 0. $N(A)$ *consists of those u which are orthogonal to all of the* $\varphi_k$*. For* $\lambda \in \rho(A)$*, the solution of [40] is given by [43].*

We see from all this that the operator [37] has many useful properties. Therefore, it would be desirable to determine conditions under which operators are guaranteed to be of that form. For this purpose, we note another property of $A$. It is expressed in terms of the Hilbert space adjoint of $A$.

Let $H_1$ and $H_2$ be Hilbert spaces, and let $A$ be an operator in $B(H_1, H_2)$. For fixed $y \in H_2$, the expression $Fx = (Ax, y)$ is a bounded linear functional on $H_1$. By the Riesz representation theorem (see, e.g., Schechter (2002) or the appendix at the end of this article), there is a $z \in H_1$ such that $Fx = (x, z)$ for all $x \in H_1$. Set $z = A^*y$. Then $A^*$ is a linear operator from $H_2$ to $H_1$ satisfying

$$(Ax, y) = (x, A^*y) \qquad [45]$$

$A^*$ is called the Hilbert space adjoint of $A$. Note the difference between $A^*$ and the operator $A'$ defined for a Banach space. As in the case of the operator $A'$, we note that $A^*$ is bounded and

$$\|A^*\| = \|A\| \qquad [46]$$

Returning to the operator $A$, we remove the assumption that each $\lambda_k \neq 0$ and note that

$$(Au, v) = \sum \lambda_k (u, \varphi_k)(\varphi_k, v) = \left(u, \sum \bar{\lambda}_k (v, \varphi_k)\varphi_k\right)$$

showing that

$$A^*v = \sum \bar{\lambda}_k (v, \varphi_k)\varphi_k \qquad [47]$$

(If $H$ is a complex Hilbert space, then the complex conjugates $\bar{\lambda}_k$ of the $\lambda_k$ are required. If $H$ is a real Hilbert space, then the $\lambda_k$ are real, and it does not matter.) Now, by Lemma 4, we see that each $\bar{\lambda}_k$ is an eigenvalue of $A^*$ with $\varphi_k$ a corresponding eigenvector. Note also that

$$\|A^*f\|^2 = \sum |\lambda_k|^2 |(f, \varphi_k)|^2 \qquad [48]$$

showing that

$$\|A^*f\| = \|Af\|, \quad f \in H \qquad [49]$$

An operator satisfying [49] is called normal. An important characterization is given by

**Theorem 24** *An operator is normal and compact if and only if it is of the form [37] with* $\{\varphi_k\}$ *an orthonormal set and* $\lambda_k \to 0$ *as* $k \to \infty$.

We also have

**Lemma 5** *If A is normal, then*

$$\|(A^* - \bar{\lambda})u\| = \|(A - \lambda)u\|, \quad u \in H \qquad [50]$$

**Corollary 2** *If A is normal and* $A\varphi = \lambda\varphi$*, then* $A^*\varphi = \bar{\lambda}\varphi$.

**Lemma 6** *If A is normal and compact, then it has an eigenvalue* $\lambda$ *such that* $|\lambda| = \|A\|$.

We also have

**Corollary 3** *If A is a normal compact operator, then there is an orthonormal sequence* $\{\varphi_k\}$ *of eigenvectors of A such that every element u in H can be written in the form*

$$u = h + \sum (u, \varphi_k)\varphi_k \qquad [51]$$

*where* $h \in N(A)$.

## Hyponormal Operators

An operator $A$ in $B(H)$ is called hyponormal if

$$\|A^*u\| \leq \|Au\|, \quad u \in H \qquad [52]$$

or, equivalently, if

$$([AA^* - A^*A]u, u) \leq 0, \quad u \in H \qquad [53]$$

Of course, a normal operator is hyponormal. An operator $A \in B(H)$ is called seminormal if either $A$ or $A^*$ is hyponormal. We have

**Theorem 25** *If A is seminormal, then*

$$r_\sigma(A) = \|A\| \qquad [54]$$

We have earlier defined the essential spectrum of an operator $A$ to be

$$\sigma_e(A) = \bigcap_{K \in K(H)} \sigma(A + K) \qquad [55]$$

It was shown that $\lambda \notin \sigma_e(A)$ if and only if $\lambda \in \Phi_A$ and $i(A - \lambda) = 0$ (Theorem 23). Let us show that we can be more specific in the case of seminormal operators.

**Theorem 26** *If A is a seminormal operator, then* $\lambda \in \sigma(A) \backslash \sigma_e(A)$ *if and only if* $\lambda$ *is an isolated eigenvalue with* $r(A - \lambda) = \lim_{n\to\infty} \alpha[(A - \lambda)^n] < \infty$.

**Lemma 7** *If A is hyponormal, then so is* $B = A - \lambda$ *for any complex* $\lambda$.

**Lemma 8** *If B is hyponormal with 0 an isolated point of* $\sigma(B)$ *and either* $\alpha(B)$ *or* $\beta(B)$ *is finite, then* $B \in \Phi(H)$ *and* $i(B) = 0$.

There is a simple consequence of Lemma 8.

**Corollary 4** *If A is seminormal and $\lambda$ is an isolated point of $\sigma(A)$, then $\lambda$ is an eigenvalue of A.*

We also have the following:

**Theorem 27** *Let A be a seminormal operator such that $\sigma(A)$ has no nonzero limit points. Then A is compact and normal. Thus, it is of the form [37] with the $\{\varphi_k\}$ orthonormal and $\lambda_k \to 0$.*

**Corollary 5** *If A is seminormal and compact, then it is normal.*

## Spectral Resolution

We saw in the section "Operational calculus" that, in a Banach space $X$, we can define $f(A)$ for any $A \in B(X)$ provided $f(z)$ is a function analytic in a neighborhood of $\sigma(A)$. In this section, we shall show that we can do better in the case of self-adjoint operators.

A linear operator $A$ on a Hilbert space $X$ is called self-adjoint if it has the property that $x \in D(A)$ and $Ax = f$ if and only if

$$(x, Ay) = (f, y), \quad y \in D(A)$$

In particular, it satisfies

$$(Ax, y) = (x, Ay), \quad x, y \in D(A)$$

A bounded self-adjoint operator is normal.

To get an idea, let $A$ be a compact, self-adjoint operator on $H$. Then by Theorem 24,

$$Au = \sum \lambda_k (u, \varphi_k)\varphi_k \qquad [56]$$

where $\{\varphi_k\}$ is an orthonormal sequence of eigenvectors and the $\lambda_k$ are the corresponding eigenvalues of $A$. Now let $p(t)$ be a polynomial with real coefficients having no constant term

$$p(t) = \sum_{1}^{m} a_k t^k \qquad [57]$$

Then $p(A)$ is compact and self-adjoint. Let $\mu \neq 0$ be a point in $\sigma(p(A))$. Then $\mu = p(\lambda)$ for some $\lambda \in \sigma(A)$ (Theorem 8). Now $\lambda \neq 0$ (otherwise we would have $\mu = p(0) = 0$). Hence, it is an eigenvalue of $A$ (see the section "The spectrum and resolvent sets"). If $\varphi$ is a corresponding eigenvector, then

$$\begin{aligned}[p(A) - \mu]\varphi &= \sum a_k A^k \varphi - \mu\varphi \\ &= \sum a_k \lambda^k \varphi - \mu\varphi \\ &= [p(\lambda) - \mu]\varphi = 0\end{aligned}$$

Thus $\mu$ is an eigenvalue of $p(A)$ and $\varphi$ is a corresponding eigenvector. This shows that

$$p(A)u = \sum p(\lambda_k)(u, \varphi_k)\varphi_k \qquad [58]$$

Now, the right-hand side of [58] makes sense if $p(t)$ is any function bounded on $\sigma(A)$ (see the section "Normal operators"). Therefore it seems plausible to define $p(A)$ by means of [58]. Of course, for such a definition to be useful, one would need certain relationships to hold. In particular, one would want $f(t)g(t) = h(t)$ to imply $f(A)g(A) = h(A)$. We shall discuss this a bit later.

If $A$ is not compact, we cannot, in general, obtain an expansion in the form [56]. However, we can obtain something similar. In fact, we have

**Theorem 28** *Let A be a self-adjoint operator in $B(H)$. Set*

$$m = \inf_{\|u\|=1} (Au, u), \qquad M = \sup_{\|u\|=1} (Au, u)$$

*Then there is a family $\{E(\lambda)\}$ of orthogonal projection operators on H depending on a real parameter $\lambda$ and such that:*

(i) $E(\lambda_1) \le E(\lambda_2)$ for $\lambda_1 \le \lambda_2$;
(ii) $E(\lambda)u \to E(\lambda_0)u$ as $\lambda_0 < \lambda \to \lambda_0, u \in H$;
(iii) $E(\lambda) = 0$ for $\lambda < m, E(\lambda) = I$ for $\lambda \ge M$;
(iv) $AE(\lambda) = E(\lambda)A$; *and*
(v) *if $a < m, b \ge M$ and $p(t)$ is any polynomial, then*

$$p(A) = \int_a^b p(\lambda)\, \mathrm{d}E(\lambda) \qquad [59]$$

*This means the following. Let $a = \lambda_0 < \lambda_1 < \cdots < \lambda_n = b$ be any partition of $[a, b]$, and let $\lambda'_k$ be any number satisfying $\lambda_{k-1} \le \lambda'_k \le \lambda_k$. Then*

$$\sum_{1}^{n} p(\lambda'_k)[E(\lambda_k) - E(\lambda_{k-1})] \to p(A) \qquad [60]$$

*in $B(H)$ as $\eta = \max(\lambda_k - \lambda_{k-1}) \to 0$.*

**Theorem 29** *Let A be a self-adjoint operator on H. Then there is a family $\{E(\lambda)\}$ of orthogonal projection operators on H satisfying* (i) *and* (ii) *of Theorem 28 and*

(i) $$E(\lambda) \to \begin{cases} 0 & \text{as } \lambda \to -\infty \\ I & \text{as } \lambda \to +\infty \end{cases}$$

(ii) $$E(\lambda)A \subset AE(\lambda)$$

(iii) $$p(A) = \int_{-\infty}^{\infty} p(\lambda)\, \mathrm{d}E(\lambda)$$

*for any polynomial $p(t)$.*

These theorems are known as the spectral theorems for self-adjoint operators.

## Appendix

Here we include some background material related to the text.

Consider a collection $C$ of elements or "vectors" with the following properties:

1. They can be added. If $f$ and $g$ are in $C$, so is $f+g$.
2. $f+(g+h)=(f+g)+h, \quad f,g,h \in C$.
3. There is an element $0 \in C$ such that $h+0=h$ for all $h \in C$.
4. For each $h \in C$ there is an element $-h \in C$ such that $h+(-h)=0$.
5. $g+h=h+g, \quad g,h \in C$.
6. For each real number $\alpha, \alpha h \in C$.
7. $\alpha(g+h)=\alpha g+\alpha h$.
8. $(\alpha+\beta)h=\alpha h+\beta h$.
9. $\alpha(\beta h)=(\alpha\beta)h$.
10. To each $h \in C$ there corresponds a real number $\|h\|$ with the following properties:
11. $\|\alpha h\|=|\alpha|\|h\|$.
12. $\|h\|=0$ if, and only if, $h=0$.
13. $\|g+h\| \leq \|g\|+\|h\|$.
14. If $\{h_n\}$ is a sequence of elements of $C$ such that $\|h_n-h_m\| \to 0$ as $m,n \to \infty$, then there is an element $h \in C$ such that $\|h_n-h\| \to 0$ as $n \to \infty$.

A collection of objects which satisfies statements (1)–(9) and the additional statement

15. $1h=h$

is called a vector space or linear space.

A set of objects satisfying statements (1)–(13) is called a normed vector space, and the number $\|h\|$ is called the norm of $h$. Although statement (15) is not implied by statements (1)–(9), it is implied by statements (1)–(13). A sequence satisfying

$$\|h_n-h_m\| \to 0 \quad \text{as } m,n \to \infty$$

is called a Cauchy sequence. Property (14) states that every Cauchy sequence converges in norm to a limit (i.e., satisfies $\|h_n-h\| \to 0$ as $n \to \infty$). Property (14) is called completeness, and a normed vector space satisfying it is called a complete normed vector space or a Banach space.

We shall write

$$h_n \to h \quad \text{as } n \to \infty$$

when we mean

$$\|h_n-h\| \to 0 \quad \text{as } n \to \infty$$

A subset $U$ of a vector space $V$ is called a subspace of $V$ if $\alpha_1 x_1+\alpha_2 x_2$ is in $U$ whenever $x_1, x_2$ are in $U$ and $\alpha_1, \alpha_2$ are scalars.

A subset $U$ of a normed vector space $X$ is called closed if for every sequence $\{x_n\}$ of elements in $U$ having a limit in $X$, the limit is actually in $U$.

Consider a vector space $X$ having a mapping $(f,g)$ from pairs of its elements to the reals such that

1. $(\alpha f,g)=\alpha(f,g)$
2. $(f+g,h)=(f,h)+(g,h)$
3. $(f,g)=(g,f)$
4. $(f,f)>0$ unless $f=0$.

Then

$$(f,g)^2 \leq (f,f)(g,g), \quad f,g \in X \qquad [61]$$

An expression $(f,g)$ that assigns a real number to each pair of elements of a vector space and satisfies the aforementioned properties is called a scalar (or inner) product.

If a vector space $X$ has a scalar product $(f,g)$, then it is a normed vector space with norm $\|f\|=(f,f)^{1/2}$. A vector space which has a scalar product and is complete with respect to the induced norm is called a Hilbert space. Every Hilbert space is a Banach space, but the converse is not true. Inequality [61] is known as the Cauchy–Schwarz inequality. $\mathbb{R}^n$ is a Hilbert space.

Let $H$ be a Hilbert space and let $(x,y)$ denote its scalar product. If we fix $y$, then the expression $(x,y)$ assigns to each $x \in H$ a number. An assignment $F$ of a number to each element $x$ of a vector space is called a functional and denoted by $F(x)$. The scalar product is not the first functional we have encountered. In any normed vector space, the norm is also a functional. The functional $F(x)=(x,y)$ satisfies

$$F(\alpha_1 x_1+\alpha_2 x_2)=\alpha_1 F(x_1)+\alpha_2 F(x_2) \qquad [62]$$

for $\alpha_1, \alpha_2$ scalars. A functional satisfying [62] is called linear. Another property is

$$|F(x)| \leq M\|x\|, \quad x \in H \qquad [63]$$

which follows immediately from Schwarz's inequality (cf. [61]). A functional satisfying [63] is called bounded. The norm of such a functional is defined to be

$$\|F\| = \sup_{x \in H, x \neq 0} \frac{|F(x)|}{\|x\|}$$

Thus for $y$ fixed, $F(x)=(x,y)$ is a bounded linear functional in the Hilbert space $H$. We have

**Theorem 30** *For every bounded linear functional F on a Hilbert space H there is a unique element y ∈ H such that*

$$F(x) = (x, y) \quad \text{for all } x \in H \qquad [64]$$

*Moreover,*

$$\|y\| = \sup_{x\in H, x\neq 0} \frac{|F(x)|}{\|x\|} = \|F\| \qquad [65]$$

Theorem 30 is known as the "Riesz representation theorem."

For any normed vector space $X$, let $X'$ denote the set of bounded linear functionals on $X$. If $f, g \in X'$, we say that $f = g$ if

$$f(x) = g(x) \quad \text{for all } x \in X$$

The "zero" functional is the one assigning zero to all $x \in X$. We define $h = f + g$ by

$$h(x) = f(x) + g(x), \quad x \in X$$

and $g = \alpha f$ by

$$g(x) = \alpha f(x), \quad x \in X$$

Under these definitions, $X'$ becomes a vector space. We have been employing the expression

$$\|f\| = \sup_{x\neq 0} \frac{|f(x)|}{\|x\|}, \quad f \in X' \qquad [66]$$

This is easily seen to be a norm. Thus $X'$ is a normed vector space.

We also have

**Theorem 31** *Let M be a subspace of a normed vector space X, and suppose that f(x) is a bounded linear functional on M. Set*

$$\|f\| = \sup_{x\in M, x\neq 0} \frac{|f(x)|}{\|x\|}$$

*Then there is a bounded linear functional F(x) on the whole of X such that*

$$F(x) = f(x), \quad x \in M \qquad [67]$$

*and*

$$\|F\| = \sup_{x\in X, x\neq 0} \frac{|F(x)|}{\|x\|} = \|f\| = \sup_{x\in M, x\neq 0} \frac{|f(x)|}{\|x\|} \qquad [68]$$

Theorem 31 is known as the "Hahn–Banach theorem."

If $A$ is a linear operator from $X$ to $Y$, with $R(A) = Y$ and $N(A) = \{0\}$ (i.e., consists only of the vector 0), we can assign to each $y \in Y$ the unique solution of

$$Ax = y$$

This assignment is an operator from $Y$ to $X$ and is usually denoted by $A^{-1}$ and called the inverse operator of $A$. It is linear because of the linearity of $A$. One can ask: "when is $A^{-1}$ continuous?" or, equivalent by, "when is it bounded?" A very important answer to this question is given by

**Theorem 32** *If X, Y are Banach spaces and A is a closed linear operator from X to Y with* $R(A) = Y, N(A) = \{0\}$, *then* $A^{-1} \in B(Y, X)$.

This theorem is sometimes referred to as the "bounded inverse theorem."

If $A$ is self-adjoint and

$$(A - \lambda)x = 0, \qquad (A - \mu)y = 0$$

with $\lambda \neq \mu$, then

$$(x, y) = 0$$

If $A$ has a compact inverse, its eigenvalues cannot have limit points. If $A^{-1}$ is compact, then the eigenelements corresponding to the same eigenvalue form a finite-dimensional subspace.

## Introduction

In loop quantum gravity (LQG) (*see* Loop Quantum Gravity) – a background independent formulation of quantum gravity – the full quantum dynamics is governed by the following (constraint) operator equations or quantum Einstein equations:

Gauss Law

$$\widehat{G}_i(A,E)|\Psi>:=\widehat{D_aE_i^a}|\Psi>=0$$

Vector constraint

$$\widehat{V}_a(A,E)|\Psi>:=\widehat{E_i^aF_{ab}^i(A)}|\Psi>=0$$

Scalar constraint

$$\widehat{S}(A,E)\Big|\Psi>:=\left[\widehat{\sqrt{\det E}^{-1}E_i^aE_j^bF_{ab}^{ij}(A)+\cdots}\right]\Big| \Psi>=0 \qquad [1]$$

where $A_a^i$ is an SU(2) connection ($i=1,2,3$, $a=1,2,3$), $E_i^a$ is its conjugate momentum (the triad field), $F^{ij}_{ab}(A)$ is the curvature of $A_a^i$, and $D_a$ is the covariant derivative (*see* Canonical General Relativity). The hat means that the classical phase-space functions are promoted to operators in a kinematical Hilbert space $\mathcal{H}_{\rm kin}$; the solutions are in the so-called physical Hilbert space $\mathcal{H}_{\rm phys}$. The goal of the spin foam approach is to construct a mathematically well-defined notion of path integral for LQG as a device for computing the solutions of the previous equations.

The space of solution of the Gauss and vector constraints [1] is well understood in LQG (*see* Loop Quantum Gravity), and often also called kinematical Hilbert space $\mathcal{H}_{\rm kin}$. The solutions of the scalar constraint can be characterized by the definition of the generalized projection operator $P$ from the kinematical Hilbert space $\mathcal{H}_{\rm kin}$ into the kernel of the scalar constraint $\mathcal{H}_{\rm phys}$. Formally, one can write $P$ as

$$P=\text{“}\prod_{x\in}\delta(\widehat{S}(x))\text{”} = \int D[N]\exp\left[i\int_\Sigma N(x)\widehat{S(x)}\right] \qquad [2]$$

A formal argument shows that $P$ can also be defined in a manifestly covariant manner as a regularization of the formal path integral of general relativity. In first-order variables, it becomes

$$P=\int D[e]\ D[A]\ \mu[A,e]\exp[iS_{\rm GR}(e,A)] \qquad [3]$$

where $e$ is the tetrad field, $A$ is the spacetime connection, and $\mu[A,e]$ denotes the appropriate measure.

In both cases, $P$ characterizes the space of solutions of quantum Einstein equations as for any arbitrary state $|\phi>\in\mathcal{H}_{\rm kin}$ then $P|\phi>$ is a (formal) solution of [1]. Moreover, the matrix elements of $P$ define the physical inner product $(<,>_{\rm p})$ providing the vector space of solutions of [1] with the Hilbert space structure that defines $\mathcal{H}_{\rm phys}$. Explicitly,

$$<s,s'>_{\rm p}\ :=\ <Ps,s'>$$

for $s,s'\in\mathcal{H}_{\rm kin}$.

When these matrix elements are computed in the spin network basis (see **Figure 1**) (*see* Loop Quantum Gravity), they can be expressed as a sum over amplitudes of “spin network histories”: spin foams (**Figure 2**). The latter are naturally given by foam-like combinatorial structures whose basic elements carry quantum numbers of geometry (*see* Loop Quantum Gravity). A spin foam history, from the state $|s>$ to the state $|s'>$, is denoted by a pair $(F_{s\to s'},\{j\})$, where $F_{s\to s'}$ is the 2-complex with boundary given by the graphs of the spin network states $|s'>$ and $|s>$, respectively, and $\{j\}$ is the set of spin quantum numbers labeling its edges (denoted $e\in F_{s\to s'}$) and faces (denoted $f\in F_{s\to s'}$). Vertices are denoted

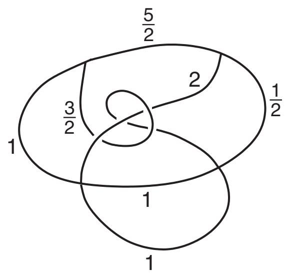

**Figure 1** A spin network state is given by a graph embedded in space whose links and nodes are labeled by unitary irreducible representations of SU(2). These states form a complete basis of the kinematical Hilbert space of LQG where the operator equations [1] are defined.

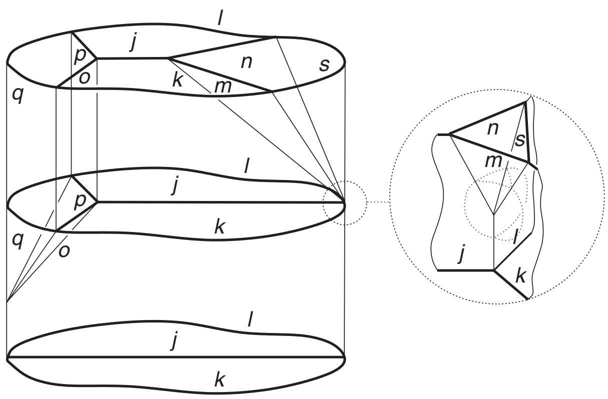

**Figure 2** A spin foam as the "colored" 2-complex representing the transition between three different spin network states. A transition vertex is magnified on the right.

$v \in F_{s \to s'}$. The physical inner product can be expressed as a sum over spin foam amplitudes

$$
\begin{aligned}
\langle s', s\rangle_{\mathrm{p}} &= \langle Ps', s\rangle \\
&= \sum_{F_{s\to s'}} N(F_{s\to s'}) \sum_{\{j\}} \prod_{f\in F_{s\to s'}} A_f(j_f) \\
&\quad \times \prod_{e\in F_{s\to s'}} A_e(j_e) \prod_{v\in F_{s\to s'}} A_v(j_v)
\end{aligned} \qquad [4]
$$

where $N(F_{s\to s'})$ is a (possible) normalization factor, and $A_f(j_f), A_e(j_e)$, and $A_v(j_v)$ are the 2-cell or face amplitude, the edge or 1-cell amplitude, and the 0-cell or vertex amplitude, respectively. These local amplitudes depend on the spin quantum numbers labeling neighboring cells in $F_{s\to s'}$ (e.g., the vertex amplitude of the vertex magnified in Figure 2 is $A_v(j,k,l,m,n,s)$).

The underlying discreteness discovered in LQG is crucial: in the spin foam representation, the functional integral for gravity is replaced by a sum over amplitudes of combinatorial objects given by foam-like configurations (spin foams) as in [4]. A spin foam represents a possible history of the gravitational field and can be interpreted as a set of transitions through different quantum states of space. Boundary data in the path integral are given by the polymer-like excitations (spin network states, Figure 1) representing 3-geometry states in LQG.

## Spin Foams in 3D Quantum Gravity

Now we introduce the concept of spin foams in a more explicit way in the context of the quantization of three-dimensional (3D) Riemannian gravity. Later in this section we will present the definition of $P$ from the canonical and covariant viewpoint formally stated in the introduction by eqns [2] and [3], respectively.

### The Classical Theory

Riemannian gravity in 3D is a theory with no local degrees of freedom, that is, a topological theory (*see* Topological Quantum Field Theory: Overview). Its action (in the first-order formalism) is given by

$$S(e,\omega) = \int_M \mathrm{tr}(e \wedge F(\omega)) \qquad [5]$$

where $M = \Sigma \times \mathbb{R}$ (for $\Sigma$ an arbitrary Riemann surface), $\omega$ is an SU(2) connection, and the triad $e$ is an su(2)-valued 1-form. The gauge symmetries of the action are the local SU(2) gauge transformations

$$\delta e = [e, \alpha], \qquad \delta\omega = d_\omega \alpha \qquad [6]$$

where $\alpha$ is an su(2)-valued 0-form, and the "topological" gauge transformation

$$\delta e = d_\omega \eta, \qquad \delta\omega = 0 \qquad [7]$$

where $d_\omega$ denotes the covariant exterior derivative and $\eta$ is an su(2)-valued 0-form. The first invariance is manifest from the form of the action, while the second is a consequence of the Bianchi identity, $d_\omega F(\omega) = 0$. The gauge symmetries are so large that all the solutions to the equations of motion are locally pure gauge. The theory has only global or topological degrees of freedom.

Upon the standard $2+1$ decomposition (*see* Canonical General Relativity), the phase space in these variables is parametrized by the pullback to $\Sigma$ of $\omega$ and $e$. In local coordinates, one can express them in terms of the two 2D connection $A_a^i$ and the triad field $E_j^b = \epsilon^{bc} e_c^k \eta_{jk}$, where $a = 1, 2$ are space coordinate indices and $i, j = 1, 2, 3$ are su(2) indices. The symplectic structure is defined by

$$\{A_a^i(x), E_j^b(y)\} = \delta_a^{\ b} \delta^i_{\ j} \delta^{(2)}(x,y) \qquad [8]$$

Local symmetries of the theory are generated by the first-class constraints

$$D_b E_j^b = 0, \qquad F_{ab}^i(A) = 0 \qquad [9]$$

which are referred to as the Gauss law and the curvature constraint, respectively – the quantization of these is the analog of [1] in 4D. This simple theory has been quantized in various ways in the literature; here we will use it to introduce the spin foam quantization.

### Kinematical Hilbert Space

In analogy with the 4D case, one follows Dirac's procedure finding first a representation of the basic variables in an auxiliary or kinematical Hilbert space $\mathcal{H}_{\text{kin}}$. The basic states are functionals of the connection depending on the parallel transport along paths $\gamma \subset \Sigma$: the so-called holonomy. Given a connection $A_a^i(x)$ and a path $\gamma$, one defines the holonomy $h_\gamma[A]$ as the path-ordered exponential

$$h_\gamma[A] = P \exp \int_\gamma A \qquad [10]$$

The kinematical Hilbert space, $\mathcal{H}_{\text{kin}}$, corresponds to the Ashtekar–Lewandowski (AL) representation of the algebra of functions of holonomies or generalized connections. This algebra is in fact a $C^*$-algebra and is denoted Cyl (*see* Loop Quantum Gravity). Functionals of the connection act in the AL representation simply by multiplication. For example, the holonomy operator acts as follows:

$$\widehat{h_\gamma[A]}\Psi[A] = h_\gamma[A]\Psi[A] \qquad [11]$$

As in 4D, an orthonormal basis of $\mathcal{H}_{\text{kin}}$ is defined by the spin network states. Each spin network is labeled by a graph $\gamma \subset \Sigma$, a set of spins $\{j_\ell\}$ labeling links $\ell \in \gamma$, and a set of intertwiners $\{\iota_n\}$ labeling nodes $n \in \gamma$ (**Figure 3**), namely:

$$s_{\gamma,\{j_\ell\},\{\iota_n\}}[A] = \bigotimes_{n\in\gamma} \iota_n \bigotimes_{\ell\in\gamma} \overset{j_\ell}{\prod}(h_\ell[A]) \qquad [12]$$

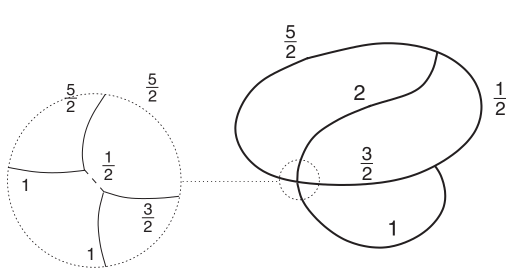

**Figure 3** A spin network state in $2+1$ LQG. The decomposition of a 4-valent node in terms of basic 3-valent intertwiners is shown.

where $\overset{j}{\Pi}$ is the unitary irreducible representation matrix of spin $j$ (for a precise definition, *see* Loop Quantum Gravity). For simplicity, we will often denote spin network states $|s>$ omitting the graph and spin labels.

### Spin Foams from the Hamiltonian Formulation

The physical Hilbert space, $\mathcal{H}_{\text{phys}}$, is defined by those "states" that are annihilated by the constraints. By construction, spin-network states solve the Gauss constraint – $\widehat{D_a E_i^a}|s>=0$ – as they are manifestly SU(2) gauge invariant (*see* Loop Quantum Gravity). To complete the quantization, one needs to characterize the space of solutions of the quantum curvature constraints $(\widehat{F}_{ab}^i)$, and to provide it with the physical inner product. The existence of $\mathcal{H}_{\text{phys}}$ is granted by the following:

**Theorem 1** *There exists a normalized positive linear form P over* Cyl, *that is,* $P(\psi^*\psi) \geq 0$ *for* $\psi \in$ Cyl *and* $P(1)=1$, *yielding (through the GNS construction* (*see* Algebraic Approach to Quantum Field Theory)) *the physical Hilbert space* $\mathcal{H}_{\text{phys}}$ *and the physical representation* $\pi_p$ *of* Cyl.

The state $P$ contains a very large Gelfand ideal (set of zero norm states) $J := \{\alpha \in \text{Cyl s.t. } P(\alpha^*\alpha)=0\}$. In fact, the physical Hilbert space $\mathcal{H}_{\text{phys}} := \overline{\text{Cyl}/J}$ corresponds to the quantization of finitely many degrees of freedom. This is expected in 3D gravity as the theory does not have local excitations (no "gravitons") (*see* Topological Quantum Field Theory: Overview). The representation $\pi_p$ of Cyl solves the curvature constraint in the sense that for any functional $f_\gamma[A] \in$ Cyl defined on the subalgebra of functionals defined on contractible graphs $\gamma \in \Sigma$, one has that

$$\pi_p[f_\gamma]\Psi = f_\gamma[0]\Psi \qquad [13]$$

This equation expresses the fact that "$\widehat{F}=0$" in $\mathcal{H}_{\text{phys}}$ (for flat connections, parallel transport is trivial around a contractible region). For $s, s' \in \mathcal{H}_{\text{kin}}$, the physical inner product is given by

$$<s, s'>_{\text{p}} := P(s^*s) \qquad [14]$$

where the $*$-operation and the product are defined in Cyl.

The previous equation admits a "sum over histories" representation. We shall introduce the concept of the spin foam representation as an explicit construction of the positive linear form $P$ which, as in [2], is formally given by

$$\begin{aligned} P &= \int D[N] \exp\left(\mathrm{i} \int_\Sigma \text{tr}[N\widehat{F}(A)]\right) \\ &= \prod_{x\in\Sigma} \delta[\widehat{F(A)}] \end{aligned} \qquad [15]$$

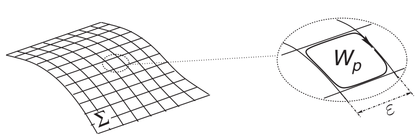

**Figure 4** Cellular decomposition of the space manifold Σ (a square lattice in this example), and the infinitesimal plaquette holonomy $W_p[A]$.

where $N(x) \in \mathrm{su}(2)$. One can make the previous formal expression a rigorous definition if one introduces a regularization. Given a partition of Σ in terms of 2D plaquettes of coordinate area $\epsilon^2$, one has that

$$\int_\Sigma \mathrm{tr}[NF(A)] = \lim_{\epsilon \to 0} \sum_{p^i} \epsilon^2 \mathrm{tr}[N_{p^i} F_{p^i}] \qquad [16]$$

where $N_{p^i}$ and $F_{p^i}$ are values of $N^i$ and $\epsilon^{ab} F^i_{ab}[A]$ at some interior point of the plaquette $p^i$ and $\epsilon^{ab}$ is the Levi-Civita tensor. Similarly, the holonomy $W_{p^i}[A]$ around the boundary of the plaquette $p^i$ (see Figure 4) is given by

$$W_{p^i}[A] = \mathbb{1} + \epsilon^2 F_{p^i}(A) + \mathcal{O}(\epsilon^2) \qquad [17]$$

where $F_{p^i} = \tau_j \epsilon^{ab} F^j_{ab}(x_{p^i})$ ($\tau_j$ are the generators of su(2) in the fundamental representation). The previous two equations lead to the following definition: given $s \in \mathrm{Cyl}$ (think of spin network state based on a graph $\gamma$), the linear form $P(s)$ is defined as

$$P(s) := \lim_{\epsilon \to 0} \left\langle \Omega \prod_{p^i} \int \mathrm{d}N_{p^i} \exp(\mathrm{i}\ \mathrm{tr}[N_{p^i} W_{p^i}]), s \right\rangle \qquad [18]$$

where $<,>$ is the inner product in the AL representation and $|\Omega>$ is the "vacuum" ($1 \in \mathrm{Cyl}$) in the AL representation. The partition is chosen so that the links of the underlying graph $\gamma$ border the plaquettes. One can easily perform the integration over the $N_{p^i}$ using the identity (Peter–Weyl theorem)

$$\int \mathrm{d}N \exp(\mathrm{i}\ \mathrm{tr}[NW]) = \sum_j (2j+1) \mathrm{tr}\left[\overset{j}{\Pi}(W)\right] \qquad [19]$$

Using the previous equation

$$P(s) := \lim_{\epsilon \to 0} \prod_{p^i} \sum_{j(p^i)} (2j(p^i) + 1) <\Omega\ \mathrm{tr}\left[\overset{j(p^i)}{\Pi}(W_{p^i})\right], s> \qquad [20]$$

where $j(p^i)$ is the spin labeling element of the sum [19] associated to the $i$th plaquette. Since the $\mathrm{tr}[\Pi^j(W)]$ commute, the ordering of plaquette operators in the previous product does not matter. It can be shown that the limit $\epsilon \to 0$ exists and one can give a closed expression of $P(s)$.

Now in the AL representation (see eqn [11]), each $\mathrm{tr}[\Pi^{j(p^i)}(W_{p^i})]$ acts by creating a closed loop in the $j_{p^i}$ representation at the boundary of the corresponding plaquette (Figures 5 and 6).

One can introduce a (nonphysical) time parameter that works simply as a coordinate providing the means of organizing the series of actions of plaquette loop operators in [20]; that is, one assumes that each of the loop actions occurs at different "times." We have introduced an auxiliary time slicing (arbitrary parametrization). If one inserts the AL partition of unity

$$\mathbb{1} = \sum_{\gamma \in \Sigma} \sum_{\{j\}_\gamma} |\gamma, \{j\} >< \gamma, \{j\}| \qquad [21]$$

where the sum is over the complete basis of spin network states $\{|\gamma, \{j\}>\}$ – based on all graphs $\gamma \in \Sigma$ and with all possible spin labeling – between each time

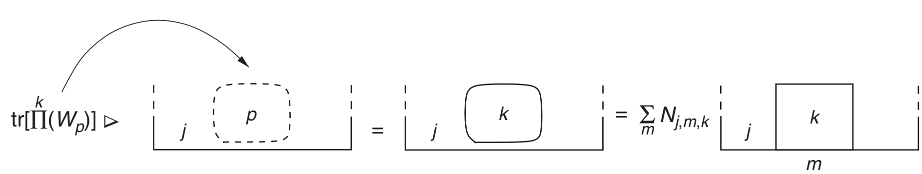

**Figure 5** Graphical notation representing the action of one plaquette holonomy on a spin network state. On the right is the result written in terms of the spin network basis. The amplitude $N_{j,m,k}$ can be expressed in terms of Clebsch–Gordan coefficients.

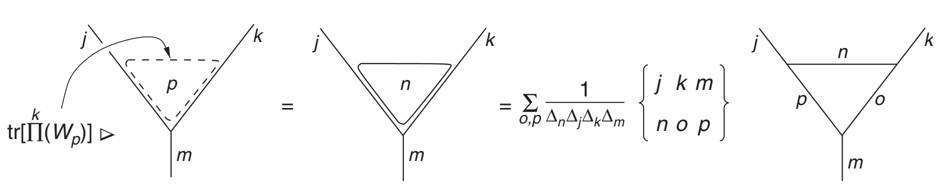

**Figure 6** Graphical notation representing the action of one plaquette holonomy on a spin network vertex. The object in brackets ({}) is a 6$j$-symbol and $\Delta_j := 2j + 1$.

slice, one arrives at a sum over spin network histories representation of $P(s)$. More precisely, $P(s)$ can be expressed as a sum over amplitudes corresponding to a series of transitions that can be viewed as the "time evolution" between the "initial" spin network $s$ and the "final" "vacuum state" $\Omega$. The physical inner product between spin networks $s$ and $s'$ is defined as

$$<s, s'>_{\mathrm{p}} := P(s^* s')$$

and can be expressed as a sum over amplitudes corresponding to transitions interpolating between the "initial" spin network $s'$ and the "final" spin network $s$ (e.g., Figures 7 and 8).

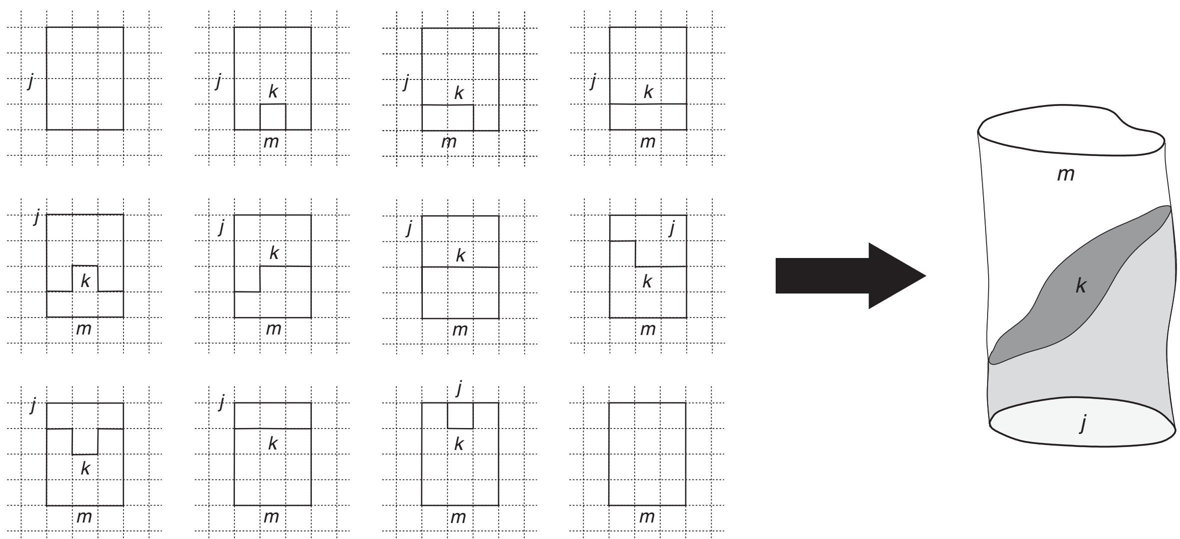

**Figure 7** A set of discrete transitions in the loop-to-loop physical inner product obtained by a series of transitions as in Figure 5. On the right, the continuous spin foam representation in the limit $\epsilon \to 0$.

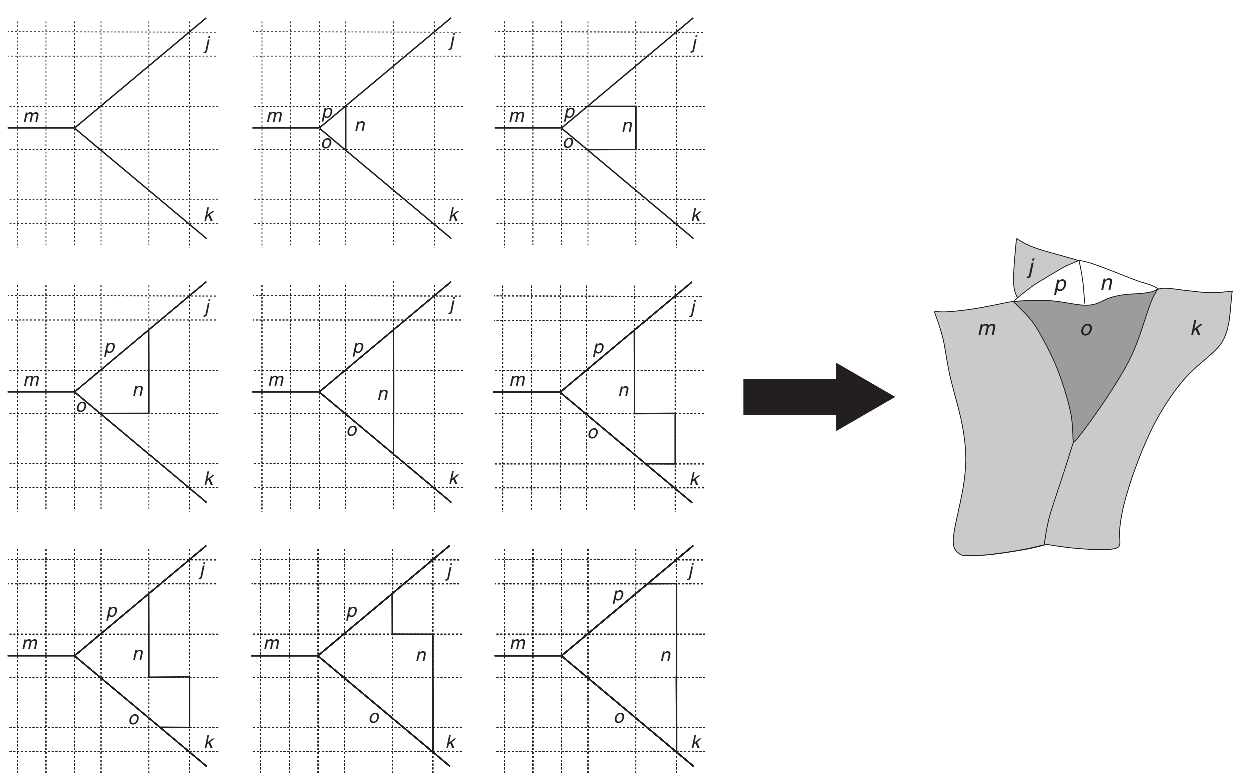

**Figure 8** A set of discrete transitions representing one of the contributing histories at a fixed value of the regulator. On the right, the continuous spin foam representation when the regulator is removed.

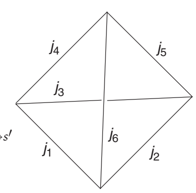
Spin network nodes evolve into edges while spin network links evolve into 2D faces. Edges inherit the intertwiners associated to the nodes and faces inherit the spins associated to links. Therefore, the series of transitions can be represented by a 2-complex whose 1-cells are labeled by intertwiners and whose 2-cells are labeled by spins. The places where the action of the plaquette loop operators create new links (Figures 6 and 8) define 0-cells or vertices. These foam-like structures are the so-called spin foams. The spin foam amplitudes are purely combinatorial and can be explicitly computed from the simple action of the loop operator in the AL representation (*see* Loop Quantum Gravity). A particularly simple case arises when the spin network states $s$ and $s'$ have only 3-valent nodes. Explicitly,

$$<s, s'>_{\mathrm{p}} := P(s^* s')$$

$$= \sum_{\{j\}} \prod_{f \in F_{s \to s'}} (2j_f + 1)^{\frac{\nu_f}{2}} \prod_{v \in F_{s \to s'}} \qquad [22]$$



where the notation is that of [4], and $\nu_f = 0$ if $f \cap s \neq 0 \wedge f \cap s' \neq 0, \nu_f = 1$ if $f \cap s \neq 0 \vee f \cap s' \neq 0$, and $\nu_f = 2$ if $f \cap s = 0 \wedge f \cap s' = 0$. The tetrahedral diagram denotes a 6*j*-symbol: the amplitude obtained by means of the natural contraction of the four intertwiners corresponding to the 1-cells converging at a vertex. More generally, for arbitrary spin networks, the vertex amplitude corresponds to 3*nj*-symbols, and $<s, s'>_{\mathrm{p}}$ takes the general form [4].

### Spin Foams from the Covariant Path Integral

In this section we re-derive the spin foam representation of the physical scalar product of $2+1$ (Riemannian) quantum gravity directly as a regularization of the covariant path integral. The formal path integral for 3D gravity can be written as

$$P = \int D[e] D[A] \exp\left[ \mathrm{i} \int_M \mathrm{tr}[e \wedge F(A)] \right] \qquad [23]$$

Assume $M = \Sigma \times I$, where $I \subset \mathbb{R}$ is a closed (time) interval (for simplicity, we ignore boundary terms).

In order to give a meaning to the formal expression above, one replaces the 3D manifold (with boundary) $M$ with an arbitrary cellular decomposition $\Delta$. One also needs the notion of the associated dual 2-complex of $\Delta$ denoted by $\Delta^*$. The dual 2-complex $\Delta^*$ is a combinatorial object defined by a set of vertices $v \in \Delta^*$ (dual to 3-cells in $\Delta$), edges $e \in \Delta^*$ (dual to 2-cells in $\Delta$), and faces $f \in \Delta^*$

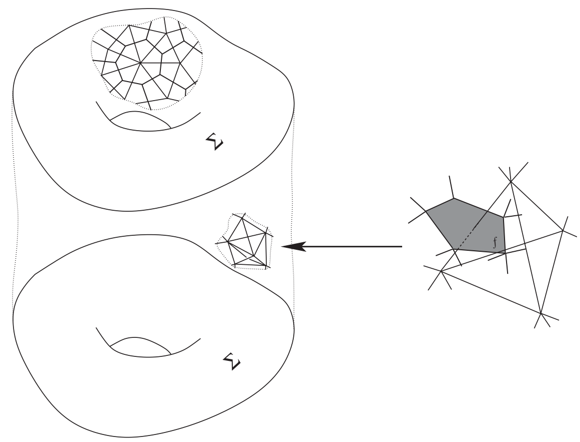


**Figure 9** The cellular decomposition of $M = \Sigma \times I$ ($\Sigma = T^2$ in this example). The illustration shows part of the induced graph on the boundary and the detail of a tetrahedron in $\Delta$ and a face $f \in \Delta^*$ in the bulk.

(dual to 1-cells in $\Delta$). The intersection of the dual 2-complex $\Delta^*$ with the boundaries defines two graphs $\gamma_1, \gamma_2 \in \Sigma$ (see Figure 9). For simplicity, we ignore the boundaries until the end of this section. The fields $e$ and $A$ are discretized as follows. The su(2)-valued 1-form field $e$ is represented by the assignment of $e_f \in \mathrm{su}(2)$ to each 1-cell in $\Delta$. We use the fact that faces in $\Delta^*$ are in one-to-one correspondence with 1-cells in $\Delta$ and label $e_f$ with a face subindex (Figure 9). The connection field $A$ is represented by the assignment of group elements $g_e \in \mathrm{SU}(2)$ to each edge in $e \in \Delta^*$ (see Figure 10).

With all this, [23] becomes the regularized version $P_\Delta$ defined as

$$P_\Delta = \int \prod_{f \in \Delta^*} \mathrm{d}e_f \prod_{e \in \Delta^*} \mathrm{d}g_e \exp\left[\mathrm{i}\ \mathrm{tr}\left[e_f W_f\right]\right] \qquad [24]$$

where $\mathrm{d}e_f$ is the regular Lebesgue measure on $\mathbb{R}^3$, $\mathrm{d}g_e$ is the Haar measure on SU(2), and $W_f$ denotes the holonomy around (spacetime) faces, that is, $W_f = g_e^1 \cdots g_e^N$ for $N$ being the number of edges bounding the corresponding face (see Figure 10). The discretization procedure is reminiscent of the one used in standard lattice gauge theory (*see* Lattice

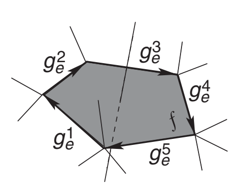

**Figure 10** A (2-cell) face $f \in \Delta^*$ in a cellular decomposition of the spacetime manifold $M$ and the corresponding dual 1-cell. The connection field is discretized by the assignment of the parallel transport group elements $g_e^i \in \mathrm{SU}(2)$ to edges $e \in \Delta^*$ ($i = 1, \ldots, 5$ in the face shown here).

Gauge Theory). The previous definition can be motivated by an analysis equivalent to the one presented in [16].

Integrating over $e_f$, and using [19], one obtains

$$P_\Delta = \sum_{\{j\}} \int \prod_{e\in\Delta^*} \mathrm{d}g_e \prod_{f\in\Delta^*} (2j_f+1) \times \mathrm{tr}\left[\overset{j_f}{\Pi}(g_e^1 \ldots g_e^N)\right] \qquad [25]$$

Now it remains to integrate over the lattice connection $\{g_e\}$. If an edge $e \in \Delta^*$ bounds $n$ faces $f \in \Delta^*$ there will be $n$ traces of the form $\mathrm{tr}[\Pi^{j_f}(\cdots g_e \cdots)]$ in [25] containing $g_e$ in the argument. In order to integrate over $g_e$ we can use the following identity:

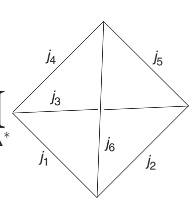
$$I^n_{\mathrm{inv}} := \int \mathrm{d}g \overset{j_1}{\Pi}(g) \otimes \overset{j_2}{\Pi}(g) \otimes \cdots \otimes \overset{j_n}{\Pi}(g) = \sum_\iota C^\iota_{j_1 j_2 \cdots j_n} C^{*\iota}_{j_1 j_2 \cdots j_n} \qquad [26]$$

where $I^n_{\mathrm{inv}}$ is the projector from the tensor product of irreducible representations $\mathcal{H}_{j_1\cdots j_n} = j_1 \otimes j_2 \otimes \cdots \otimes j_n$ onto the invariant component $\mathcal{H}^0_{j_1\cdots j_n} = \mathrm{Inv}[j_1 \otimes j_2 \otimes \cdots \otimes j_n]$. On the right-hand side, we have chosen an orthonormal basis of invariant vectors (intertwiners) in $\mathcal{H}_{j_1\cdots j_n}$ to express the projector. Notice that the assignment of intertwiners to edges is a consequence of the integration over the connection. Using [26] one can write $P_\Delta$ in the general spin foam representation form [4]

$$P_\Delta = \sum_{\{f\}} \prod_{f\in\Delta^*} (2j_f+1) \prod_{v\in\Delta^*} A_v(j_v) \qquad [27]$$

where $A_v(\iota_v, j_v)$ is given by the appropriate trace of the intertwiners corresponding to the edges bounded by the vertex. As in the previous section, this amplitude is given in general by an SU(2) $3Nj$-symbol. When $\Delta$ is a simplicial complex, all the edges in $\Delta^*$ are 3-valent and vertices are 4-valent. Consequently, the vertex amplitude is given by the contraction of the corresponding four 3-valent intertwiners, that is, a $6j$ symbol. In that case, the path integral takes the (Ponzano–Regge) form

$$P_\Delta = \sum_{\{j\}} \prod_{f\in\Delta^*} (2j_f+1) \prod_{v\in\Delta^*} \qquad [28]$$



The labeling of faces that intersect the boundary naturally induces a labeling of the edges of the graphs $\gamma_1$ and $\gamma_2$ induced by the discretization. Thus, the boundary states are given by spin network states on $\gamma_1$ and $\gamma_2$, respectively. A careful analysis of the boundary contribution shows that only the face amplitude is modified to $(\Delta_{j_\ell})^{\nu_f/2}$, and that the spin foam amplitudes are as in eqn [22].

A crucial property of the path integral in 3D gravity (and of the transition amplitudes in general) is that it does not depend on the discretization $\Delta$ – this is due to the absence of local degrees of freedom in 3D gravity and not expected to hold in 4D. Given two different cellular decompositions $\Delta$ and $\Delta'$, one has

$$\tau^{-n_0} P_\Delta = \tau^{-n'_0} P_{\Delta'} \qquad [29]$$

where $n_0$ is the number of 0-simplexes in $\Delta$, and $\tau = \sum_j (2j+1)^2$. As $\tau$ is given by a divergent sum, the discretization independence statement is formal. Moreover, the sum over spins in [28] is typically divergent. Divergences occur due to infinite gauge-volume factors in the path integral corresponding to the topological gauge freedom [7]. Freidel and Louapre have shown how these divergences can be avoided by gauge-fixing unphysical degrees of freedom in [24]. In the case of 3D gravity with positive cosmological constant, the state sum generalizes to the Turaev–Viro invariant (*see* Topological Quantum Field Theory: Overview) defined in terms of the quantum group $\mathrm{SU}_q(2)$ with $q^n = 1$ where the representations are finitely many and thus $\tau < \infty$. Equation [29] is a rigorous statement in that case. No such infrared divergences appear in the canonical treatment of the previous section.

## Spin Foams in 4D

### Spin Foam from the Canonical Formulation

There is no rigorous construction of the physical inner product of LQG in 4D. The spin foam representation as a device for its definition has been introduced formally by Rovelli. In 4D LQG, difficulties in understanding dynamics are centered around the quantum scalar constraint $\widehat{S} = \widehat{\sqrt{\det E}^{-1} E^a_i E^b_j F^{ij}_{ab}(A)} + \cdots$ (see [1]) – the vector constraint $\widehat{V}_a(A, E)$ is solved in a simple manner (*see* Loop Quantum Gravity). The physical inner product formally becomes

$$\langle Ps, s' \rangle_{\mathrm{diff}} = \prod_x \delta[\widehat{S}(x)] = \int D[N] < \exp\left[\mathrm{i}\int_\Sigma N(x)\widehat{S}(x)\right] s, s' >_{\mathrm{diff}} = \int D[N] \sum_{n=0}^{\infty} \frac{i^n}{n!} < \left[\int_\Sigma N(x)\widehat{S}(x)\right]^n s, s' >_{\mathrm{diff}} \qquad [30]$$

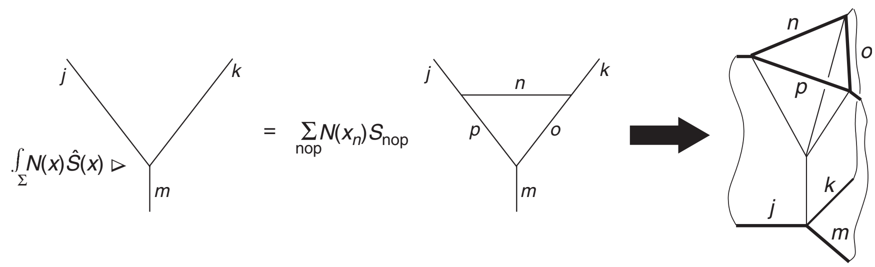


**Figure 11** The action of the scalar constraint and its spin foam representation. $N(x_n)$ is the value of $N$ at the node and $S_{nop}$ are the matrix elements of $\widehat{S}$.

where $< , >_{\text{diff}}$ denotes the inner product in the Hilbert space of solutions of the vector constraint, and the exponential has been expanded in powers in the last expression on the right-hand side.

From early on, it was realized that smooth loop states are naturally annihilated by $\widehat{S}$ (independently of any quantization ambiguity). Consequently, $\widehat{S}$ acts only on spin network nodes. Generically, it does so by creating new links and nodes modifying the underlying graph of the spin network states (**Figure 11**).

Therefore, each term in the sum [30] represents a series of transitions – given by the local action of $\widehat{S}$ at spin network nodes – through different spin network states interpolating the boundary states $s$ and $s'$, respectively. The action of $\widehat{S}$ can be visualized as an "interaction vertex" in the "time" evolution of the node (**Figure 11**). As in the explicit 3D case, eqn [30] can be expressed as sum over "histories" of spin networks pictured as a system of branching surfaces described by a 2-complex whose elements inherit the representation labels on the intermediate states. The value of the "transition" amplitudes is controlled by the matrix elements of $\widehat{S}$. Therefore, although the qualitative picture is independent of quantization ambiguities, transition amplitudes are sensitive to them.

Before even considering the issue of convergence of [30], the problem with this definition is evident: every single term in the sum is a divergent integral! Therefore, this way of presenting spin foams has to be considered as formal until a well-defined regularization of [2] is provided. That is the goal of the spin foam approach.

Instead of dealing with an infinite number of constraints Thiemann recently proposed to impose one single master constraint defined as

$$M = \int_\Sigma \mathrm{d}x^3 \, \frac{S^2(x) - q^{ab} V_a(x) V_b(x)}{\sqrt{\det q(x)}} \qquad [31]$$

Using techniques developed by Thiemann, this constraint can indeed be promoted to a quantum operator acting on $\mathcal{H}_{\text{kin}}$. The physical inner product is given by

$$<s, s'>_{\text{p}} := \lim_{T\to\infty} <s, \int_{-T}^{T} \mathrm{d}t \; \mathrm{e}^{\mathrm{i}t\widehat{M}} s'> \qquad [32]$$

A spin foam representation of the previous expression could now be achieved by the standard skeletonization that leads to the path-integral representation in quantum mechanics. In this context, one splits the $t$-parameter in discrete steps and writes

$$\mathrm{e}^{\mathrm{i}t\widehat{M}} = \lim_{N\to\infty} [\mathrm{e}^{\mathrm{i}t\widehat{M}/N}]^N = \lim_{N\to\infty} [1 + \mathrm{i}t\widehat{M}/N]^N \qquad [33]$$

The spin foam representation follows from the fact that the action of the basic operator $1 + \mathrm{i}t\widehat{M}/N$ on a spin network can be written as a linear combination of new spin networks whose graphs and labels have been modified by the creation of new nodes (in a way qualitatively analogous to the local action shown in **Figure 11**). An explicit derivation of the physical inner product of 4D LQG along these lines is under current investigation.

### Spin Foams from the Covariant Formulation

In 4D, the spin foam representation of the dynamics of LQG has been investigated more intensively in the covariant formulation. This has led to a series of constructions which are referred to as spin foam models. These treatments are related more closely to the construction based on the covariant path-integral approach of the last section. Here we illustrate the formulation which has captured much interest in the literature: the Barrett–Crane (BC) model.

**Spin foam models for gravity as constrained quantum BF theory** The BC model is one of the most extensively studied spin foam models for quantum gravity. To introduce the main ideas involved, we concentrate on the definition of the model in the Riemannian sector. The BC model can be formally

viewed as a spin foam quantization of SO(4) Plebanski's formulation of general relativity. Plebanski's Riemannian action depends on an SO(4) connection $A$, a Lie-algebra-valued 2-form $B$, and Lagrange multiplier fields $\lambda$ and $\mu$. Writing explicitly the Lie algebra indices, the action is given by

$$S[B, A, \lambda, \mu] = \int \left[ B^{IJ} \wedge F_{IJ}(A) + \lambda_{IJKL}\, B^{IJ} \wedge B^{KL} + \mu \epsilon^{IJKL} \lambda_{IJKL} \right] \quad [34]$$

where $\mu$ is a 4-form and $\lambda_{IJKL} = -\lambda_{JIKL} = -\lambda_{IJLK} = \lambda_{KLIJ}$ is a tensor in the internal space. Variation with respect to $\mu$ imposes the constraint $\epsilon^{IJKL}\lambda_{IJKL} = 0$ on $\lambda_{IJKL}$. The Lagrange multiplier tensor $\lambda_{IJKL}$ has then 20 independent components. Variation with respect to $\lambda$ imposes 20 algebraic equations on the 36 components of $B$. The (nondegenerate) solutions to the equations obtained by varying the multipliers $\lambda$ and $\mu$ are

$$B^{IJ} = \pm \epsilon^{IJKL} e_K \wedge e_L$$

and

$$B^{IJ} = \pm e^I \wedge e^J \quad [35]$$

in terms of the 16 remaining degrees of freedom of the tetrad field $e^I_a$. If one substitutes the first solution into the original action, one obtains Palatini's formulation of general relativity; therefore, on shell (and on the right sector), the action is that of classical gravity.

The key idea in the definition of the model is that the path integral for the theory corresponding to the action $S[B, A, 0, 0]$, namely

$$P_{\text{topo}} = \int D[B]D[A] \exp\left[ \mathrm{i} \int \left[ B^{IJ} \wedge F_{IJ}(A) \right] \right] \quad [36]$$

can be given a meaning as a spin foam sum, [4], in terms of a simple generalization of the construction of the previous section. In fact, $S[B, A, 0, 0]$ corresponds to a simple theory known as BF theory that is formally very similar to 3D gravity (*see* BF Theories). The result is independent of the chosen discretization because BF theory does not have local degrees of freedom (just as 3D gravity).

The BC model aims at providing a definition of the path integral of gravity pursuing a well-posed definition of the formal expression

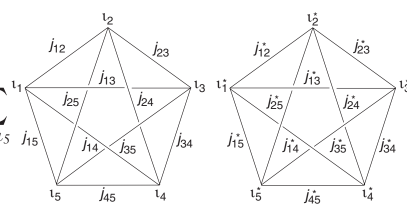
$$P_{\text{GR}} = \int D[B]D[A] \delta\left[ B \to \epsilon^{IJKL} e_K \wedge e_L \right] \times \exp\left[ \mathrm{i} \int \left[ B^{IJ} \wedge F_{IJ}(A) \right] \right] \quad [37]$$

where $D[B]D[A]\delta(B \to \epsilon^{IJKL} e_K \wedge e_L)$ means that one must restrict the sum in [36] to those configurations of the topological theory satisfying the constraints $B = *(e \wedge e)$ for some tetrad $e$. The remarkable fact is that this restriction can be implemented in a systematic way directly on the spin foam configurations that define $P_{\text{topo}}$.

In $P_{\text{topo}}$ spin foams are labeled with spins corresponding to the unitary irreducible representations of SO(4) (given by two spin quantum numbers $(j_{\text{R}}, j_{\text{L}})$). Essentially, the factor "$\delta(B \to \epsilon^{IJKL} e_K \wedge e_L)$" restricts the set of spin foam quantum numbers to the so-called simple representations (for which $j_{\text{R}} = j_{\text{L}} = j$). This is the "quantum" version of the solution to the constraints [35]. There are various versions of this model. The simplest definition of the transition amplitudes in the BC model is given by

$$P(s^* s) = \sum_{\{j\}} \prod_{f \in F_{s \to s'}} (2j_f + 1)^{\nu_f} \prod_{v \in F_{s \to s'}}$$

$$\sum_{\iota_1 \cdots \iota_5} \quad [38]$$



where we use the notation of [22], the graphs denote $15j$-symbols, and $\iota_i$ are half-integers labeling SU(2) normalized 4-intertwiners. No rigorous connection with the Hilbert space picture of LQG has yet been established. The self-dual version of Plebanski's action leads, through a similar construction, to Reisenberger's model.

The simplest amplitude in the BC model corresponds to a single 4-simplex, which can be viewed as the simplest triangulation of the 4D spacetime given by the interior of a 3-sphere (the corresponding 2-complex is shown in Figure 12). States of the 4-simplex are labeled by ten spins $j$ (labeling the ten edges of the boundary spin network, see Figure 12) which can be shown to be related to the area in

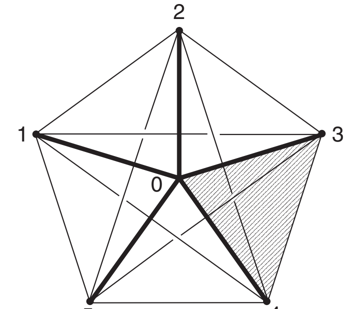


**Figure 12** The dual of a 4-simplex.

Planck units of the ten triangular faces that form the 4-simplex. A first indication of the connection of the model with gravity was that the large-$j$ asymptotics appeared to be dominated by the exponential of the Regge action (the action derived by Regge as a discretization of general relativity). This estimate was done using the stationary-phase approximation to the integral that gives the amplitude of a 4-simplex in the BC model. However, more detailed calculations showed that the amplitude is dominated by configurations corresponding to degenerate 4-simplexes. This seems to invalidate a simple connection to general relativity and is one of the main puzzles in the model.

### Spin Foams as Feynman Diagrams

The main problem with the models of the previous section is that they are defined on a discretization $\Delta$ of $M$ and that – contrary to what happens with a topological theory, for example, 3D gravity (eqn [29]) – the amplitudes depend on the discretization $\Delta$. Various possibilities to eliminate this regulator have been discussed in the literature but no explicit results are yet known in 4D. An interesting proposal is a discretization-independent definition of spin foam models achieved by the introduction of an auxiliary field theory living on an abstract group manifold – $\mathrm{Spin}(4)^4$ and $\mathrm{SL}(2,\mathbb{C})^4$ for Riemannian and Lorentzian gravity, respectively. The action of the auxiliary group field theory (GFT) takes the form

$$S[\phi] = \int_{G^4} \phi^2 + \frac{\lambda}{5!}\int_{G^{10}} M^{(5)}[\phi] \qquad [39]$$

where $M^{(5)}[\phi]$ is a fifth-order monomial, and $G$ is the corresponding group. In the simplest model, $M^{(5)}[\phi] = \phi(g_1, g_2, g_3, g_4)\phi(g_4, g_5, g_6, g_7)\times \phi(g_7, g_3, g_8, g_9)\phi(g_9, g_6, g_2, g_{10})\phi(g_{10}, g_8, g_5, g_1)$. The field $\phi$ is required to be invariant under the (simultaneous) right action of the group on its four arguments in addition to other symmetries (not described here for simplicity). The perturbative expansion in $\lambda$ of the GFT Euclidean path integral is given by

$$P = \int D[\phi]\mathrm{e}^{-S[\phi]} = \sum_{F_N} \frac{\lambda^N}{\mathrm{sym}[F_N]} A[F_N] \qquad [40]$$

where $A[F_N]$ corresponds to a sum of Feynman-diagram amplitudes for diagrams with $N$ interaction vertices, and $\mathrm{sym}[F_N]$ denotes the standard symmetry factor. A remarkable property of this expansion is that $A[F_N]$ can be expressed as a sum over spin foam amplitudes, that is, 2-complexes labeled by unitary irreducible representations of $G$. Moreover, for very simple interaction $M^{(5)}[\phi]$, the spin foam amplitudes are in one-to-one correspondence to those found in the models of the previous section (e.g., the BC model). This duality is regarded as a way of providing a fully combinatorial definition of quantum gravity where no reference to any discretization or even a manifold structure is made. Transition amplitudes between spin network states correspond to $n$-point functions of the field theory. These models have been inspired by generalizations of matrix models applied to BF theory.

Divergent transition amplitudes can arise by the contribution of "loop" diagrams as in standard quantum field theory. In spin foams, diagrams corresponding to 2D bubbles are potentially divergent because spin labels can be arbitrarily high leading to unbounded sums in [4]. Such divergences do not occur in certain field theories dual (in the sense above) to the BC model. However, little is known about the convergence of the series in $\lambda$ and the physical meaning of this constant. Nevertheless, Freidel and Louapre have shown that the series can be re-summed in certain models dual to lower-dimensional theories.

### Causal Spin Foams

Let us conclude by presenting a fundamentally different construction leading to spin foams. Using the kinematical setting of LQG with the assumption of the existence of a microlocal (in the sense of Planck scale) causal structure, Markopoulou and Smolin define a general class of (causal) spin foam models for gravity. The elementary transition amplitude $A_{s_I \to s_{I+1}}$ from an initial spin network $s_I$ to another spin network $s_{I+1}$ is defined by a set of simple combinatorial rules based on a definition of causal propagation of the information at nodes. The rules and amplitudes have to satisfy certain causal restrictions (motivated by the standard concepts in classical Lorentzian physics). These rules generate surface-like excitations of the same kind one encounters in the previous formulations. Spin foams $F^N_{s_i \to s_f}$ are labeled by the number of times, $N$, these elementary transitions take place. Transition amplitudes are defined as

$$\langle s_i, s_f\rangle = \sum_N A(F^N_{s_i \to s_f}) \qquad [41]$$

which is of the generic form [4]. The models are not related to any continuum action. The only guiding principles in the construction are the restrictions imposed by causality, and the requirement of the existence of a nontrivial critical behavior that reproduces general relativity at large scales. Some indirect evidence of a possible nontrivial continuum limit has been obtained in certain versions of these models in $1 + 1$ dimensions.

# Spin Glasses

**F Guerra**, Università di Roma "La Sapienza", Rome, Italy

## Introduction

From a physical point of view, spin glasses, as dilute magnetic alloys, are very interesting systems. They are characterized by such features as exhibiting a new magnetic phase, where magnetic moments are frozen into disordered equilibrium orientations, without any long-range order. See, for example, Young (1987) for general reviews, and also Stein (1989) for a very readable account about the physical properties of spin glasses. The experimental laboratory study of spin glasses is a very difficult subject, because of their peculiar properties. In particular, the existence of very slowly relaxing modes, with consequent memory effects, makes it difficult to realize the very basic physical concept of a system at thermodynamical equilibrium, at a given temperature.

From a theoretical point of view some models have been proposed, which try to capture the essential physical features of spin glasses, in the frame of very simple assumptions.

The basic model has been proposed by Edwards and Anderson (1975) many years ago. It is a simple extension of the well-known nearest-neighbor Ising model. On a large region $\Lambda$ of the unit lattice in $d$ dimensions, we associate an Ising spin $\sigma(n)$ to each lattice site $n$, and then we introduce a lattice Hamiltonian

$$H_\Lambda(\sigma, J) = -\sum_{(n,n')} J(n,n')\sigma(n)\sigma(n') \qquad [1]$$

Here, the sum runs over all couples of nearest-neighbor sites in $\Lambda$, and $J$ are quenched random couplings, assumed for simplicity to be independent identically distributed random variables, with centered unit Gaussian distribution. The quenched character of the $J$ means that they do not contribute to thermodynamic equilibrium, but act as a kind of random external noise on the coupling of the $\sigma$ variables. In the expression of the Hamiltonian, we have indicated with $\sigma$ the set of all $\sigma(n)$, and with $J$ the set of all $J(n,n')$. The region $\Lambda$ must be taken very large, by letting it invade all lattice in the limit. The physical motivation for this choice is that for real spin glasses the interaction between the spins dissolved in the matrix of the alloy oscillates in sign according to distance. This effect is taken into account in the model through the random character of the couplings between spins.

Even though very drastic simplifications have been introduced in the formulation of this model, as compared to the extremely complicated nature of physical spin glasses, nevertheless a rigorous study of all properties emerging from the static and dynamic behavior of a thermodynamic system of this kind is far from being complete. In particular, with reference to static equilibrium properties, it is not yet possible to reach a completely substantiated description of the phases emerging in the low-temperature region. Even physical intuition gives completely different guesses for different people.

In the same way as a mean-field version can be associated to the ordinary Ising model, so it is possible for the disordered model described by [1]. Now we consider a number of sites $i = 1, 2, \ldots, N$, and let each spin $\sigma(i)$ at site $i$ interact with all other spins, with the intervention of a quenched noise $J_{ij}$. The precise form of the Hamiltonian will be given in the following.

This is the mean-field model for spin glasses, introduced by Sherrington and Kirkpatrick (1975).

It is a celebrated model. Numerous articles have been devoted to its study during the years, appearing in the theoretical physics literature.

The relevance of the model stems surely from the fact that it is intended to represent some important features of the physical spin glass systems, of great interest for their peculiar properties, at least at the level of the mean-field approximation.

But another important source of interest is connected with the fact that disordered systems, of the Sherrington–Kirkpatrick type, and their generalizations, seem to play a very important role for theoretical and practical assessments about hard optimization problems, as it is shown, for example, by Mézard *et al.* (2002).

It is interesting to remark that the original paper was entitled "Solvable model of a spin-glass," while a previous draft, as told by David Sherrington, contained the even stronger designation "Exactly solvable." However, it turned out that the very natural solution devised by the authors is valid only at high temperatures, or for large external magnetic fields. At low temperatures, the proposed solution exhibits a nonphysical drawback given by a negative entropy, as properly recognized by the authors in their very first paper.

It took some years to find an acceptable solution. This was done by Giorgio Parisi in a series of papers, marking a radical departure from the previous methods. In fact, a very intense method of "spontaneous replica symmetry breaking" was developed. As a consequence, the physical content of the theory was encoded in a functional order parameter of new type, and a remarkable structure emerged for the pure states of the theory, a kind of hierarchical, ultrametric organization. These very interesting developments, due to Parisi, and his coworkers, are explained in a brilliant way in the classical book by Mézard *et al.* (1987). Part of this structure will be recalled in the following.

It is important to remark that the Parisi solution is presented in the form of an ingenious and clever "ansatz." Until few years ago, it was not known whether this ansatz would give the true solution for the model, in the so-called thermodynamic limit, when the size of the system becomes infinite, or it would be only a very good approximation for the true solution.

The general structures offered by the Parisi solution, and their possible generalizations for similar models, exhibit an extremely rich and interesting mathematical content. Very appropriately, Talagrand (2003) has used a strongly suggestive sentence in the title to his recent book: "Spin glasses: a challenge for mathematicians."

As a matter of fact, how to face this challenge is a very difficult problem. Here we would like to recall the main features of a very powerful method, yet extremely simple in its very essence, based on a comparison and interpolation argument on sets of Gaussian random variables.

The method found its first simple application in Guerra (2001), where it was shown that the Sherrington–Kirkpatrick replica symmetric approximate solution was a rigorous lower bound for the quenched free energy of the system, uniformly in the size. Then, it was possible to reach a long-awaited result (Guerra and Toninelli 2002): the convergence of the free energy density in the thermodynamic limit, by an intermediate step where the quenched free energy was shown to be subadditive in the size of the system.

Moreover, still by interpolation on families of Gaussian random variables, the first mentioned result was extended to give a rigorous proof that the expression given by the Parisi ansatz is also a lower bound for the quenched free energy of the system, uniformly in the size (Guerra 2003). The method gives not only the bound, but also the explicit form of the correction in a complex form. As a recent and very important result, along the task of facing the challenge, Michel Talagrand has been able to dominate these correction terms, showing that they vanish in the thermodynamic limit. This milestone achievement was first announced in a short note, containing only a synthetic sketch of the proof, and then presented with all details in a long paper (Talagrand 2006).

The interpolation method is also at the basis of the far-reaching generalized variational principle proved by Aizenman *et al.* (2003).

In our presentation, we will try to be as self-contained as possible. We will give all definitions, explain the basic structure of the interpolation method, and show how some of the results are obtained. We will concentrate mostly on questions connected with the free energy, its properties of subadditivity, the existence of the infinite-volume limit, and the replica bounds.

For the sake of comparison, and in order to provide a kind of warm-up, we will recall also some features of the standard elementary mean-field model of ferromagnetism, the so-called Curie–Weiss model. We will concentrate also here on the free energy, and systematically exploit elementary comparison and interpolation arguments. This will show the strict analogy between the treatment of the ferromagnetic model and the developments in the mean-field spin glass case. Basic roles will be played in the two cases, but with different expressions, by positivity and convexity properties.

Then, we will consider the problem of connecting results for the mean-field case to the short-range case. An intermediate position is occupied by the so-called diluted models. They can be studied through a generalization of the methods exploited in the mean-field case, as shown, for example, in De Sanctis (2005).

The organization of the paper is as follows. We first introduce the ferromagnetic model and discuss behavior and properties of the free energy in the thermodynamic limit, by emphasizing, in this very elementary case, the comparison and interpolation methods that will be also exploited, in a different context, in the spin glass case.

The basic features of the mean-field spin glass models are discussed next, by introducing all necessary definitions. This is followed by the introduction, for generic Gaussian interactions, of some important formulas, concerning the derivation with respect to the strength of the interaction, and the Gaussian comparison and interpolation method.

We then give simple applications to the mean-field spin glass model, in particular to the existence of the infinite-volume limit of the quenched free energy (Guerra and Toninelli 2002), and to the proof of general variational bounds, by following the useful strategy developed in Aizenman *et al.* (2003).

The main features of the Parisi representation are recalled briefly, and the main theorem concerning the free energy is stated. This is followed by a brief mention of results for diluted models.

We also attack the problem of connecting the results for the mean-field case to the more realistic short-range models.

Finally we provide conclusions and outlook for future foreseen developments.

Our treatment will be as simple as possible, by relying on the basic structural properties, and by describing methods of presumably very long lasting power. The emphasis given to the mean-field case reflects the status of research. After some years from now this review would perhaps be written according to completely different patterns.

## A Warm-up. The Mean-field Ferromagnetic Model: Structure and Results

The mean-field ferromagnetic model is among the simplest models of statistical mechanics. However, it contains very interesting features, in particular a phase transition, characterized by spontaneous magnetization, at low temperatures. We refer to standard textbooks for a full treatment and a complete appreciation of the model in the frame of the theory of ferromagnetism. Here we first consider some properties of the free energy, easily obtained through comparison methods.

The generic configuration of the mean-field ferromagnetic model is defined through Ising spin variables $\sigma_i = \pm 1$, attached to each site $i = 1, 2, \ldots, N$.

The Hamiltonian of the model, in some external field of strength $h$, is given by the mean-field expression

$$H_N(\sigma, h) = -\frac{1}{N}\sum_{(i,j)} \sigma_i\sigma_j - h\sum_i \sigma_i \qquad [2]$$

Here, the first sum extends to all $N(N-1)/2$ site couples, and the second to all sites.

For a given inverse temperature $\beta$, let us now introduce the partition function $Z_N(\beta, h)$ and the free energy per site $f_N(\beta, h)$, according to the well-known definitions

$$Z_N(\beta, h) = \sum_{\sigma_1 \ldots \sigma_N} \exp(-\beta H_N(\sigma, h)) \qquad [3]$$

$$-\beta f_N(\beta, h) = N^{-1} E \log Z_N(\beta, h) \qquad [4]$$

It is also convenient to define the average spin magnetization

$$m = \frac{1}{N}\sum_i \sigma_i \qquad [5]$$

Then, it is immediately seen that the Hamiltonian in [2] can be equivalently written as

$$H_N(\sigma, h) = -\frac{1}{2}Nm^2 - h\sum_i \sigma_i \qquad [6]$$

where an unessential constant term has been neglected. In fact, we have

$$\sum_{(i,j)} \sigma_i\sigma_j = \frac{1}{2}\sum_{i,j;i\neq j} \sigma_i\sigma_j = \frac{1}{2}N^2m^2 - \frac{1}{2}N \qquad [7]$$

where the sum over all couples has been equivalently written as one half the sum over all $i$, $j$ with $i \neq j$, and the diagonal terms with $i = j$ have been added and subtracted out. Notice that they give a constant because $\sigma_i^2 = 1$.

Therefore, the partition function in [3] can be equivalently substituted by the expression

$$Z_N(\beta, h) = \sum_{\sigma_1 \ldots \sigma_N} \exp\left(\frac{1}{2}\beta N m^2\right) \exp\left(\beta h \sum_i \sigma_i\right) \qquad [8]$$

which will be our starting point.

Our interest will be in the $\lim_{N\to\infty} N^{-1} \log Z_N(\beta, h)$. To this purpose, let us establish the important subadditivity property, holding for the splitting of the

large-$N$ system in two smaller systems with $N_1$ and $N_2$ sites, respectively, with $N = N_1 + N_2$,

$$\log Z_N(\beta, h) \leq \log Z_{N_1}(\beta, h) + \log Z_{N_2}(\beta, h) \qquad [9]$$

The proof is very simple. Let us denote, in the most natural way, by $\sigma_1, \ldots, \sigma_{N_1}$ the spin variables for the first subsystem, and by $\sigma_{N_1+1}, \ldots, \sigma_N$ the $N_2$ spin variables of the second subsystem. Introduce also the subsystem magnetizations $m_1$ and $m_2$, by adapting the definition [5] to the smaller systems, in such a way that

$$Nm = N_1 m_1 + N_2 m_2 \qquad [10]$$

Therefore, we see that the large system magnetization $m$ is the linear convex combination of the smaller system ones, according to the obvious

$$m = \frac{N_1}{N} m_1 + \frac{N_2}{N} m_2 \qquad [11]$$

Since the mapping $m \to m^2$ is convex, we also have the general bound, holding for all values of the $\sigma$ variables

$$m^2 \leq \frac{N_1}{N} m_1^2 + \frac{N_2}{N} m_2^2 \qquad [12]$$

Then, it is enough to substitute the inequality in the definition [8] of $Z_N(\beta, h)$, and recognize that we achieve factorization with respect to the two subsystems, and therefore the inequality $Z_N \leq Z_{N_1} Z_{N_2}$. So we have established [9]. From subadditivity, the existence of the limit follows by standard arguments. In fact, we have

$$\lim_{N\to\infty} N^{-1} \log Z_N(\beta, h) = \inf_N N^{-1} \log Z_N(\beta, h) \qquad [13]$$

Now we will calculate explicitly this limit, by introducing an order parameter $M$, a trial function, and an appropriate variational scheme. In order to get a lower bound, we start from the elementary inequality $m^2 \geq 2mM - M^2$, holding for any value of $m$ and $M$. By inserting the inequality in the definition [8] we arrive at a factorization of the sum over $\sigma$'s. The sum can be explicitly calculated, and we arrive immediately to the lower bound, uniform in the size of the system,

$$N^{-1} \log Z_N(\beta, h) \geq \log 2 + \log\cosh \beta(h + M) - \tfrac{1}{2}\beta M^2 \qquad [14]$$

holding for any value of the trial order parameter $M$. Clearly, it is convenient to take the supremum over $M$. Then, we establish the optimal uniform lower bound

$$N^{-1} \log Z_N(\beta, h) \geq \sup_M \left(\log 2 + \log\cosh \beta(h + M) - \tfrac{1}{2}\beta M^2\right) \qquad [15]$$

It is simple to realize that the supremum coincides with the limit as $N \to \infty$. To this purpose we follow the following simple procedure. Let us consider all possible values of the variable $m$. There are $N + 1$ of them, corresponding to any number $K$ of possible spin flips, starting from a given $\sigma$ configuration, $K = 0, 1, \ldots, N$. Let us consider the trivial decomposition of the identity, holding for any $m$,

$$1 = \sum_M \delta_{mM} \qquad [16]$$

where $M$ in the sum runs over the $N + 1$ possible values of $m$, and $\delta$ is Kroneker delta, being equal to 1 if $M = N$, and zero otherwise. Let us now insert [16] in the definition [8] of the partition function inside the sum over $\sigma$'s, and invert the two sums. Because of the forcing $m = M$ given by the $\delta$, we can write $m^2 = 2mM - M^2$ inside the sum. Then if we neglect the $\delta$, by using the trivial $\delta \leq 1$, we have an upper bound, where the sum over $\sigma$'s can be explicitly performed as before. Then it is enough to take the upper bound with respect to $M$, and consider that there are $N + 1$ terms in the now trivial sum over $M$, in order to arrive at the upper bound

$$N^{-1} \log Z_N(\beta, h) \leq \sup_M \left(\log 2 + \log\cosh \beta(h + M) - \tfrac{1}{2}\beta M^2\right) + N^{-1} \log(N + 1) \qquad [17]$$

Therefore, by going to the limit as $N \to \infty$, we can collect all our results in the form of the following theorem giving the full characterization of the thermodynamic limit of the free energy.

**Theorem 1** *For the mean-field ferromagnetic model we have*

$$\lim_{N\to\infty} N^{-1} \log Z_N(\beta, h) = \inf_N N^{-1} \log Z_N(\beta, h) \qquad [18]$$

$$= \sup_M \left(\log 2 + \log\cosh \beta(h + M) - \tfrac{1}{2}\beta M^2\right) \qquad [19]$$

This ends our discussion about the free energy in the ferromagnetic model.

Other properties of the model can be easily established. Introduce the Boltzmann–Gibbs state

$$\omega_N(A) = Z_N^{-1} \sum_{\sigma_1 \ldots \sigma_N} A \exp\left(\frac{1}{2}\beta N m^2\right) \exp\left(\beta h \sum_i \sigma_i\right) \qquad [20]$$

where $A$ is any function of $\sigma_1 \ldots \sigma_N$.

The observable $m(\sigma)$ becomes self-averaging under $\omega_N$, in the infinite-volume limit, in the sense that

$$\lim_{N\to\infty} \omega_N((m - M(\beta, h))^2) = 0 \qquad [21]$$

This property of $m$ is the deep reason for the success of the strategy exploited earlier for the convergence of the free energy. Easy consequences are the following. In the infinite-volume limit, for $h \neq 0$, the Boltzmann–Gibbs state becomes a factor state

$$\lim_{N\to\infty} \omega_N(\sigma_1 \ldots \sigma_s) = M(\beta, h)^s \qquad [22]$$

A phase transition appears in the form of spontaneous magnetization. In fact, while for $h = 0$ and $\beta \leq 1$ we have $M(\beta, h) = 0$, on the other hand, for $\beta > 1$, we have the discontinuity

$$\lim_{h\to 0^+} M(\beta, h) = -\lim_{h\to 0^-} M(\beta, h) \equiv M(\beta) > 0 \qquad [23]$$

Fluctuations can also be easily controlled. In fact, one proves that the rescaled random variable $\sqrt{N}(m - M(\beta, h))$ tends in distribution, under $\omega_N$, to a centered Gaussian with variance given by the susceptibility

$$\chi(\beta, h) \equiv \frac{\partial}{\partial h} M(\beta, h) \equiv \frac{\beta(1 - M^2)}{1 - \beta(1 - M^2)} \qquad [24]$$

Notice that the variance becomes infinite only at the critical point $h = 0, \beta = 1$, where $M = 0$.

Now we are ready to attack the much more difficult spin glass model. But it will be surprising to see that, by following a simple extension of the methods described here, we will arrive at similar results.

## Basic Definitions for the Mean-Field Spin Glass Model

As in the ferromagnetic case, the generic configuration of the mean-field spin glass model is defined through Ising spin variables $\sigma_i = \pm 1$, attached to each site $i = 1, 2, \ldots, N$.

But now there is an external quenched disorder given by the $N(N-1)/2$ independent and identical distributed random variables $J_{ij}$, defined for each pair of sites. For the sake of simplicity, we assume each $J_{ij}$ to be a centered unit Gaussian with averages $E(J_{ij}) = 0, E(J_{ij}^2) = 1$. By quenched disorder we mean that the $J$ have a kind of stochastic external influence on the system, without contributing to the thermal equilibrium.

Now the Hamiltonian of the model, in some external field of strength $h$, is given by the mean-field expression

$$H_N(\sigma, h, J) = -\frac{1}{\sqrt{N}} \sum_{(i,j)} J_{ij}\sigma_i\sigma_j - h \sum_i \sigma_i \qquad [25]$$

Here, the first sum extends to all site pairs, and the second to all sites. Notice the $\sqrt{N}$, necessary to ensure a good thermodynamic behavior to the free energy.

For a given inverse temperature $\beta$, let us now introduce the disorder-dependent partition function $Z_N(\beta, h, J)$ and the quenched average of the free energy per site $f_N(\beta, h)$, according to the definitions

$$Z_N(\beta, h, J) = \sum_{\sigma_1 \ldots \sigma_N} \exp(-\beta H_N(\sigma, h, J)) \qquad [26]$$

$$-\beta f_N(\beta, h) = N^{-1} E \log Z_N(\beta, h, J) \qquad [27]$$

Notice that in [27] the average $E$ with respect to the external noise is made "after" the log is taken. This procedure is called quenched averaging. It represents the physical idea that the external noise does not contribute to the thermal equilibrium. Only the $\sigma$'s are thermalized.

For the sake of simplicity, it is also convenient to write the partition function in the following equivalent form. First of all let us introduce a family of centered Gaussian random variables $\mathcal{K}(\sigma)$, indexed by the configurations $\sigma$, and characterized by the covariances

$$E(\mathcal{K}(\sigma)\mathcal{K}(\sigma')) = q^2(\sigma, \sigma') \qquad [28]$$

where $q(\sigma, \sigma')$ are the overlaps between two generic configurations, defined by

$$q(\sigma, \sigma') = N^{-1} \sum_i \sigma_i \sigma'_i \qquad [29]$$

with the obvious bounds $-1 \leq q(\sigma, \sigma') \leq 1$, and the normalization $q(\sigma, \sigma) = 1$. Then, starting from the definition [25], it is immediately seen that the partition function in [26] can also be written, by neglecting unessential constant terms, in the form

$$Z_N(\beta, h, J) = \sum_{\sigma_1 \ldots \sigma_N} \exp\left(\beta \sqrt{\frac{N}{2}} \mathcal{K}(\sigma)\right) \exp\left(\beta h \sum_i \sigma_i\right) \qquad [30]$$

which will be the starting point of our treatment.

## Basic Formulas of Derivation and Interpolation

We work in the following general setting. Let $U_i$ be a family of centered Gaussian random variables, $i = 1, \ldots, K$, with covariance matrix given by $E(U_i U_j) \equiv S_{ij}$. We treat the index $i$ now as configuration space for some statistical mechanics system, with partition function $Z$ and quenched free energy given by

$$E \log \sum_i w_i \exp(\sqrt{t} U_i) \equiv E \log Z \qquad [31]$$

where $w_i \geq 0$ are generic weights, and $t$ is a parameter ruling the strength of the interaction.

It would be hard to underestimate the relevance of the following derivation formula

$$\frac{\mathrm{d}}{\mathrm{d}t} E \log \sum_i w_i \exp(\sqrt{t} U_i) = \frac{1}{2} E\left( Z^{-1} \sum_i w_i \exp(\sqrt{t} U_i\right) S_{ii} - \frac{1}{2} E\left( Z^{-2} \sum_i \sum_j w_i w_j \exp(\sqrt{t} U_i) \right. \left. \times \exp(\sqrt{t} U_j) S_{ij} \right) \quad [32]$$

The proof is straightforward. First we perform directly the $t$-derivative. Then, we notice that the random variables appear in expressions of the form $E(U_i F)$, where $F$ are functions of the $U$'s. These can be easily handled through the following integration by parts formula for generic Gaussian random variables, strongly reminiscent of the Wick theorem in quantum field theory,

$$E(U_i F) = \sum_j S_{ij} E\left( \frac{\partial}{\partial U_j} F \right) \quad [33]$$

Therefore, we see that always two derivatives are involved. The two terms in [32] come from the action of the $U_j$ derivatives, the first acting on the Boltzmann factor, and giving rise to a Kronecker $\delta_{ij}$, the second acting on $Z^{-1}$, and giving rise to the minus sign and the duplication of variables.

The derivation formula can be expressed in a more compact form by introducing replicas and suitable averages. In fact, let us introduce the state $\omega$ acting on functions $F$ of $i$ as follows

$$\omega(F(i)) = Z^{-1} \sum_i w_i \exp(\sqrt{t} U_i) F(i) \quad [34]$$

together with the associated product state $\Omega$ acting on replicated configuration spaces $i_1, i_2, \ldots, i_s$. By performing also a global $E$ average, finally we define the averages

$$\langle F \rangle_t \equiv E\Omega(F) \quad [35]$$

where the subscript is introduced in order to recall the $t$ dependence of these averages.

Then, eqn [32] can be written in a more compact form

$$\frac{\mathrm{d}}{\mathrm{d}t} E \log \sum_i w_i \exp(\sqrt{t} U_i) = \tfrac{1}{2} \langle S_{i_1 i_1} \rangle - \tfrac{1}{2} \langle S_{i_1 i_2} \rangle \quad [36]$$

Our basic comparison argument will be based on the following very simple theorem.

**Theorem 2** *Let $U_i$ and $\hat{U}_i$, for $i = 1, \ldots, K$, be independent families of centered Gaussian random variables, whose covariances satisfy the inequalities for generic configurations*

$$E(U_i U_j) \equiv S_{ij} \geq E(\hat{U}_i \hat{U}_j) \equiv \hat{S}_{ij} \quad [37]$$

*and the equalities along the diagonal*

$$E(U_i U_i) \equiv S_{ii} = E(\hat{U}_i \hat{U}_i) \equiv \hat{S}_{ii} \quad [38]$$

*then for the quenched averages we have the inequality in the opposite sense*

$$E \log \sum_i w_i \exp(U_i) \leq E \log \sum_i w_i \exp(\hat{U}_i) \quad [39]$$

*where the $w_i \geq 0$ are the same in the two expressions.*

Considerations of this kind are present in the mathematical literature, as mentioned, for example, in Talagrand (2003).

The proof is extremely simple and amounts to a straightforward calculation. In fact, let us consider the interpolating expression

$$E \log \sum_i w_i \exp(\sqrt{t} U_i + \sqrt{1-t} \hat{U}_i) \quad [40]$$

where $0 \leq t \leq 1$. Clearly, the two expressions under comparison correspond to the values $t = 0$ and $t = 1$, respectively. By taking the derivative with respect to $t$, with the help of the previous derivation formula, we arrive at the evaluation of the $t$ derivative in the form

$$\frac{\mathrm{d}}{\mathrm{d}t} E \log \sum_i w_i \exp(\sqrt{t} U_i + \sqrt{1-t} \hat{U}_i) = \frac{1}{2} E\left( Z^{-1} \sum_i w_i \exp(\sqrt{t} U_i)(S_{ii} - \hat{S}_{ii} \right) - \frac{1}{2} E\left( Z^{-2} \sum_i \sum_j w_i w_j \exp(\sqrt{t} U_i) \right. \left. \times \exp(\sqrt{t} U_j)(S_{ij} - \hat{S}_{ij} \right) \quad [41]$$

From the conditions assumed for the covariances, we immediately see that the interpolating function is nonincreasing in $t$, and the theorem follows.

The derivation formula and the comparison theorem are not restricted to the Gaussian case. Generalizations in many directions are possible. For the diluted spin glass models and optimization problems we refer, for example, to Franz and Leone (2003), and to De Sanctis (2005), and references therein.

## Thermodynamic Limit and the Variational Bounds

We give here some striking applications of the basic comparison theorem. Guerra and Toninelli (2002) have given a very simple proof of a long-awaited result, about the convergence of the free energy per site in the thermodynamic limit. Let us show the argument. Let us consider a system of size $N$ and two smaller systems of sizes $N_1$ and $N_2$ respectively, with $N = N_1 + N_2$, as before in the ferromagnetic case. Let us now compare

$$E \log Z_N(\beta, h, J) = E \log \sum_{\sigma_1 \ldots \sigma_N} \exp\left(\beta \sqrt{\frac{N}{2}} \mathcal{K}(\sigma)\right) \times \exp\left(\beta h \sum_i \sigma_i\right) \qquad [42]$$

with

$$E \log \sum_{\sigma_1 \ldots \sigma_N} \exp\left(\beta \sqrt{\frac{N_1}{2}} \mathcal{K}^{(1)}(\sigma^{(1)})\right) \times \exp\left(\beta \sqrt{\frac{N_2}{2}} \mathcal{K}^{(2)}(\sigma^{(2)})\right) \exp\left(\beta h \sum_i \sigma_i\right) \equiv E \log Z_{N_1}(\beta, h, J) + E \log Z_{N_2}(\beta, h, J) \qquad [43]$$

where $\sigma^{(1)}$ stands for $\sigma_i, i = 1, \ldots, N_1$, and $\sigma^{(2)}$ for $\sigma_i, i = N_1 + 1, \ldots, N$. Covariances for $\mathcal{K}^{(1)}$ and $\mathcal{K}^{(2)}$ are expressed as in [28], but now the overlaps are substituted with the partial overlaps of the first and second block, $q_1$ and $q_2$, respectively. It is very simple to apply the comparison theorem. All one has to do is to observe that the obvious

$$Nq = N_1 q_1 + N_2 q_2 \qquad [44]$$

analogous to [10], implies, as in [12],

$$q^2 \le \frac{N_1}{N} q_1^2 + \frac{N_2}{N} q_2^2 \qquad [45]$$

Therefore, the comparison gives the superaddivity property, to be compared with [9],

$$E \log Z_N(\beta, h, J) \ge E \log Z_{N_1}(\beta, h, J) + E \log Z_{N_2}(\beta, h, J) \qquad [46]$$

From the superaddivity property the existence of the limit follows in the form

$$\lim_{N\to\infty} N^{-1} E \log Z_N(\beta, h, J) = \sup_N N^{-1} E \log Z_N(\beta, h, J) \qquad [47]$$

to be compared with [13].

The second application is in the form of the Aizenman–Sims–Starr generalized variational principle. Here, we will need to introduce some auxiliary system. The denumerable configuration space is given by the values of $\alpha = 1, 2, \ldots$. We introduce also weights $w_\alpha \ge 0$ for the $\alpha$ system, and suitably defined overlaps between two generic configurations $p(\alpha, \alpha')$, with $p(\alpha, \alpha) = 1$.

A family of centered Gaussian random variables $\hat{\mathcal{K}}(\alpha)$, now indexed by the configurations $\alpha$, will be defined by the covariances

$$E(\hat{\mathcal{K}}(\alpha)\hat{\mathcal{K}}(\alpha')) = p^2(\alpha, \alpha') \qquad [48]$$

We will also need a family of centered Gaussian random variables $\eta_i(\alpha)$, indexed by the sites $i$ of our original system and the configurations $\alpha$ of the auxiliary system, so that

$$E(\eta_i(\alpha)\eta_{i'}(\alpha')) = \delta_{ii'} p(\alpha, \alpha') \qquad [49]$$

Both the probability measure $w_\alpha$, and the overlaps $p(\alpha, \alpha')$ could depend on some additional external quenched noise, which does not appear explicitly in our notation.

In the following, we will denote by $E$ averages with respect to all random variables involved.

In order to start the comparison argument, we will consider first the case where the two $\sigma$ and $\alpha$ systems are not coupled, so as to appear factorized in the form

$$E \log \sum_{\sigma_1 \ldots \sigma_N} \sum_\alpha w_\alpha \exp\left(\beta \sqrt{\frac{N}{2}} \mathcal{K}(\sigma)\right) \times \exp\left(\beta \sqrt{\frac{N}{2}} \hat{\mathcal{K}}(\alpha)\right) \exp\left(\beta h \sum_i \sigma_i\right) \equiv E \log Z_N(\beta, h, J) + E \log \sum_\alpha w_\alpha \times \exp\left(\beta \sqrt{\frac{N}{2}} \hat{\mathcal{K}}(\alpha)\right) \qquad [50]$$

In the second case, the $\mathcal{K}$ fields are suppressed and the coupling between the two systems will be taken in a very simple form, by allowing the $\eta$ field to act as an external field on the $\sigma$ system. In this way the $\sigma$'s appear as factorized, and the sums can be explicitly performed. The chosen form for the second term in the comparison is

$$E \log \sum_{\sigma_1 \ldots \sigma_N} \sum_\alpha w_\alpha \exp\left(\beta \sum_i \eta_i(\alpha)\sigma_i\right) \exp\left(\beta h \sum_i \sigma_i\right) \equiv N \log 2 + E \log \sum_\alpha w_\alpha (c_1 c_2 \ldots c_N) \qquad [51]$$

where we have defined

$$c_i = \cosh\beta(h + \eta_i(\alpha)) \qquad [52]$$

as arising from the sums over $\sigma$'s.

Now we apply the comparison theorem. In the first case, the covariances involve the sums of squares of overlaps

$$\tfrac{1}{2}(q^2(\sigma,\sigma') + p^2(\alpha,\alpha')) \qquad [53]$$

In the second case, a very simple calculation shows that the covariances involve the overlap products

$$q(\sigma,\sigma')p(\alpha,\alpha'\prime) \qquad [54]$$

Therefore, the comparison is very easy and, by collecting all expressions, we end up with the useful estimate, as in Aizenman *et al.* (2003), holding for any auxiliary system as defined before,

$$\begin{aligned} &N^{-1}E\log Z_N(\beta,h,J) \\ &\quad\le \log 2 + N^{-1}\left(E\log\sum_\alpha w_\alpha(c_1c_2\cdots c_N)\right. \\ &\qquad \left. - E\log\sum_\alpha w_\alpha \exp\left(\beta\sqrt{\frac{N}{2}}\hat{\mathcal{K}}(\alpha)\right)\right) \end{aligned} \qquad [55]$$

## The Parisi Representation for the Free Energy

We refer to the original papers, reprinted in the extensive review given in Mézard *et al.* (2002), for the general motivations, and the derivation of the broken replica ansatz, in the frame of the ingenious replica trick. Here, we limit ourselves to a synthetic description of its general structure, independently from the replica trick.

First of all, let us introduce the convex space $\mathcal{X}$ of the functional order parameters $x$, as nondecreasing functions of the auxiliary variable $q$, both $x$ and $q$ taking values on the interval $[0,1]$, that is,

$$\mathcal{X} \ni x : [0,1] \ni q \to x(q) \in [0,1] \qquad [56]$$

Notice that we call $x$ the function, and $x(q)$ its values. We introduce a metric on $\mathcal{X}$ through the $L^1([0,1], \mathrm{d}q)$-norm, where $\mathrm{d}q$ is the Lebesgue measure.

For our purposes, we will consider the case of piecewise constant functional order parameters, characterized by an integer $K$, and two sequences $q_0, q_1, \ldots, q_K, m_1, m_2, \ldots, m_K$ of numbers satisfying

$$\begin{aligned} 0 = q_0 \le q_1 \le \cdots \le q_{K-1} \le q_K = 1 \\ 0 \le m_1 \le m_2 \le \cdots \le m_K \le 1 \end{aligned} \qquad [57]$$

such that

$$\begin{aligned} &x(q) = m_1 \quad \text{for } 0 = q_0 \le q < q_1 \\ &x(q) = m_2 \quad \text{for } q_1 \le q < q_2 \\ &\vdots \\ &x(q) = m_K \quad \text{for } q_{K-1} \le q \le q_K \end{aligned} \qquad [58]$$

In the following, we will find it convenient to define also $m_0 \equiv 0$, and $m_{K+1} \equiv 1$. The replica symmetric case of Sherrington and Kirkpatrick corresponds to

$$K = 2, \quad q_1 = \bar{q}, \quad m_1 = 0, \quad m_2 = 1 \qquad [59]$$

Let us now introduce the function $f$, with values $f(q,y;x,\beta)$, of the variables $q \in [0,1], y \in R$, depending also on the functional order parameter $x$, and on the inverse temperature $\beta$, defined as the solution of the nonlinear antiparabolic equation

$$\begin{aligned} &(\partial_q f)(q,y) + \tfrac{1}{2}(\partial_y^2 f)(q,y) \\ &\qquad + \tfrac{1}{2}x(q)(\partial_y f)^2(q,y) = 0 \end{aligned} \qquad [60]$$

with final condition

$$f(1,y) = \log\cosh(\beta y) \qquad [61]$$

Here, we have stressed only the dependence of $f$ on $q$ and $y$.

It is very simple to integrate eqn [60] when $x$ is piecewise constant. In fact, consider $x(q) = m_a$, for $q_{a-1} \le q \le q_a$, firstly with $m_a > 0$. Then, it is immediately seen that the correct solution of eqn [60] in this interval, with the right final boundary condition at $q = q_a$, is given by

$$\begin{aligned} &f(q,y) \\ &= \frac{1}{m_a}\log\int \exp(m_a f(q_a, y + z\sqrt{q_a - q}))\,\mathrm{d}\mu(z) \end{aligned} \qquad [62]$$

where $\mathrm{d}\mu(z)$ is the centered unit Gaussian measure on the real line. On the other hand, if $m_a = 0$, then [60] loses the nonlinear part and the solution is given by

$$f(q,y) = \int f(q_a, y + z\sqrt{q_a - q})\,\mathrm{d}\mu(z) \qquad [63]$$

which can be seen also as deriving from [62] in the limit $m_a \to 0$. Starting from the last interval $K$, and using [62] iteratively on each interval, we easily get the solution of [60], [61], in the case of piecewise order parameter $x$, as in [58], through a chain of interconnected Gaussian integrations.

Now, we introduce the following important definitions. The trial auxiliary function, associated to a given mean-field spin glass system, as described

earlier, depending on the functional order parameter $x$, is defined as

$$\log 2 + f(0, h; x, \beta) - \frac{\beta^2}{2}\int_0^1 q\, x(q)\, \mathrm{d}q \qquad [64]$$

Notice that in this expression the function $f$ appears evaluated at $q = 0$, and $y = h$, where $h$ is the value of the external magnetic field. This trial expression shoul be considered as the analog of that appearing in [14] for the ferromagnetic case.

The Parisi spontaneously broken replica symmetry expression for the free energy is given by the definition

$$-\beta f_P(\beta, h) \equiv \inf_x \left(\log 2 + f(0, h; x, \beta) - \frac{\beta^2}{2}\int_0^1 q\, x(q)\, \mathrm{d}q\right) \qquad [65]$$

where the infimum is taken with respect to all functional order parameters $x$. Notice that the infimum appears here, as compared to the supremum in the ferromagnetic case.

By exploiting a kind of generalized comparison argument, involving a suitably defined interpolation function, Guerra (2003) has established the following important result.

**Theorem 3** *For all values of the inverse temperature* $\beta$, *and the external magnetic field* $h$, *and for any functional order parameter* $x$, *the following bound holds*:

$$N^{-1} E \log Z_N(\beta, h, J) \le \log 2 + f(0, h; x, \beta) - \frac{\beta^2}{2}\int_0^1 q\, x(q)\, \mathrm{d}q$$

*uniformly in* $N$. *Consequently, we have also*

$$N^{-1} E \log Z_N(\beta, h, J) \le \inf_x \left(\log 2 + f(0, h; x, \beta) - \frac{\beta^2}{2}\int_0^1 q\, x(q)\, \mathrm{d}q\right)$$

*uniformly in* $N$.

However, this result can also be understood in the framework of the generalized variational principle established by Aizenman–Sims–Starr as described earlier.

In fact, one can easily show that there exist $\alpha$ systems such that

$$N^{-1} E \log \sum_\alpha w_\alpha c_1 c_2 \ldots c_N \equiv f(0, h; x, \beta) \qquad [66]$$

$$N^{-1} E \log \sum_\alpha w_\alpha \exp\left(\beta \sqrt{\frac{N}{2}} \hat{\mathcal{K}}(\alpha)\right) \equiv \frac{\beta^2}{2}\int_0^1 q\, x(q)\, \mathrm{d}q \qquad [67]$$

uniformly in $N$. This result stems from earlier work of Derrida, Ruelle, Neveu, Bolthausen, Sznitman, Aizenman, Contucci, Talagrand, Bovier, and others, and in a sense is implicit in the treatment given in Mézard *et al.* (1987). It can be reached in a very simple way. Let us sketch the argument.

First of all, let us consider the Poisson point process $y_1 \ge y_2 \ge y_3 \ldots$, uniquely characterized by the following conditions. For any interval $A$, introduce the occupation numbers $N(A)$, defined by

$$N(A) = \sum_\alpha \chi(y_\alpha \in A) \qquad [68]$$

where $\chi(\,) = 1$, if the random variable $y_\alpha$ belongs to the interval $A$, and $\chi(\,) = 0$, otherwise. We assume that $N(A)$ and $N(B)$ are independent if the intervals $A$ and $B$ are disjoint, and moreover that for each $A$, the random variable $N(A)$ has a Poisson distribution with parameter

$$\mu(A) = \int_a^b \exp(-y)\, \mathrm{d}y \qquad [69]$$

if $A$ is the interval $(a, b)$, that is,

$$P(N(A) = k) = \exp(-\mu(A))\mu(A)^k / k! \qquad [70]$$

We will exploit $-y_\alpha$ as energy levels for a statistical mechanics system with configurations indexed by $\alpha$. For a parameter $0 < m < 1$, playing the role of inverse temperature, we can introduce the partition function

$$v = \sum_\alpha \exp\left(\frac{y_\alpha}{m}\right) \qquad [71]$$

For $m$ in the given interval it turns out that $v$ is a very well defined random variable, with the sum over $\alpha$ extending to infinity. In fact, there is a strong inbuilt smooth cutoff in the very definition of the stochastic energy levels.

From the general properties of Poisson point processes, it is very well known that the following basic invariance property holds. Introduce a random variable $b$, independent of $y$, subject to the condition $E(\exp b) = 1$, and let $b_\alpha$ be independent copies. Then, the randomly biased point process $y'_\alpha = y_\alpha + b_\alpha$, $\alpha = 1, 2, \ldots$, is equivalent to the original one in distribution. An immediate consequence is the following. Let $f$ be a random variable, independent of $y$, such that $E(\exp f) < \infty$, and let $f_\alpha$ be independent copies. Then, the two random variables

$$\sum_\alpha \exp\left(\frac{y_\alpha}{m}\right) \exp(f_\alpha) \qquad [72]$$

$$\sum_\alpha \exp\left(\frac{y_\alpha}{m}\right) E(\exp(mf))^{1/m} \qquad [73]$$

have the same distribution. In particular, they can be freely substituted under averages.

The auxiliary system which gives rise to the Parisi representation according to [66] and [67], for a piecewise constant order parameter, is expressed in the following way. Now $\alpha$ will be a multi-index $\alpha = (\alpha_1, \alpha_2, \ldots, \alpha_K)$, where each $\alpha_a$ runs on $1, 2, 3, \ldots$. Define the Poisson point process $y_{\alpha_1}$, then, independently, for each value of $\alpha_1$ processes $y_{\alpha_1\alpha_2}$, and so on up to $y_{\alpha_1\alpha_2\ldots\alpha_K}$. Notice that in the cascade of independent processes $y_{\alpha_1}, y_{\alpha_1\alpha_2}, \ldots, y_{\alpha_1\alpha_2\ldots\alpha_K}$, the last index refers to the numbering of the various points of the process, while the first indices denote independent copies labeled by the corresponding $\alpha$'s.

The weights $w_\alpha$ have to be chosen according to the definition

$$w_\alpha = \exp\frac{y_{\alpha_1}}{m_1}\exp\frac{y_{\alpha_1\alpha_2}}{m_2}\ldots\exp\frac{y_{\alpha_1\alpha_2\ldots\alpha_K}}{m_K} \qquad [74]$$

The cavity fields $\eta$ and $\mathcal{K}$ have the following expression in terms of independent unit Gaussian random variables $J^i_{\alpha_1}, J^i_{\alpha_1\alpha_2}, \ldots, J^i_{\alpha_1\alpha_2\ldots\alpha_K}, J'_{\alpha_1}, J'_{\alpha_1\alpha_2}, \ldots, J'_{\alpha_1\alpha_2\ldots\alpha_K}$,

$$\eta_i(\alpha) = \sqrt{q_1 - q_0}\,J^i_{\alpha_1} + \sqrt{q_2 - q_1}\,J^i_{\alpha_1\alpha_2} + \cdots + \sqrt{q_K - q_{K-1}}\,J^i_{\alpha_1\alpha_2\ldots\alpha_K} \qquad [75]$$

$$\mathcal{K}(\alpha) = \sqrt{q_1^2 - q_0^2}\,J'_{\alpha_1} + \sqrt{q_2^2 - q_1^2}\,J'_{\alpha_1\alpha_2} + \cdots + \sqrt{q_K^2 - q_{K-1}^2}\,J'_{\alpha_1\alpha_2\ldots\alpha_K} \qquad [76]$$

It is immediate to verify that $E(\eta_i(\alpha)\eta_{i'}(\alpha'))$ is zero if $i \neq i'$, while

$$E(\eta_i(\alpha)\eta_i(\alpha')) = \begin{cases} 0 & \text{if } \alpha_1 \neq \alpha'_1 \\ q_1 & \text{if } \alpha_1 = \alpha'_1, \alpha_2 \neq \alpha'_2 \\ q_2 & \text{if } \alpha_1 = \alpha'_1, \alpha_2 = \alpha'_2, \alpha_3 \neq \alpha'_3, \\ \vdots & \\ 1 & \text{if } \alpha_1 = \alpha'_1, \alpha_2 = \alpha'_2, \ldots, \\ & \alpha_K = \alpha'_K \end{cases} \qquad [77]$$

Similarly, we have

$$E(\mathcal{K}(\alpha)\mathcal{K}(\alpha')) = \begin{cases} 0 & \text{if } \alpha_1 \neq \alpha'_1 \\ q_1^2 & \text{if } \alpha_1 = \alpha'_1, \alpha_2 \neq \alpha'_2 \\ q_2^2 & \text{if } \alpha_1 = \alpha'_1, \alpha_2 = \alpha'_2, \alpha_3 \neq \alpha'_3, \\ \vdots & \\ 1 & \text{if } \alpha_1 = \alpha'_1, \alpha_2 = \alpha'_2, \ldots, \\ & \alpha_K = \alpha'_K \end{cases} \qquad [78]$$

This ends the definition of the $\alpha$ system, associated to a given piecewise constant order parameter.

Now, it is simple to verify that [66] and [67] hold. Let us consider, for example, [66]. With the $\alpha$ system chosen as before, the repeated application of the stochastic equivalence of [72] and [73] will give rise to a sequence of interchained Gaussian integrations exactly equivalent to those arising from the expression for $f$, as solution of the eqn [60]. For [73], there are equivalent considerations.

Therefore, we see that the estimate in Theorem 3 is also a consequence of the generalized variational principle.

Up to this point we have seen how to obtain upper bounds. The problem arises whether, as in the ferromagnetic case, we can also get lower bounds, so as to shrink the thermodynamic limit to the value given by the $\inf_x$ in Theorem 3. After a short announcement, Talagrand (2005) has firmly established the complete proof of the control of the lower bound. We refer to the original paper for the complete details of this remarkable achievement. About the methods, here we only recall that in Guerra (2003) we have given also the corrections to the bounds appearing in Theorem 3, albeit in a quite complicated form. Talagrand has been able to establish that these corrections do in fact vanish in the thermodynamic limit.

In conclusion, we can establish the following extension of Theorem 1 to spin glasses.

**Theorem 4** *For the mean-field spin glass model we have*

$$\lim_{N\to\infty} N^{-1} E \log Z_N(\beta, h, J) = \sup_N N^{-1} E \log Z_N(\beta, h, J) \qquad [79]$$

$$= \inf_x \left( \log 2 + f(0, h; x, \beta) - \frac{\beta^2}{2}\int_0^1 q x(q)\, dq \right) \qquad [80]$$

## Diluted Models

Diluted models, in a sense, play a role intermediate between the mean-field case and the short-range case. In fact, while in the mean-field model each site is interacting with all other sites, on the other hand, in the diluted model, each site is interacting with only a fixed number of other sites. However, while for the short-range models there is a definition of distance among sites, relevant for the interaction, no such definition appears in the diluted models, where all sites are in any case equivalent. From this point of view, the diluted models are structurally similar to the mean-field models, and most of the

techniques and results explained before can be extended to them.

Let us define a typical diluted model. The quenched noise is described as follows. Let $K$ be a Poisson random variable with parameter $\alpha N$, where $N$ is the number of sites, and $\alpha$ is a parameter entering the theory, together with the temperature. We consider also a sequence of independent centered random variables $J_1, J_2, \ldots$, and a sequence of discrete independent random variables $i_1, j_1, i_2, j_2, \ldots$, uniformly distributed over the set of sites $1, 2, \ldots, N$. Then we assume as Hamiltonian

$$H_N(\sigma) = -\sum_{k=0}^{K} J_k \sigma_{i_k} \sigma_{j_k} \qquad [81]$$

Only the variables $\sigma$ contribute to thermodynamic equilibrium. All noise coming from $K, J_k, i_k, j_k$ is considered quenched, and it is not explicitly indicated in our notation for $H$.

The role played by Gaussian integration by parts in the Sherrington–Kirckpatrick model, here is assumed by the following elementary derivation formula, holding for Poisson distributions,

$$\begin{aligned} \frac{\mathrm{d}}{\mathrm{d}t} P(K = k, t\alpha N) &\equiv \frac{\mathrm{d}}{\mathrm{d}t} \exp(-t\alpha N)(t\alpha N)^k / k! \\ &= \alpha N (P(K = k-1, t\alpha N) \\ &\quad - P(K = k, t\alpha N)) \end{aligned} \qquad [82]$$

Then, all machinery of interpolation can be easily extended to the diluted models, as firstly recognized by Franz and Leone in (2003).

In this way, the superaddivity property, the thermodynamic limit, and the generalized variational principle can be easily established. We refer to Franz and Leone (2003), and De Sanctis (2005), for a complete treatment.

There is an important open problem here. While in the fully connected case, the Poisson probability cascades provide the right auxiliary $\alpha$ systems to be exploited in the variational principle, on the other hand in the diluted case more complicated probability cascades have been proposed, as shown, for example, in Franz and Leone (2003), and in Panchenko and Talagrand (2004). On the other hand, in De Sanctis (2005), the very interesting proposal has been made that also in the case of diluted models the Poisson probability cascades play a very important role. Of course, here the auxiliary system interacts with the original system differently, and involves a multi-overlap structure as explained in De Sanctis (2005). In this way a kind of very deep universality is emerging. Poisson probability cascades are a kind of universal class of auxiliary systems. The different models require different cavity fields ruling the interaction between the original system and the auxiliary system. But further work will be necessary in order to clarify this very important issue. For results about diluted models in the high-temperature region, we refer to Guerra and Toninelli (2004).

## Short-Range Model and Its Connections with the Mean-Field Version

The investigations of the connections between the short-range version of the model and its mean-field version are at the beginning. Here, we limit ourselves to a synthetic description of what should be done, and to a short presentation of the results obtained so far.

First of all, according to the conventional wisdom, the mean-field version should be a kind of limit of the short-range model on a lattice in dimension $d$, when $d \to \infty$, with a proper rescaling of the strength of the Hamiltonian, of the form $d^{-1/2}$. Results of this kind are very well known in the ferromagnetic case, but the present technology of interpolation does not seem sufficient to assure a proof in the spin glass case. So, this very basic result is still missing. In analogy with the ferromagnetic case, it would be necessary to arrive at the notion of a critical dimension, beyond which the features of the mean-field case still hold, for example, in the expression of the critical exponents and in the ultrametric hierarchical structure of the pure phases, or at least for the overlap distributions. For physical dimensions less than the critical one, the short-range model would need corrections with respect to its mean-field version. Therefore, this is a completely open problem.

Moreover, always according to the conventional wisdom, the mean-field version should be a kind of limit of the short-range models, in finite fixed dimensions, as the range of the interaction goes to infinity, with proper rescaling. Important work of Franz and Toninelli shows that this is effectively the case, if a properly defined Kac limit is performed. Here, interpolation methods are effective, and we refer to Franz and Toninelli (2004), and references quoted there, for full details.

Due to the lack of efficient analytical methods, it is clear that numerical simulations play a very important role in the study of the physical properties emerging from short-range spin glass models. In particular, we refer to Marinari *et al.* (2000) for a detailed account of the evidence, coming from theoretical considerations and extensive computer simulations, that some of the more relevant features of the spontaneous replica breaking scheme of the mean field are also present in

short-range models in three dimensions. Different views are expressed, for example, in Newman and Stein (1998), where it is argued that the phase-space structure of short-range spin glass models is much simpler than that foreseen by the Parisi spontaneous replica symmetry mechanism.

Such very different views, both apparently strongly supported by reasonable theoretical considerations and powerful numerical simulations, are a natural consequence of the extraordinary difficulty of the problem.

It is clear that extensive additional work will be necessary before the clarification of the physical features exhibited by the realistic short-range spin glass models.

## Conclusion and Outlook for Future Developments

As we have seen, in these last few years, there has been an impressive progress in the understanding of the mathematical structure of spin glass models, mainly due to the systematic exploration of comparison and interpolation methods. However, many important problems are still open. The most important one is to establish rigorously the full hierarchical ultrametric organization of the overlap distributions, as appears in Parisi theory, and to fully understand the decomposition in pure states of the glassy phase, at low temperatures.

Moreover, it would be important to extend these methods to other important disordered models as, for example, neural networks. Here the difficulty is that the positivity arguments, so essential in comparison methods, do not seem to emerge naturally inside the structure of the theory.

Finally, the problem of connecting properties of the short-range model, with those arising in the mean-field case, is still almost completely open.

## Acknowledgment

We gratefully acknowledge useful conversations with Michael Aizenman, Pierluigi Contucci, Giorgio Parisi, and Michel Talagrand. The strategy explained in this report grew out from a systematic exploration of comparison and interpolation methods, developed in collaboration with Fabio Lucio Toninelli, and Luca De Sanctis.

This work was supported in part by MIUR (Italian Ministry of Instruction, University and Research), and by INFN (Italian National Institute for Nuclear Physics).

# Spinors and Spin Coefficients

**K P Tod**, University of Oxford, Oxford, UK

## Introduction

Spinors were invented by the mathematician E Cartan (see, e.g., Cartan (1981)) in the early years of the last century in the course of his study of rotation groups. The physicist Pauli reinvented what Cartan would have called the spinors of SU(2), which is the double cover of the rotation group SO(3), in order to explain the spectroscopy of alkali atoms and the anomalous Zeeman effect. For this, he needed an essential two-valuedness of the electron, an internal quantum number to contribute to the angular momentum, which is now called spin. Now the wave function becomes a two-component column vector. It is worth noting that, despite the name, Pauli resisted the picture of an electron as a spinning "thing" on the grounds that, as a representation of SU(2) which was not a representation of SO(3), it should have no classical kinematic model, which a spinning object would have.

According to the review article of van der Waerden (1960), the term "spinor" is due to Ehrenfest in 1929, and was introduced in the flurry of interest after the next important step in the evolution of spinors in the physics literature, which was the introduction of a relativistic equation for the electron by Dirac (1928).

Dirac sought a linear, first-order but Lorentz-invariant equation for the electron which was to be the square root of the linear, Lorentz-invariant but second-order Klein–Gordon equation. He assumed the equation for the wave function $\psi$ would take the form

$$L\psi := (\mathrm{i}\gamma^a p_a + mcI)\psi = 0 \qquad [1]$$

where $p_a = -\mathrm{i}\hbar\partial/\partial x^a$ for $a = 0, 1, 2, 3$, but where $\gamma^a$ are complex square matrices, of a size to be determined, and $I$ is the corresponding identity matrix. Differentiating [1] again, one obtains the Klein–Gordon equation for $\psi$ provided these matrices satisfy the equation

$$\gamma^a\gamma^b + \gamma^b\gamma^a = 2\eta^{ab}I \qquad [2]$$

where $\eta^{ab}$ is the Minkowski metric, diag(1, −1, −1, −1).

Assuming the $\gamma^a$ have been found, the usual substitution $p \to p - \mathrm{i}eA$, for a particle in a magnetic field with vector potential $A$, leads to the correct magnetic moment for the electron, so that this equation does describe an electron with spin in the form made familiar by Pauli.

To decide on the size of the matrices $\gamma^a$ and therefore the dimension of the space of $\psi$'s, one notices, with the aid of [2], that the following are a basis for the algebra generated by the $\gamma^a$:

$$1, \gamma^a, \gamma^{[a}\gamma^{b]}, \gamma^{[a}\gamma^b\gamma^{c]}, \gamma^{[a}\gamma^b\gamma^c\gamma^{d]} \qquad [3]$$

There are 16 elements in this basis, assuming that there are no extra identities among them, so that we might hope to find a representation as $4 \times 4$ matrices. This can be done, and Dirac gave explicit formulas in terms of Pauli matrices. The space of Dirac spinors is now a complex four-dimensional vector space, which turns out to split as the sum of a complex two-dimensional vector space $S$, which is referred to as a spin space, and its complex conjugate $\bar{S}$ (the relationship between a complex vector space and its complex conjugate is described in the text below and eqn [9]). Under proper, orthochronous Lorentz transformations, $S$ transforms into itself by $SL(2, \mathbb{C})$ transformation, but space and time reflections relate $S$ to $\bar{S}$. The fact that there are two spin spaces $S$ and $\bar{S}$ in dimension 4 is the basis of chirality: an electron is represented by a Dirac spinor, which is a pair of spinors, one in each of $S$ and $\bar{S}$, which are related under space reflection; a particle represented just by a spinor in $S$ cannot be invariant under space reflection.

The Clifford algebra (see Clifford Algebras and their Representations) associated with a vector space $V$ with metric $g$ is defined as the algebra generated by elements $v$, $w$ of $V$ with the multiplication $\cup$ satisfying

$$v \cup w + w \cup v = 2g(v, w) \qquad [4]$$

The matrices $\gamma^a$ define a representation of the Clifford algebra by associating a covector $v_a$ with a matrix $v = v_a\gamma^a$, since [2] is then equivalent to [4].

This part of the process works in any dimension $n$ and signature $s$. For odd $n$, as, for example, with Pauli spinors, the $\gamma^a$ are square matrices of size $2^N \times 2^N$, where $N = (n-1)/2$, and there is a single spin space of dimension $2^N$. For even $n$, as with the original Dirac spinors, the $\gamma^a$ are square matrices of size $2^N \times 2^N$, where $N = n/2$, but there are two spin spaces each of dimension $2^{N-1}$. Reality properties of the spin spaces and the existence of other structures on them depend in an intricate way on $n$ and $s$ (Penrose and Rindler 1984, 1986, Benn and Tucker 1987).

The dimension of the space of spinors rises rapidly with $n$, which is one reason why historically spinors have been most useful in spaces of dimensions 3 and 4, where the spin space has dimension 2. In a space of dimension 11, a case considered in supergravity, the spin space already has dimension 32.

## Spinors in General Relativity: Spinor Algebra

In this section, we start again with a different emphasis. Conventions follow Penrose and Rindler (1984, 1986). To introduce spinors as a calculus in a four-dimensional, Lorentzian spacetime $\mathcal{M}$, one can begin by choosing an orthonormal tetrad of vectors $(\boldsymbol{e}_0, \boldsymbol{e}_1, \boldsymbol{e}_2, \boldsymbol{e}_3)$ at a point $p$. The following conventions are used:

$$g(\boldsymbol{e}_a, \boldsymbol{e}_b) = \eta_{ab} = \mathrm{diag}(1, -1, -1, -1)$$

Any vector $\boldsymbol{v}$ in the tangent space $V = T_p\mathcal{M}$ at $p$ has components $v^a$ in this basis, which we arrange as a matrix and label in two ways:

$$\Psi(\boldsymbol{v}) = \frac{1}{\sqrt{2}}\begin{pmatrix} v^0 + v^3 & v^1 + \mathrm{i}v^2 \\ v^1 - \mathrm{i}v^2 & v^0 - v^3 \end{pmatrix} = \begin{pmatrix} v^{00'} & v^{01'} \\ v^{10'} & v^{11'} \end{pmatrix} \quad [5]$$

The reason for the factor $1/\sqrt{2}$ will be seen below, as will the rationale for the second form of the matrix. Note that $\Psi(\boldsymbol{v})$ is Hermitian and that

$$2 \det \Psi(\boldsymbol{v}) = g(\boldsymbol{v}, \boldsymbol{v}) = \eta_{ab} v^a v^b \quad [6]$$

Clearly, there is a one-to-one correspondence between elements of $V$ and Hermitian $2 \times 2$ matrices. Further, if $t$ is any matrix in $\mathrm{SL}(2, \mathbb{C})$,then the transformation

$$\Psi(\boldsymbol{v}) \to t\Psi(\boldsymbol{v})t^\dagger \quad [7]$$

where $t^\dagger$ is the Hermitian conjugate of $t$, is linear in $\boldsymbol{v}$, and preserves both Hermiticity and the norm of $\boldsymbol{v}$. Thus, it must represent a Lorentz transformation. It is straightforward to check that it is a proper, orthochronous Lorentz transformation and that all such transformations arise in this way (recall that "proper" means transformations of determinant 1 so that orientation is preserved, and "orthochronous" means that future-pointing timelike or null vectors are taken to future-pointing timelike or null vectors, so that time orientation is preserved; the proper, orthochronous Lorentz group is equivalently the identity-connected component of the Lorentz group). Since both $t$ and $-t$ give the same Lorentz transformation, this provides an explicit demonstration of the (2 – 1)-homomorphism of SL(2,$\mathbb{C}$) with the proper, orthochronous Lorentz group $\mathrm{O}_+^\uparrow(1,3)$.

If the vector $\boldsymbol{v}$ in [5] is null, then the matrix has vanishing determinant, or, equivalently, it has rank 1, and so it can be written as the outer product of a two-component column vector $\alpha = (\alpha^0, \alpha^1)^{\mathrm{T}}$ and its Hermitian conjugate:

$$\Psi(\boldsymbol{v}) = \alpha\alpha^\dagger \quad [8]$$

Furthermore, under [7], $\alpha$ transforms as

$$\alpha \to t\alpha \quad [9]$$

The two-complex-dimensional space to which $\alpha$ belongs is the spin space $S$ at $p$, already met in the previous section, and it follows from [8], since null vectors span $V$, that the tensor product $S \otimes \bar{S}$ of $S$ with its complex conjugate vector space $\bar{S}$ is the complexification of $V$. Complex conjugation gives an antilinear map from $S$ to $\bar{S}$. (One associates the complex-conjugate vector space $\bar{V}$ to any given complex vector space $V$ as follows: scalar multiplication for $V$ can be considered as a function $\phi : \mathbb{C} \times V \to V$ given by $\phi(z, v) = zv$, while vector addition is a map $\psi : V \times V \to V$ given by $\psi(u, v) = u + v$. Define another complex vector space by taking the same vectors and the same $\psi$ but with scalar multiplication $\bar{\phi}$, where $\bar{\phi}(z, v) = \phi(\bar{z}, v)$. This is the complex-conjugate vector space $\bar{V}$. Given a choice of basis, we think of $V$ as, say, $n$-component column vectors of complex numbers, and then $\bar{V}$ is the corresponding complex-conjugate columns.)

Conventionally, $S$ is the space of unprimed spinors and $\bar{S}$ the space of primed spinors, and one also has the two duals $S'$ and $\bar{S}'$ which are associated in the corresponding way to the dual $V'$ of $V$. Analogously to the situation with vectors and covectors, index conventions for spinors are as follows:

$$\alpha^A \in S, \quad \beta^{A'} \in \bar{S}, \quad \gamma_A \in S', \quad \delta_{A'} \in \bar{S}'$$

where $A = 0, 1, A' = 0', 1'$.

Spinor algebra mirrors tensor algebra: a spinor $\phi^{A_1 \ldots A_p A'_1 \ldots A'_q}{}_{B_1 \ldots B_r B'_1 \ldots B'_s}$ is an element of the tensor product of $p$ copies of $S$, $q$ copies of $\bar{S}$, $r$ copies of $S'$, and $s$ copies of $\bar{S}'$. The second way of writing the matrix in [5] enables the identification of a vector with a matrix to be conventionally written as

$$v^a = v^{AA'} \quad [10]$$

and then extended to any tensor $T^{a \ldots b}{}_{c \ldots d}$ by replacing each vector index, say $b$, with a pair $BB'$ of spinor indices. In particular, from [8], it follows that any real null vector $n^a$ can be written in the form

$$n^a = \nu^A \bar{\nu}^{A'}$$

for some spinor $\nu^A$.

One must pay attention to the order of spinor indices of a given type, primed or unprimed, but by convention may permute primed and unprimed indices. A spinor with an equal number $n$ of primed and unprimed indices corresponds to a tensor of valence $n$, and the tensor is real if the spinor satisfies a suitable Hermiticity relation.

Spinors may have various symmetries among their indices, much as tensors have. However, since $S$ is two dimensional, there is only a one-dimensional space of 2-forms on $S$. This has two consequences: no spinor can be antisymmetric over more than two indices; and if we make a choice of canonical 2-form, all spinors can be written in terms of symmetric spinors and the canonical 2-form. This is a decomposition of spinors into irreducibles for $SL(2,\mathbb{C})$.

One makes a choice of 2-form $\epsilon_{AB}$ according to

$$\epsilon_{AB} = -\epsilon_{BA}, \quad \epsilon_{01} = 1$$

There is an inverse $\epsilon^{AB}$ defined by

$$\epsilon^{AC}\epsilon_{BC} = \delta^A_B \qquad [11]$$

where $\delta^A_B$ is the Kronecker delta. The complex conjugate of $\epsilon_{AB}$ is conventionally written without an overbar as $\epsilon_{A'B'}$, and analogously $\epsilon^{A'B'}$ is the complex conjugate of $\epsilon^{AB}$.

Because of the antisymmetry of $\epsilon_{AB}$, order of indices is crucial in equations such as [11]. The 2-form $\epsilon_{AB}$ has a role akin to that of a metric as it provides an identification of $S$ and its dual, according to

$$\alpha^A \to \alpha_B = \alpha^A \epsilon_{AB}$$

$$\beta_B \to \beta^A = \epsilon^{AB}\beta_B$$

with corresponding formulas for primed spinors. Note that, because of the antisymmetry of $\epsilon_{AB}$, necessarily $\alpha_A\alpha^A = 0$ for any $\alpha^A$.

With conventions made so far, it can be checked that

$$g_{ab}v^a v^b = \epsilon_{AB}\epsilon_{A'B'}v^{AA'}v^{BB'} \qquad [12]$$

for any vector $v^a$, where $g_{ab}$ is the spacetime metric at $p$, so that

$$g_{ab} = \epsilon_{AB}\epsilon_{A'B'}$$

It is the desire to have this formula without constants that necessitates the choice of the factor $1/\sqrt{2}$ in [5].

One final piece of spinor algebra that we note is the following: given a symmetric spinor $\phi_{A_1\ldots A_n}$ there is a factorization

$$\phi_{A_1\ldots A_n} = \alpha^{(1)}_{(A_1} \cdots \alpha^{(n)}_{A_n)} \qquad [13]$$

where the round brackets indicate symmetrization over the indices $A_1, \ldots, A_n$, and the $n$ spinors $\alpha^{(1)}_{A_1}, \ldots, \alpha^{(n)}_{A_n}$, which are determined only up to reordering and rescaling, are known as the principal spinors of $\phi$. To prove this, note that the principal spinors can be identified with the solutions $\zeta^A$ of the equation

$$\phi_{A_1\ldots A_n}\zeta^{A_1}\cdots\zeta^{A_n} = 0$$

and there are $n$ of these, counting multiplicities, by the "fundamental theorem of algebra."

## Spinors in General Relativity: Spinor Calculus

We now want to define spinor fields on the spacetime $\mathcal{M}$ as sections of a spinor bundle $\mathcal{S}$ whose fiber at each point is $S$ and such that the tensor product $\mathcal{S}\otimes\bar{\mathcal{S}}$ is the complexified tangent bundle. The existence of such an $\mathcal{S}$ imposes global restrictions on $\mathcal{M}$: $\mathcal{M}$ must be orientable and time orientable, and a certain characteristic class, the second Stiefel–Whitney class, must vanish (for an explanation of these terms see, e.g., Penrose and Rindler (1984, 1986)). Assuming that $\mathcal{M}$ satisfies these conditions, spinor fields can be defined. It is convenient to retain the algebraic formulas from the previous section (e.g., [10] or [12]) but with indices now regarded as abstract (a note on the abstract index convention appears in Twistors).

By an argument analogous to that for the fundamental theorem of Riemannian geometry, there is a unique covariant derivative that satisfies the Leibniz condition, coincides with the Levi-Civita derivative on tensors and the gradient on scalars, and annihilates $\epsilon_{AB}$ and $\epsilon_{A'B'}$. Following the conventions of the previous section, the spinor covariant derivative will be denoted as $\nabla_{AA'}$. The commutator of derivatives can be written in terms of irreducible parts (for $SL(2,\mathbb{C})$) according to the formula

$$\nabla_{AA'}\nabla_{BB'} - \nabla_{BB'}\nabla_{AA'} = \epsilon_{A'B'}\Delta_{AB} + \epsilon_{AB}\Delta_{A'B'}$$

where $\Delta_{AB} = \nabla_{C'(A}\nabla^{C'}_{B)}$. The definition of the Riemann curvature tensor is in terms of the Ricci identity

$$(\nabla_a\nabla_b - \nabla_b\nabla_a)v^c = R_{abd}{}^c v^d$$

and then this translates into two Ricci identities for a spinor field:

$$\Delta_{AB}\alpha_C = \chi_{ABCD}\alpha^D$$

$$\Delta_{A'B'}\alpha_C = \Phi_{A'B'CD}\alpha^D$$

The curvature spinors $\chi_{ABCD}$ and $\Phi_{A'B'CD}$ are related to the curvature tensor. The Ricci spinor $\Phi_{A'B'AB}$ is Hermitian and symmetric on both index pairs and is a multiple of the trace-free part of the Ricci tensor:

$$\Phi_{A'B'AB} = -\tfrac{1}{2}\left(R_{ab} - \tfrac{1}{4}Rg_{ab}\right)$$

The spinor $\chi_{ABCD}$ is symmetric on the first and last pairs of indices and decomposes into irreducibles according to

$$\chi_{ABCD} = \Psi_{ABCD} - 2\Lambda\epsilon_{D(A}\epsilon_{B)C}$$

where $\Lambda = R/24$ in terms of the Ricci scalar or scalar curvature $R$, while $\Psi_{ABCD}$, which is totally symmetric and is known as the Weyl spinor, is related to the Weyl tensor $C_{abcd}$ by the equation

$$C_{abcd} = \Psi_{ABCD}\epsilon_{A'B'}\epsilon_{C'D'} + \bar{\Psi}_{A'B'C'D'}\epsilon_{AB}\epsilon_{CD}$$

Thus, the ten real components of the Weyl tensor are coded into the five complex components of the Weyl spinor.

Following the last remark in the previous section, the Weyl spinor has four principal spinors, each of which defines a null direction, the principal null directions of the Weyl tensor. There is a classification of Weyl tensors, the Petrov–Pirani–Penrose classification, based on coincidences among the principal null directions (Penrose and Rindler 1984, 1986).

As a final exercise in spinor calculus, we recall the zero-rest-mass equations (see Twistors). In flat spacetime, these are the equations

$$\nabla^{A'A}\phi_{AB\ldots C} = 0$$

on a totally symmetric spinor field $\phi_{AB\ldots C}$. The field is said to have spin $s$ if it has $2s$ indices, and the cases $s = 1/2$, 1, or 2, respectively, are the Weyl neutrino equation, the Maxwell equation, and the linearized Einstein equation. In flat spacetime, these hyperbolic equations are well understood and solvable in a variety of ways. In curved spacetime, however, if $s \geq 3/2$, then there are curvature obstructions to the existence of solutions, known as Buchdahl conditions. This can be seen at once by differentiating again, say by $\nabla^{B}_{A'}$, and using the spinor Ricci identity. After a little algebra, one finds

$$\Psi^{ABC}{}_{(D}\phi_{E\ldots F)ABC} = 0$$

so that, whenever the field has three or more indices, there are algebraic constraints on its components in terms of the Weyl spinor.

## The Spin-Coefficient Formalism

The spin-coefficient formalism of Newman and Penrose is a formalism for spinor calculus in space-times (see, e.g., Penrose and Rindler (1984, 1986) and Stewart (1990)). It finds application in any calculation dealing with curvature tensors, including solving the Einstein equations. The formalism exploits the compression of terminology which the introduction of complex quantities permits.

The formalism starts with a choice of spinor dyad, a basis of spinor fields $(o^A, \iota^A)$ normalized so that $o_A\iota^A = 1$. From the dyad, one constructs a null tetrad, which is a basis of vector fields, according to the scheme

$$\ell^a = o^A\bar{o}^{A'},\ n^a = \iota^A\bar{\iota}^{A'},\ m^a = o^A\bar{\iota}^{A'},\ \bar{m}^a = \iota^A\bar{o}^{A'}$$

Given the normalization of the spinor dyad, each of the vectors in the null tetrad is null (hence the name) and all inner products are zero, except for

$$\ell^a n_a = 1 = -m^a\bar{m}_a$$

It follows that the metric can be written in the basis as

$$g_{ab} = 2\ell_{(a}n_{b)} - 2m_{(a}\bar{m}_{b)}$$

The components of the covariant derivative in the null tetrad are given separate names according to the following scheme:

$$\ell^a\nabla_a = D,\ n^a\nabla_a = \Delta,\ m^a\nabla_a = \delta,\ \bar{m}^a\nabla_a = \bar{\delta}$$

and the spin coefficients are the 12 components of the covariant derivative of the basis. Each is labeled with a Greek letter according to the following scheme:

$$\begin{aligned} Do^A &= \epsilon o^A - \kappa\iota^A, & \Delta o^A &= \gamma o^A - \tau\iota^A \\ \delta o^A &= \beta o^A - \sigma\iota^A, & \bar{\delta}o^A &= \alpha o^A - \rho\iota^A \\ D\iota^A &= \pi o^A - \epsilon\iota^A, & \Delta\iota^A &= \nu o^A - \gamma\iota^A \\ \delta\iota^A &= \mu o^A - \beta\iota^A, & \bar{\delta}\iota^A &= \lambda o^A - \alpha\iota^A \end{aligned} \quad [14]$$

The spin coefficients code the 24 real Ricci rotation coefficients into 12 complex quantities. Some of the spin coefficients have direct geometrical interpretation. For example, the vanishing of $\kappa$ is the condition for the integral curves of $\ell^a$ to be geodesic, while, if $\sigma$ is also zero, this congruence of geodesics is shear free. The same role is played by $\nu$ and $\lambda$ for the $n^a$-congruence. The real and imaginary parts of $\rho$ are, respectively (minus), the expansion and the twist of the congruence of integral curves of $\ell^a$.

In practice, it is often simpler to calculate the spin coefficients from the commutators of the basis vectors, now regarded as directional derivatives, as follows:

$$\begin{aligned}\Delta D - D\Delta &= (\gamma+\bar{\gamma})D + (\epsilon+\bar{\epsilon})\Delta - (\bar{\tau}+\pi)\delta - (\tau+\bar{\pi})\bar{\delta}\\ \delta D - D\delta &= (\bar{\alpha}+\beta-\bar{\pi})D + \kappa\Delta - (\bar{\rho}+\epsilon-\bar{\epsilon})\delta - \sigma\bar{\delta}\\ \delta\Delta - \Delta\delta &= -\bar{\nu}D + (\tau-\bar{\alpha}-\beta)\Delta + (\mu-\gamma+\bar{\gamma})\delta + \bar{\lambda}\bar{\delta}\\ \bar{\delta}\delta - \delta\bar{\delta} &= (\bar{\mu}-\mu)D + (\bar{\rho}-\rho)\Delta + (\alpha-\bar{\beta})\delta - (\bar{\alpha}-\beta)\bar{\delta}\end{aligned} \qquad [15]$$

The commutator of second derivatives applied to the spinor dyad expresses the components of the curvature tensor in terms of the derivatives of the spin coefficients. Before presenting these, we adopt a convention for labeling the components of curvature. The components of the Weyl spinor are given as follows:

$$\begin{aligned}\Psi_0 &= \Psi_{ABCD}o^A o^B o^C o^D\\ \Psi_1 &= \Psi_{ABCD}o^A o^B o^C \iota^D\\ \Psi_2 &= \Psi_{ABCD}o^A o^B \iota^C \iota^D\\ \Psi_3 &= \Psi_{ABCD}o^A \iota^B \iota^C \iota^D\\ \Psi_4 &= \Psi_{ABCD}\iota^A \iota^B \iota^C \iota^D\end{aligned} \qquad [16]$$

so that these five complex scalars encode the ten real components of the Weyl tensor. For the Ricci spinor, set

$$\begin{aligned}\Phi_{00} &= \Phi_{ABA'B'}o^A o^B \bar{o}^{A'} \bar{o}^{B'}, & \Phi_{01} &= \Phi_{ABA'B'}o^A o^B \bar{o}^{A'} \bar{\iota}^{B'}\\ \Phi_{02} &= \Phi_{ABA'B'}o^A o^B \bar{\iota}^{A'} \bar{\iota}^{B'}, & \Phi_{11} &= \Phi_{ABA'B'}o^A \iota^B \bar{o}^{A'} \bar{\iota}^{B'}\\ \Phi_{12} &= \Phi_{ABA'B'}o^A \iota^B \bar{\iota}^{A'} \bar{\iota}^{B'}, & \Phi_{22} &= \Phi_{ABA'B'}\iota^A \iota^B \bar{\iota}^{A'} \bar{\iota}^{B'}\end{aligned}$$

together with $\Phi_{10} = \overline{\Phi_{01}}, \Phi_{20} = \overline{\Phi_{02}}$, and $\Phi_{21} = \overline{\Phi_{12}}$. The nine components of the trace-free Ricci tensor are encoded in these scalars of which three are real and three complex. The Ricci scalar, as before, is replaced by the real scalar $\Lambda = R/24$.

Now the commutators of covariant derivatives on the spinor dyad lead to the following system:

$$\begin{aligned}D\rho - \bar{\delta}\kappa &= \rho^2 + \sigma\bar{\sigma} + (\epsilon+\bar{\epsilon})\rho - \bar{\kappa}\tau\\ &\quad - (3\alpha + \bar{\beta} - \pi)\kappa + \Phi_{00}\\ D\sigma - \delta\kappa &= (\rho+\bar{\rho}+3\epsilon-\bar{\epsilon})\sigma\\ &\quad - (\tau - \bar{\pi} + \bar{\alpha} + 3\beta)\kappa + \Psi_0\\ D\tau - \Delta\kappa &= (\tau+\bar{\pi})\rho + (\bar{\tau}+\pi)\sigma + (\epsilon-\bar{\epsilon})\tau\\ &\quad - (3\gamma+\bar{\gamma})\kappa + \Psi_1 + \Phi_{01}\\ D\alpha - \bar{\delta}\epsilon &= (\rho+\bar{\epsilon}-2\epsilon)\alpha + \beta\bar{\sigma} - \bar{\beta}\epsilon - \kappa\lambda - \bar{\kappa}\gamma\\ &\quad + (\epsilon+\rho)\pi + \Phi_{10}\\ D\beta - \delta\epsilon &= (\alpha+\pi)\sigma + (\bar{\rho}-\bar{\epsilon})\beta - (\mu+\gamma)\kappa\\ &\quad - (\bar{\alpha}-\bar{\pi})\epsilon + \Psi_1\\ D\gamma - \Delta\epsilon &= (\tau+\bar{\pi})\alpha + (\bar{\tau}+\pi)\beta - (\epsilon+\bar{\epsilon})\gamma - (\gamma+\bar{\gamma})\epsilon\\ &\quad + \tau\kappa - \nu\kappa + \Psi_2 - \Lambda + \Phi_{11}\\ D\lambda - \bar{\delta}\pi &= (\rho - 3\epsilon + \bar{\epsilon})\lambda + \bar{\sigma}\mu + (\pi+\alpha-\bar{\beta})\pi\\ &\quad - \nu\bar{\kappa} + \Phi_{20}\\ D\mu - \delta\pi &= (\bar{\rho}-\epsilon-\bar{\epsilon})\mu + \sigma\lambda + (\bar{\pi}-\bar{\alpha}+\beta)\pi\\ &\quad - \nu\kappa + \Psi_2 + 2\Lambda\\ D\nu - \Delta\pi &= (\pi+\bar{\tau})\mu + (\bar{\pi}+\tau)\lambda + (\gamma-\bar{\gamma})\pi\\ &\quad - (3\epsilon+\bar{\epsilon})\nu + \Psi_3 + \Phi_{21}\\ \Delta\lambda - \bar{\delta}\nu &= -(\mu+\bar{\mu}+3\gamma-\bar{\gamma})\lambda\\ &\quad + (3\alpha+\bar{\beta}+\pi-\bar{\tau})\nu - \Psi_4\\ \delta\rho - \bar{\delta}\sigma &= (\bar{\alpha}+\beta)\rho - (3\alpha-\bar{\beta})\sigma + (\rho-\bar{\rho})\tau\\ &\quad + (\mu-\bar{\mu})\kappa - \Psi_1 + \Phi_{01}\\ \delta\alpha - \bar{\delta}\beta &= \mu\rho - \lambda\sigma + \alpha\bar{\alpha} + \beta\bar{\beta} - 2\alpha\beta + (\rho-\bar{\rho})\gamma\\ &\quad + (\mu-\bar{\mu})\epsilon - \Psi_2 + \Lambda + \Phi_{11}\\ \delta\lambda - \bar{\delta}\mu &= (\rho-\bar{\rho})\nu + (\mu-\bar{\mu})\pi + (\alpha+\bar{\beta})\mu\\ &\quad + (\bar{\alpha}-3\beta)\lambda - \Psi_3 + \Phi_{21}\\ \Delta\mu - \delta\nu &= -(\mu+\gamma+\bar{\gamma})\mu - \lambda\bar{\lambda} + \bar{\nu}\pi\\ &\quad + (\bar{\alpha}+3\beta-\tau)\nu - \Phi_{22}\\ \Delta\beta - \delta\gamma &= (\bar{\alpha}+\beta-\tau)\gamma - \mu\tau + \sigma\nu + \epsilon\bar{\nu}\\ &\quad + (\gamma-\bar{\gamma}-\mu)\beta - \alpha\bar{\lambda} - \Phi_{12}\\ \Delta\sigma - \delta\tau &= -(\mu-3\gamma+\bar{\gamma})\sigma - \bar{\lambda}\rho - (\tau+\beta-\bar{\alpha})\tau\\ &\quad + \kappa\bar{\nu} - \Phi_{02}\\ \Delta\rho - \bar{\delta}\tau &= (\gamma+\bar{\gamma}-\bar{\mu})\rho - \sigma\lambda + (\bar{\beta}-\alpha-\bar{\tau})\tau\\ &\quad + \nu\kappa - \Psi_2 - 2\Lambda\\ \Delta\alpha - \bar{\delta}\gamma &= (\rho+\epsilon)\nu - (\tau+\beta)\lambda + (\bar{\gamma}-\bar{\mu})\alpha\\ &\quad + (\bar{\beta}-\bar{\tau})\gamma - \Psi_3\end{aligned} \qquad [17]$$

Finally, it is possible to write out the Bianchi identities in this formalism. For simplicity, and with a view to an application, we do this below only for vacuum, so that the Ricci tensor is zero:

$$\begin{aligned}D\Psi_1 - \bar{\delta}\Psi_0 &= (\pi - 4\alpha)\Psi_0 + 2(2\rho+\epsilon)\Psi_1 - 3\kappa\Psi_2\\ \Delta\Psi_0 - \delta\Psi_1 &= (4\gamma-\mu)\Psi_0 - 2(2\tau+\beta)\Psi_1 + 3\sigma\Psi_2\\ D\Psi_2 - \bar{\delta}\Psi_1 &= -\lambda\Psi_0 + 2(\pi-\alpha)\Psi_1 + 3\rho\Psi_2 - 2\kappa\Psi_3\\ \Delta\Psi_1 - \delta\Psi_2 &= \nu\Psi_0 + 2(\gamma-\mu)\Psi_1 - 3\tau\Psi_2 + 2\sigma\Psi_3\\ D\Psi_3 - \bar{\delta}\Psi_2 &= -2\lambda\Psi_1 + 3\pi\Psi_2 + 2(\rho-\epsilon)\Psi_3 - \kappa\Psi_4\\ \Delta\Psi_2 - \delta\Psi_3 &= 2\nu\Psi_1 - 3\mu\Psi_2 + 2(\beta-\tau)\Psi_3 + \sigma\Psi_4\\ D\Psi_4 - \bar{\delta}\Psi_3 &= -3\lambda\Psi_2 + 2(\alpha+2\pi)\Psi_3 + (\rho-4\epsilon)\Psi_4\\ \Delta\Psi_3 - \delta\Psi_4 &= 3\nu\Psi_2 - 2(\gamma+2\mu)\Psi_3 + (4\beta-\tau)\Psi_4\end{aligned} \qquad [18]$$

The whole system is then loosely described as the spin-coefficient equations.

As a simple application, we shall prove the Goldberg–Sachs theorem: for vacuum spacetimes, a

spinor field $o^A$ is geodesic and shear free iff it is a repeated principal spinor of the Weyl spinor.

In the spin-coefficient formalism, $o^A$ is geodesic and shear-free iff $\kappa$ and $\sigma$ vanish, and, from [16], is a repeated principal spinor of the Weyl spinor provided $\Psi_0 = \Psi_1 = 0$. It will be repeated three times if also $\Psi_2 = 0$ and four times if $\Psi_3 = 0$, but one must have $\Psi_k \neq 0$ for some $k$ if the spacetime is not to be flat.

Suppose that $o^A$ is a (twice) repeated principal spinor of the Weyl spinor, then at once from the first two expressions in [18] both $\kappa$ and $\sigma$ vanish. If it is repeated three times, one gets the same result from the third and fourth expressions in [18], while if $o^A$ is repeated four times then the fifth and sixth expressions of [18] should be used.

For the converse, suppose that $\kappa = \sigma = 0$. Then, by the first equation in [14], $o^A$ can be rescaled to ensure that $\epsilon = 0$ and a spinor field $\iota^A$ can be chosen which is normalized against $o^A$ and parallelly propagated along $\ell^a$, so that, by the fifth equation in [14], $\pi = 0$. From the second expression in [17], one can see at once that $\Psi_0 = 0$, so that the first two equations in [18] simplify to give expressions for $D\Psi_1$ and $\delta\Psi_1$. By commuting $D$ and $\delta$ on $\Psi_1$ and using the second expression of [15] with the relevant parts of [17], it can be concluded that $\Psi_1 = 0$, as required.

Another application which is easy to describe is the solution of the type-D vacuum equations. A type-D solution is one for which the Weyl spinor has two (linearly independent) repeated principal spinors. If these are taken as the normalized dyad, then from [16] only $\Psi_2$ is nonzero among the $\Psi_k$. By the Goldberg–Sachs theorem, both spinors are geodesic and shear free, so that the spin coefficients $\sigma, \kappa, \lambda$, and $\nu$ all vanish. With these conditions, the spin-coefficient equations simplify to the point that careful choices of coordinates and the remaining freedom in the dyad enable the equations to be solved explicitly. One obtains metrics that depend only on a few parameters. Analogous methods reduce the Einstein equations to simpler systems for the other vacuum algebraically special metrics, that is, the other vacuum metrics for which the Weyl spinor does not have four distinct principal null directions (Mason 1998).

The spin-coefficient formalism has also been extensively used in the study of asymptotically flat spacetimes and gravitational radiation (Penrose and Rindler 1984, 1986, Stewart 1990).

## The Positive-Mass Theorem

A very important application of spinor calculus in recent years was the proof by Witten (1981) of the positive-mass (or positive-energy) theorem. The proof was motivated by ideas from supergravity and gave rise to an increased interest in spinors in general relativity.

The positive-mass theorem is the following assertion: *given an asymptotically flat spacetime $\mathcal{M}$ with a spacelike hypersurface $\Sigma$, which is topologically $\mathbb{R}^3$ and in which the dominant energy condition holds, the total (or Arnowitt–Deser–Misner (ADM)) momentum is timelike and future-pointing*. (The dominant-energy condition is the requirement that $T_{ab}U^aV^b$ is non-negative for every pair of future-pointing timelike or null vectors $U^a$ and $V^b$.)

We follow the notation of Penrose and Rindler (1984, 1986), where the proof begins by considering the 2-form $\Xi$ defined in terms of a spinor field $\lambda^A$ on $\Sigma$ by

$$\Xi = -\mathrm{i}\bar{\lambda}_{B'}\nabla_a\lambda_B \mathrm{d}x^a \wedge \mathrm{d}x^b$$

If $\lambda^a$ tends to a constant spinor at spatial infinity on $\Sigma$, then

$$\frac{1}{4\pi G}\oint_S \Xi \to p_a\lambda^A\bar{\lambda}^{A'} \qquad [19]$$

as the spacelike spherical surface $S$ tends to spatial infinity, where $p_a$ is the ADM momentum. Suppose $\Sigma$ has unit normal $t^a$, intrinsic metric $h_{ab} = g_{ab} - t_at_b$ and the dual-volume 3-form is $\mathrm{d}\Sigma^a = t^a\mathrm{d}\Sigma$. Then Stokes' theorem states that

$$\oint_S \Xi = \int_\Sigma \mathrm{d}\Xi$$

We calculate

$$\mathrm{d}\Xi = \alpha + \beta$$

where

$$\alpha = 4\pi G T_{ab}\ell^a \mathrm{d}\Sigma^b$$
$$\beta = -\mathrm{i}\epsilon_{ab}{}^{cd}\nabla_c\lambda^B\nabla_d\bar{\lambda}^{B'}\mathrm{d}\Sigma^a$$

where $\ell^a = \lambda^a\bar{\lambda}^{A'}$ and we have used the Einstein field equations to replace curvature terms in $\alpha$ by the energy–momentum tensor $T_{ab}$. Provided the matter satisfies the dominant-energy condition, $\alpha$ is everywhere a positive multiple of the volume form on $\Sigma$ and its integral is positive (it can vanish only in vacuum). To make the integral of $\beta$ positive, $\lambda^A$ is required to satisfy

$$D_{AA'}\lambda^A = 0 \qquad [20]$$

where $D_a = h_a^b\nabla_b$, which is the projection of the four-dimensional covariant derivative rather than the intrinsic covariant derivative of $\Sigma$. Equation [20] is the Sen–Witten equation; it is elliptic and reduces to

the Dirac equation on a maximal surface; furthermore, given an asymptotically constant value for $\lambda^A$ on an asymptotically flat 3-surface $\Sigma$ with the topology of $\mathbb{R}^3$, it has a unique solution. Equation [20] removes part of the derivative of $\lambda^A$ from $\beta$ to leave

$$\beta = -h^{ab} D_a \lambda_C D_b \bar{\lambda}_{C'} \mathrm{d}\Sigma^c$$

Now $h_{ab}$ is negative definite and $\Sigma$ has timelike normal so that $\beta$ is a positive multiple of the volume form on $\Sigma$ (unless $\lambda^A$ is covariantly constant, a case which is dealt with separately). Thus, the integral of $\mathrm{d}\Xi$ is non-negative and therefore, by [19], so is the inner product of the ADM momentum $p_a$ with any null vector constructed from asymptotically constant spinors. Furthermore, this inner product is strictly positive, except in a vacuum spacetime admitting a constant spinor. Such spacetimes can be found explicitly and cannot be asymptotically flat, so that the ADM momentum is always timelike and future pointing, and vanishes only in flat spacetime.

The basic positive-energy theorem outlined above can be extended in several directions:

- to prove that the total momentum at future null infinity is also timelike and future pointing;
- to deal with surfaces $\Sigma$ which have inner boundaries, for example, at black holes;
- to prove inequalities between charge and mass; and
- to deal with spacetimes which are asymptotically anti-de Sitter rather than flat.

## Further Applications of Spinors

Supersymmetry is a symmetry in quantum field theory relating bosons and fermions. In the language of spinors, bosons are represented by fields with an even number of spinor indices and fermions by fields with an odd number of indices. Thus, the gauge transformations of supersymmetry are generated by spinors with a single index.

Supergravity is supersymmetry in the case that one of the fields is the graviton. A supergravity theory is labeled by an integer $N$ for the number of independent supersymmetries and much of the numerology of these theories follows from properties of spinors. $N=1$ supergravity contains a graviton and a spin-3/2 field coupled together, and the presence of the supersymmetry allows the Buchdahl condition to be evaded. Supergravity theory with one supersymmetry in 11 spacetime dimensions depends on one spinor, which, in 11 dimensions, has 32 components. This is as many components as eight Dirac spinors in a four-dimensional spacetime, and, by a process of dimensional reduction, $N=1$ supergravity in 11 dimensions is related to $N=8$ supergravity in four dimensions. For reasons related to the Buchdahl conditions, 8 is the largest $N$ that is considered in four dimensions.

In superstring theory and in some supergravity theories, one often wishes to consider spaces with "residual supersymmetry," by which is meant that there is a spinor field satisfying a condition of covariant constancy in some connection (Candelas *et al.* 1985). The existence of such constant spinors, as a result of spinor Ricci identities analogous to those given above, typically imposes strong restrictions on the curvature. Riemannian manifolds admitting constant spinors for the Levi-Civita connection are Ricci-flat (Hitchin 1974); Lorentzian ones can often be found in terms of a few functions. Manifolds of special holomorphy, which are of interest in superstring theory, can usually be characterized as admitting special spinors (Wang 1989).

# Stability of Flows

**S Friedlander**, University of Illinois-Chicago, Chicago, IL, USA

## Introduction

This article gives a brief discussion of a topic with an enormous literature, namely the stability/instability of fluid flows. Following the seminal observations and experiments of Reynolds in 1883, the issue of stability of a fluid flow became one of the central problems in fluid dynamics: stable flows are robust under inevitable disturbances in the environment, while unstable flows may break up, sometimes rapidly. These possibilities were demonstrated in a relatively simple experiment where flow in a pipe is examined at increasing speeds. As a dimensionless parameter (now known as the Reynolds number) increases, the flow completely changes its nature from a stable flow to a completely different regime that is irregular in space and time. Reynolds called this "turbulence" and observed that the transition from the simple flow to the chaotic flow was caused by the phenomenon of instability.

Even though the topic has been the subject of intense study over more than a century, Reynolds experiment is still not fully explained by current theory. Although there is no rigorous proof of stability of the simple flow (known as Poiseuille flow in a circular pipe), analytical and numerical investigations of the equations suggest theoretical stability for all Reynolds numbers. However, experiments show instability for sufficiently large Reynolds numbers. A plausible explanation for this phenomenon is the instability of such flows with respect to small but finite disturbances combined with their stability to infinitesimal disturbances.

The issue of fluid stability, in contexts much more complex than the fundamental experiment of Reynolds, arises in a multitude of branches of science, including engineeering, physics, astrophysics, oceanography, and meteorology. It is far beyond the scope of this short article to even touch upon most of the extensive literature. In the bibliography we list just a few of the substantive books where classical results can be found (Chandrasekhar 1961, Drazin and Reid 1981, Gershuni and Zhukovitiskii 1976, Joseph 1976, Lin 1967, Swinney and Gollub 1985). Recent extensive bibliographies on mathematical aspects of fluid instability are given in several articles in the *Handbook of Mathematical Fluid Dynamics* (Friedlander and Serre 2003) and the compendium of articles on hydrodynamics and nonlinear instabilities in Godreche and Maneville (1998).

## The Equations of Motion

The Navier–Stokes equations for the motion of an incompressible, constant density, viscous fluid are

$$\frac{\partial \boldsymbol{q}}{\partial t} + (\boldsymbol{q} \cdot \nabla)\, \boldsymbol{q} = -\frac{1}{\rho}\, \nabla P + \nu\, \nabla^2 \boldsymbol{q} \qquad [1a]$$

$$\operatorname{div} \boldsymbol{q} = 0 \qquad [1b]$$

where $\boldsymbol{q}(\boldsymbol{x}, t)$ denotes the velocity vector, $P(\boldsymbol{x}, t)$ the pressure, and the constants $\rho$ and $\nu$ are the density and kinematic viscosity, respectively. This system is considered in three (or sometimes two) spatial dimensions with a specified initial velocity field

$$\boldsymbol{q}(\boldsymbol{x}, 0) = \boldsymbol{q}_0(\boldsymbol{x}) \qquad [1c]$$

and physically appropriate boundary conditions: for example, zero velocity on a rigid boundary, or periodicity conditions for flow on a torus. This nonlinear system of partial differential equations (PDEs) has proved to be remarkably challenging, and in three dimensions the fundamental issues of existence and uniqueness of physically reasonable solutions are still open problems.

It is often useful to consider the Navier–Stokes equations in nondimensional form by scaling the velocity and length by some intrinsic scale in the problem, for example, in Reynolds' experiment by the mean speed $U$ and the diameter of the pipe $d$. This leads to the nondimensional equations

$$\frac{\partial \boldsymbol{q}}{\partial t} + (\boldsymbol{q} \cdot \nabla)\, \boldsymbol{q} = -\nabla P + \frac{1}{R}\, \nabla^2 \boldsymbol{q} \qquad [2a]$$

$$\operatorname{div} \boldsymbol{q} = 0 \qquad [2b]$$

where the Reynolds number $R$ is

$$R = Ud/\nu \qquad [3]$$

In many situations, the size of $R$ has a crucial influence on stability. Roughly speaking, when $R$ is small the flow is very sluggish and likely to be stable. However, the effects of viscosity are actually very complicated and not only is viscosity able to smooth and stabilize fluid motions, sometimes it actually also destroys and destabilizes flows.

The Euler equations, which predate the Navier–Stokes equations by many decades, neglect the effects of viscosity and are obtained from [1a] by setting the viscosity parameter $\nu$ to zero. Since this

removes the highest-derivative term from the equations, the nature of the Euler equations is fundamentally different from that of the Navier–Stokes equations and the limit of vanishing viscosity (or infinite Reynolds number) is a very singular limit. Since all real fluids are at least very weakly viscous, it could be argued that only the the Navier–Stokes equations are physically relevant. However, many important physical phenomena, such as turbulence, involve flows at very high Reynolds numbers ($10^4$ or higher). Hence, an understanding of turbulence is likely to involve the asymptotics of the Navier–Stokes equations as $R \to \infty$. The first step towards the construction of such asymptotics is the study of inviscid fluids governed by the Euler equations:

$$\frac{\partial \boldsymbol{q}}{\partial t} + (\boldsymbol{q} \cdot \nabla)\, \boldsymbol{q} = -\nabla P \qquad [4a]$$

$$\operatorname{div} \boldsymbol{q} = 0 \qquad [4b]$$

Stability issues for the Euler equations are in many respects distinct from those of the Navier–Stokes equations and in this article we will briefly touch upon stability results for both systems.

## Comments on Some "Classical" Instabilities

To illustrate the complexity of the structure of instabilities that can arise in the Navier–Stokes equations, we mention one classical example, namely the centrifugal instabilities called Taylor–Couette instabilities. Consider a fluid between two concentric cylinders rotating with different angular velocities. If the inner cylinder rotates sufficiently faster than the outer one, the centrifugal force is stronger on inside particles than outside particles and a disturbance which exchanges the radial position of particles is enhanced, that is, the configuration is unstable. As the angular velocity of the inner cylinder is increased above a certain critical rate, the instability is manifested in a series of small toroidal (Taylor) vortices that fill the space between the cylinders. There follows a hierarchy of successive instabilities: azimuthal traveling waves, twisting regimes, and quasiperiodic regimes until chaotic solutions appear. Such a sequence of bifurcations is a scenario for a transition to turbulence postulated by Ruelle–Takens. Details concerning bifurcation theory and fluid behavior can be found in the book of Chossat and Iooss (1994).

We note that phenomena of successive bifurcations connected with loss of stability, such as regimes of Taylor–Couette instabilities, occur at moderately large Reynolds numbers. Fully developed turbulence is a phenomenon associated with very high Reynolds numbers. These are parameter regimes basically inaccessible in current numerical investigations of the Navier–Stokes equations and turbulent models. The Euler equations lie at the limit as $R \to \infty$. It is an interesting observation that results at the limit of infinite Reynolds number are sometimes also applicable and consistent with experiments for flows with only moderate Reynolds number.

There is a huge diversity of forces that couple with fluid motion to produce instability. We will merely mention a few of these which an interested reader could pursue in consultation with texts listed in the "Further reading" section and references therein.

1. The so-called Bénard problem of convective instability concerns a horizontal layer of fluid between parallel plates and subject to a temperature gradient. The governing equations are the Navier–Stokes equation for a nonconstant density fluid and the heat equation. In this problem, the critical parameter governing the onset of instability is called the Rayleigh number. The patterns that can develop as a result of instability are strongly influenced by the boundary conditions in the horizontal coordinates. With lattice type conditions, bifurcating solutions include rolls, rectangles, and hexagons. Convection rolls are themselves subject to secondary instabilities that may break the translation symmetry and deform the rolls into meandering shapes. Further refinements of convective instabilities include doubly diffusive convection, where the density depends on concentration as well as temperature. Competition between stabilizing diffusivity and destabilizing diffusivity can lead to the so-called "salt-finger" instabilities.
2. Of considerable interest in astrophysics and plasma physics are the instabilities that occur in electrically conducting fluilds. Here the fluid equations are coupled with Maxwell's equations. Much work has been done on the topic of magnetohydrodynamical (MHD) stability, which was developed to address various important physical issues such as thermonuclear fusion, stellar and planetary interiors, and dynamo theory. For example, dynamo theory addresses the issue of how a magnetic field can be generated and sustained by the motion of an electrically conducting fluid. In the simplest scenario, the fluid motion is assumed to be a given divergence-free vector field and the study of

the instabilities that may occur in the evolution of the magnetic field is called the kinematic dynamo problem. This gives rise to interesting problems in dynamical systems and actually is closely analogous to the topic of vorticity generation in the three-dimensional (3D) fluid equations in the absence of MHD effects.

In the next section we discuss certain mathematical results that have been rigorously proved for particular problems in the stability of fluid flows. We restrict our attention to the "basic" equations, that is, [2a] and [2b], [4a] and [4b], observing that even in rather simple configurations there are still more open problems than precise rigorous results.

## The Navier–Stokes Equations: Mathematical Definitions of Stability/Instability

Instability occurs when there is some disturbance of the internal or external forces acting on the fluid and, loosely speaking, the question of stability or instability considers whether there exist disturbances that grow with time. There are many mathematical definitions of stability of a solution to a PDE. Most of these definitions are closely related but they may not be equivalent. Because of the distinctly different nature of the Navier–Stokes equations for a viscous fluid and the Euler equations for an inviscid fluid, we will adopt somewhat different precise definitions of stability for the two systems of PDEs. Both definitions are related to the concept known as Lyapunov stability. A steady state described by a velocity field $\boldsymbol{U}_0(\boldsymbol{x})$ is called Lyapunov stable if every state $\boldsymbol{q}(\boldsymbol{x},t)$ "close" to $\boldsymbol{U}_0(\boldsymbol{x})$ at $t=0$ stays close for all $t>0$. In mathematical terms, "closeness" is defined by considering metrics in a normed space $X$. While in finite-dimensional systems the choice of norm is not significant because all Banach norms are equivalent, in infinite-dimensional systems, such as a fluid configuration, this choice is crucial. The point was emphasized by Yudovich (1989) and it is a version of the definition of stability given in this book that we will adopt in connection with the parabolic Navier–Stokes equations.

### Definitions for a General Nonlinear Evolution Equation

Consider an evolution equation for $\boldsymbol{u}(\boldsymbol{x},t)$ whose phase space is a Banach space $X$:

$$\frac{\partial \boldsymbol{u}}{\partial t} = L\boldsymbol{u} + N(\boldsymbol{u},\boldsymbol{u})$$

We assume that if the initial value $\boldsymbol{u}(\boldsymbol{x},0) \in X$ is given, the future evolution $\boldsymbol{u}(\boldsymbol{x},t), t>0$, of the equation is uniquely defined (at least for sufficiently small initial data). Without loss of generality, we can assume that zero is a steady state.

We define a version of Lyapunov (nonlinear) stability and its converse instability.

**Definition 1** Let $(X, Z)$ be a pair of Banach spaces. The zero steady state is called $(X, Z)$ nonlinearly stable if, no matter how small $\epsilon > 0$, there exists $\delta > 0$ so that $\boldsymbol{u}(\boldsymbol{x},0) \in X$ and

$$\|\boldsymbol{u}(\boldsymbol{x},0)\|_Z < \delta$$

imply the following two assertions:

(i) there exists a global in time solution such that $\boldsymbol{u}(\boldsymbol{x},t) \in (([0,\infty); X)$;
(ii) $\|\boldsymbol{u}(\boldsymbol{x},t)\|_Z < \epsilon$ for a.e. $t \in [0,\infty)$.

The zero state is called nonlinearly unstable if either of the above assertions is violated. We note that under this strong definition of stability, loss of existence of a solution is a particular case of instability. The concept of existence that we will invoke in considering the Navier–Stokes equations is the existence of "mild" solutions introduced by Kato and Fujita (1962). Local-in-time existence of mild solutions is known in $X = L^q$ for $q \geq n$, where $n$ denotes the space dimension. ($L^q$ denotes the usual Lebesque space).

We now state two theorems for the Navier–Stokes equations [2a] and [2b]. The theorems are valid in any space dimension $n$ and in finite or infinite domains. Of course, the most physically relevant cases are $n=3$ or 2. Both theorems relate properties of the spectrum of the linearized Navier–Stokes equations to stability or instability of the full nonlinear system. Let $\boldsymbol{U}_0(\boldsymbol{x})$, $P_0(\boldsymbol{x})$ be a steady state flow:

$$(\boldsymbol{U}_0 \cdot \nabla)\boldsymbol{U}_0 = -\nabla P_0 + \frac{1}{R}\nabla^2 \boldsymbol{U}_0 + \frac{1}{R}\boldsymbol{F} \qquad [5a]$$

$$\nabla \cdot \boldsymbol{U}_0 = 0 \qquad [5b]$$

where $\boldsymbol{U}_0 \in C^\infty$ vanishes on the boundary of the domain $D$ and $\boldsymbol{F}$ is a suitable external force. We write [2a] and [2b] in perturbation form as

$$\boldsymbol{q}(\boldsymbol{x},t) = \boldsymbol{U}_0(\boldsymbol{x}) + \boldsymbol{u}(\boldsymbol{x},t) \qquad [6]$$

where

$$\frac{\partial \boldsymbol{u}}{\partial t} = L_{\mathrm{NS}}\boldsymbol{u} + N(\boldsymbol{u},\boldsymbol{u}) \qquad [7a]$$

$$\nabla \cdot \boldsymbol{u} = 0 \qquad [7b]$$

with

$$L_{NS}\boldsymbol{u} \equiv -(\boldsymbol{U}_0 \cdot \nabla)\boldsymbol{u} - (\boldsymbol{u} \cdot \nabla)\boldsymbol{U}_0 + \frac{1}{R}\nabla^2\boldsymbol{u} - \nabla P_1 \qquad [8]$$

$$N(\boldsymbol{u}, \boldsymbol{u}) \equiv -(\boldsymbol{u} \cdot \nabla)\boldsymbol{u} - \nabla P_2 \qquad [9]$$

Here $P_1$ and $P_2$ are, respectively, the portions of the pressure required to ensure that $L_{NS}u$ and $N(\boldsymbol{u}, \boldsymbol{u})$ remain divergence free. The operators $L_{NS}$ and $N$ act on the space of divergence-free vector-valued functions in the closure of the Sobolev space $W^{s,p}$ that vanish on the boundary of $D$.

We note that the spectrum of the elliptic linear operator $L_{NS}$ with appropriate boundary conditions in a bounded domain is purely discrete: that is, it consists of a countable number of eigenvalues of finite multiplicity with the sole limit point being at infinity.

**Theorem 2** (Nonlinear instability). *Let $1 < p < \infty$ be arbitrary. Suppose that the operator $L_{NS}$ over $L^p$ has spectrum in the right half of the complex plane. Then the flow $\mathbf{U}_0(\boldsymbol{x})$ is $(L^q, L^p)$ nonlinearly unstable for any $q > \max(p, n)$.*

**Theorem 3** (Asymptotic Lyapunov stability). *Let $q > n$ be arbitrary. Assume that the operator $L_{NS}$ over $L^q$ has spectrum confined to the left half of the complex plane. Then the flow $\mathbf{U}_0(\boldsymbol{x})$ is $(L^q, L^q)$ nonlinearly stable.*

A recent proof of these theorems is given in Friedlander *et al.* (2006) using a bootstrap type argument. In Theorem 2, the space $L^q, q > n$, is used as an auxiliary space inwhich the norm of the nonlinear term is controlled, while the final instability result is proved in $L^p$ for $p \in (1, \infty)$. We note that this includes the most physically relevant case of instability in the $L^2$ energy norm. An earlier proof of the theorems under the restriction $p \geq n$ was given by Yudovich (1989).

To apply Theorem 2 or 3 to conclude nonlinear instability or stability of a given flow $\boldsymbol{U}_0$, it is necessary to have information concerning the spectrum of the linear operator $L_{NS}$. Obtaining such information has been the goal of much of the literature concerning fluid stability (see the bibliography and the references therein). However, except in the case of some relatively simple flows, the eigenvalues of $L_{NS}$ have not yet been calculated explicitly. Perhaps the example that is the most tractable is plane parallel shear flows. Here the eigenvalue problem is governed by an ordinary differential equation (ODE) known as the Orr–Sommerfeld equation, which has been the subject of extensive analytical and numerical investigations. Consider the parallel flow $\boldsymbol{U}_0 = (U(z), 0, 0)$ in the strip $-1 \leq z \leq 1$. For disturbances of the form

$$\phi(z)\, e^{i(k_1 x + k_2 y)}\, e^{\lambda t} \qquad [10]$$

the eigenvalue $\lambda$ is determined by the following equation with $k^2 = k_1^2 + k_2^2$:

$$\left(U - i\frac{\lambda}{k}\right)\left[\frac{d^2}{dz^2} - k^2\right]\phi - U''\phi = \frac{1}{ikR}\left[\frac{d^2}{dz^2} - k^2\right]\phi \qquad [11]$$

with boundary conditions $\phi = 0$ at $z = \pm 1$. We note that the discreteness of the spectrum is preserved if periodicity conditions are imposed in the $(x, y)$ plane.

The complexity of the spectral problem [11] is apparent even for the simple case $U(z) = 1 - z^2$ (known as plane Poiseuille flow). Unstable eigenvalues exist but only in certain regions of $(k, R)$ parameter space. There is a critical Reynolds number, $R_c = 5772$, below which $\text{Re}\,\lambda < 0$ for all wave numbers $k$. For $R > R_c$, instability occurs in a band of wave numbers and the thickness of this band shrinks to zero as $R \to \infty$ (i.e., the inviscid limit). Hence, Poiseuille flow with $R < R_c$ can be considered as an example where the stability Theorem 3 can be applied, that is, the flow is nonlinearly stable to infinitesimal disturbances. However, extremely careful experiments are needed to obtain agreement with the theoretical value of $R_c = 5772$. Rather it is more usual in an experiment with $R \sim 2000$ that the flow exhibits instability in the form of streamwise streaks that appear near the walls. These structures do not look like traveling waves of the form given by expression [10], rather they are finite-amplitude effects of nonmodal growth. Such linear growth of disturbances, along with energy growth and pseudospectra have recently been investigated extensively.

An example where Theorem 3, proving nonlinear instability, can be applied is the so-called Kolmogorov flow. This is also a shear flow with the spectral problem for the linearized operator given by eqn [11]. In this example, the profile is oscillatory in $z$ with $U(z) = \sin mz$. In an elegant paper, Meshalkin and Sinai (1961) used continued fractions to prove the existence of a real unstable positive eigenvalue. It is interesting, and in some sense surprising, that the particular case of sinusoidal profiles leads to a nonconstant-coefficient eigenvalue problem, where it is possible to construct in explicit form the transcendental characteristic equation that relates the eigenvalues $\lambda$ and the wave numbers. Usually,

this can be done only for constant-coefficient equations. In the case $U(z) = \sin mz$, a Fourier series representation for the eigenfunctions leads to a tridiagonal infinite matrix for the algebraic system satisfied by the Fourier coefficients. This is amenable to examination using continued fractions. Analysis of the characteristic equation shows that there exist real eigenvalues $\lambda > 0$ provided $R$ is larger than some critical value for each wave number $k$ with $k^2 < m^2$.

## The Euler Equation: Linear and Nonlinear Stability/Instability

We conclude this brief article with some discussion of instabilities in the inviscid Euler equations whose existence is likely to be important as a "trigger" for the development of instabilities in high-Reynolds-number viscous flows. As we mentioned, the Euler equations are very different from the Navier–Stokes equations in their mathematical structure. The Euler equations are degenerate and nonelliptic. As such, the spectrum of the linearized operator $L_{\mathrm{E}}$ is not amenable to standard spectral theory of elliptic operators. For example, unlike the Navier–Stokes operator, the spectrum of $L_{\mathrm{E}}$ is not purely discrete even in bounded domains. To define $L_{\mathrm{E}}$ we consider a steady Euler flow $\{\boldsymbol{U}_0(\boldsymbol{x}), P_0(\boldsymbol{x})\}$, where

$$\boldsymbol{U}_0 \cdot \nabla \boldsymbol{U}_0 = -\nabla P_0 \qquad [12a]$$

$$\nabla \cdot \boldsymbol{U}_0 = 0 \qquad [12b]$$

We assume that $\boldsymbol{U}_0 \in C^\infty$. For the Euler equations, appropriate boundary conditions include zero normal component of $\boldsymbol{U}_0$ on a rigid boundary, or periodicity conditions (i.e., flow on a torus) or suitable decay at infinity in an unbounded domain. The theorems that we will be describing have been proved mainly in the cases of the second and third conditions stated above. There are many classes of vector fields $\boldsymbol{U}_0(\boldsymbol{x})$, in two and three dimensions, that satisfy [12a] and [12b]. We write [4a] and [4b] in perturbation form as

$$\boldsymbol{q}(\boldsymbol{x}, t) = \boldsymbol{U}_0(\boldsymbol{x}) + \boldsymbol{u}(\boldsymbol{x}, t) \qquad [13]$$

with

$$\frac{\partial \boldsymbol{u}}{\partial t} = L_{\mathrm{E}}\, \boldsymbol{u} + N(\boldsymbol{u}, \boldsymbol{u}) \qquad [14a]$$

$$\nabla \cdot \boldsymbol{u} = 0 \qquad [14b]$$

Here

$$L_{\mathrm{E}}\, \boldsymbol{u} \equiv -(\boldsymbol{U}_0 \cdot \nabla)\, \boldsymbol{u} - (\boldsymbol{u} \cdot \nabla) \boldsymbol{U}_0 - \nabla P_1 \qquad [15]$$

$$N(\boldsymbol{u}, \boldsymbol{u}) \equiv -(\boldsymbol{u} \cdot \nabla)\, \boldsymbol{u} - \nabla P_2 \qquad [16]$$

Linear (spectral) instability of a steady Euler flow $\boldsymbol{U}_0(\boldsymbol{x})$ concerns the structure of the spectrum of $L_{\mathrm{E}}$. Assuming $\boldsymbol{U}_0 \in \mathrm{C}^\infty(T^n)$, the linear equation

$$\frac{\partial \boldsymbol{u}}{\partial t} = L_{\mathrm{E}}\, \boldsymbol{u}, \qquad \nabla \cdot \boldsymbol{u} = 0 \qquad [17]$$

defines a strongly continuous group in every Sobolev space $W^{s,p}$ with generator $L_{\mathrm{E}}$. We denote this group by $\exp\{L_{\mathrm{E}}\, t\}$. For the issue of spectral instability of the Euler equation it proves useful to study not only the spectrum of $L_{\mathrm{E}}$ but also the spectrum of the evolution operator $\exp\{L_{\mathrm{E}}\, t\}$. This permits the development of an explicit formula for the growth rate of a small perturbation due to the essential (or continuous) spectrum. It was proved by Vishik (1996) that a quantity $\Lambda$, refered to as a "fluid Lyapunov exponent" gives the maximum growth rate of the essential spectrum of $\exp\{L_{\mathrm{E}}\, t\}$. This quantity is obtained by computing the exponential growth rate of a certain vector that satisfies a specific system of ODEs over the trajectories of the flow $\boldsymbol{U}_0(\boldsymbol{x})$. This proves to be an effective mechanism for detecting instabilities in the essential spectrum which result due to high-spatial-frequency perturbations. For example, for this reason any flow $\boldsymbol{U}_0(\boldsymbol{x})$ with a hyperbolic fixed point is linearly unstable with growth in the sense of the $L^2$-norm. In two dimensions, $\Lambda$ is equal to the maximal classical Lyapunov exponent (i.e., the exponential growth of a tangent vector over the ODE $\dot{\boldsymbol{x}} = \boldsymbol{U}_0(\boldsymbol{x})$). In three dimensions, the existence of a nonzero classical Lyapunov exponent implies that $\Lambda > 0$. However, in three dimensions there are also examples where the classical Lyapunov exponent is zero and yet $\Lambda > 0$. We note that the delicate issue of the unstable essential spectrum is strongly dependent on the function space for the perturbations and that $\Lambda$, for a given $\boldsymbol{U}_0$, will vary with this function space. More details and examples of instabilities in the essential spectrum can be found in references in the bibliography.

In contrast with instabilities in the essential spectrum, the existence of discrete unstable eigenvalues is independent of the norm in which growth is measured. From this point of view, such instabilities can be considered as "strong." However, for most flows $\boldsymbol{U}_0(\boldsymbol{x})$ we do not know the existence of such unstable eigenvalues. For fully 3D flows there are no examples, to our knowledge, where such unstable eigenvalues have been proved to exist for flows with standard metrics. The case that has received the most attention in the literature is the "relatively simple" case of plane parallel shear flow. The eigenvalue problem is governed by the Rayleigh

equation (which is the inviscid version of the Orr–Sommerfeld equation [11]):

$$\left(U - \frac{\mathrm{i}\lambda}{k}\right)\left[\frac{\mathrm{d}^2}{\mathrm{d}z^2} - k^2\right]\phi - U''\phi = 0$$
$$\phi = 0 \quad \text{at} \quad z = \pm 1 \qquad [18]$$

The celebrated Rayleigh stability criterion says that a sufficient condition for the eigenvalues $\lambda$ to be pure imaginary is the absence of an inflection point in the shear profile $U(z)$. It is more difficult to prove the converse; however, there have been several recent results that show that oscillating profiles indeed produce unstable eigenvalues. For example, if $U(z) = \sin mz$ the continued fraction proof of Meshalkin and Sinai can be adapted to exhibit the full unstable spectrum for [18]. We note the "fluid Lyapunov exponent" $\Lambda$ is zero for all shear flows; thus the only way the unstable spectrum can be nonempty for shear flows is via discrete unstable eigenvalues.

As we have discussed, it is possible to show that many classes of steady Euler flows are linearly unstable, either due to a nonempty unstable essential spectrum (i.e., cases where $\Lambda > 0$) or due to unstable eigenvalues or possibly for both reasons. It is natural to ask what this means about the stability/instability of the full nonlinear Euler equations [14]–[16]. The issue of nonlinear stability is complex and there are several natural precise definitions of nonlinear stability and its converse instability.

One definition is to consider nonlinear stability in the energy norm $L^2$ and the enstrophy norm $H^1$, which are natural function spaces to measure growth of disturbances but are not "correct" spaces for the Euler equations in terms of proven properties of existence and uniqueness of solutions to the nonlinear equation. Falling under this definition is the most frequently employed method to prove nonlinear stability, which is an elegant technique developed by Arnol'd (cf. Arnol'd and Khesin (1998) and references therein). This is based on the existence of the so-called energy-Casimirs. The vorticity curl $q$ is transported by the motion of the fluid so that at time $t$ it is obtained from the vorticity at time $t = 0$ by a volume-preserving diffeomorphism. In the terminology of Arnol'd, the velocity fields obtained in this manner at any two times are called isovortical. For a given field $\boldsymbol{U}_0(\boldsymbol{x})$, the class of isovortical fields is an infinite-dimensional manifold $M$, which is the orbit of the group of volume-preserving diffeomorphisms in the space of divergence-free vector fields. The steady flows are exactly the critical points of the energy functional $E$ restricted to $M$. If a critical point is a strict local maximum or minimum of $E$, then the steady flow is nonlinearly stable in the space $J_1$ of divergence-free vectors $\boldsymbol{u}(\boldsymbol{x}, t)$ (satisfying the boundary conditions) that have finite norm,

$$\|\boldsymbol{u}\|_{J_1} \equiv \|\boldsymbol{u}\|_{L^2} + \|\text{curl } \boldsymbol{u}\|_{L^2} \qquad [19]$$

This theory can be applied, for example, to show that any shear flow with no inflection points in the profile $U(z)$ is nonlinearly unstable in the function space $J_1$, that is, the classical Rayleigh criterion implies not only spectral stability but also nonlinear stability.

We note that Arnol'd's stability method cannot be applied to the Euler equations in three dimensions because the second variation of the energy defined on the tangent space to $M$ is never definite at a critical point $\boldsymbol{U}_0(\boldsymbol{x})$. This result is suggestive, but does not prove, that most Euler flows in three dimensions are nonlinearly unstable in the Arnol'd sense. To quote Arnol'd, in the context of the Euler equations "there appear to be an infinitely great number of unstable configurations."

In recent years, there have been a number of results concerning nonlinear instability for the Euler equation. Most of these results prove nonlinear instability under certain assumptions on the structure of the spectrum of the linearized Euler operator. To date, none of the approaches prove the definitive result that in general linear instability implies nonlinear instability. As we have remarked, this is a much more delicate issue for Euler than for Navier–Stokes because of the existence, for a generic Euler flow, of a nonempty essential unstable spectrum. To give a flavor of the mathematical treatment of nonlinear instability for the Euler equations, we present one recent result and refer the interested reader to articles listed in the "Further reading" section for further results and discussions.

In the context of Euler equations in two dimensions, we adopt the following definition of Lyapunov stability.

**Definition 4** An equilibrium solution $\boldsymbol{U}_0(\boldsymbol{x})$ is called Lyapunov stable if for every $\varepsilon > 0$ there exists $\delta > 0$ so that for any divergence-free vector $\boldsymbol{u}(\boldsymbol{x}, 0) \in W^{1+s,p}$, $s > 2/p$, such that $\|\boldsymbol{u}(\boldsymbol{x}, 0)\|_{L^2} < \delta$ the unique solution $\boldsymbol{u}(\boldsymbol{x}, t)$ to [14]–[16] satisfies

$$\|\boldsymbol{u}(\boldsymbol{x}, t)\|_{L^2} < \varepsilon \quad \text{for} \quad t \in [0, \infty)$$

We note that we require the initial value $\boldsymbol{u}(\boldsymbol{x}, 0)$ to be in the Sobolev space $W^{1+s,p}$, $s > p/2$, since it is known that the 2D Euler equations are globally in time well posed in this function space.

**Definition 5** Any steady flow $U_0(x)$ for which the conditions of Definition 4 are violated is called nonlinearly unstable in $L^2$.

Observe that the open issues (in three dimensions) of nonuniqueness or nonexistence of solutions to [14]–[16] would, under Definition 5, be scenarios for instability.

**Theorem 6** (Nonlinear instability for 2D Euler flows). *Let $U_0(x) \in C^\infty(T^2)$ be satisfy [12]. Let $\Lambda$ be the maximal Lyapunov exponent to the ODE $\dot{x} = U_0(x)$. Assume that there exists an eigenvalue $\lambda$ in the $L^2$ spectrum of the linear operator $L_E$ given by [15] with $\mathrm{Re}\,\lambda > \Lambda$. Then in the sense of Definition 5, $U_0(x)$ is Lyapunov unstable with respect to growth in the $L^2$-norm.*

The proof of this result is given in Vishik and Friedlander (2003) and uses a so-called "bootstrap" argument whose origins can be found in references in that article. We remark that the above result gives nonlinear instability with respect to growth of the energy of a perturbation which seems to be a physically reasonable measure of instability.

In order to apply Theorem 6 to a specific 2D flow it is necessary to know that the linear operator $L_E$ has an eigenvalue with $\mathrm{Re}\,\lambda > \Lambda$. As we have discussed, such knowledge is lacking for a generic flow $U_0(x)$. Once again, we turn to shear flows. As we noted $\Lambda = 0$ for shear flows, any shear profile for which unstable eigenvalues have been proved to exist provides an example of nonlinear instability with respect to growth in the energy.

We conclude with the observation that it is tempting to speculate that, given the complexity of flows in three dimensions, most, if not all, such inviscid flows are nonlinearly unstable. It is clear from the concept of the fluid Lyapunov exponent that stretching in a flow is associated with instabilities and there are more mechanisms for stretching in three, as opposed to two, dimensions. However, to date there are virtually no mathematical results for the nonlinear stability problem for fully 3D flows and many challenging issues remain entirely open.

## Acknowledgments

The author is very grateful to IHES and ENS-Cachan for their hospitality during the writing of this paper. She thanks Misha Vishik for much helpful advice.

# Stability of Matter

**J P Solovej**, University of Copenhagen, Copenhagen, Denmark

## Introduction

The theorem on stability of matter is one of the most celebrated results in mathematical physics. It is one of the rare cases where a result of such great importance to our understanding of the world around us appeared first in a completely rigorous formulation.

Issues of stability are, of course, extremely important in physics. One of the major triumphs of the theory of quantum mechanics is the explanation it gives of the stability of the hydrogen atom (and the complete description of its spectrum). Quantum mechanics or, more precisely, the uncertainty principle explains not only the stability of tiny microscopic objects, but also the stability of gigantic stellar objects such as white dwarfs. Chandrasekhar's famous theory on the stability of white dwarfs required, however, not only the usual uncertainty principle, but also the Pauli exclusion principle for the fermionic electrons.

Whereas both the stability of atoms and the stability of white dwarfs were early triumphs of quantum mechanics, it, surprisingly, took nearly 40 years before the question of stability of everyday macroscopic objects was even raised (Fisher and Ruelle 1966). The rigorous answer to the question came shortly thereafter in what came to be known as the "theorem on stability of matter" proved first by Dyson and Lenard (1967).

Both the stability of hydrogen and the stability of white dwarfs simply mean that the total energy of the system cannot be arbitrarily negative. If there were no such lower bound to the energy, one would have a system from which it would be possible, in principle, to extract an infinite amount of energy. One often refers to this kind of stability as *stability of the first kind*.

Stability of matter is somewhat different. Stability of the first kind for atoms generalizes, as noted later, to objects of macroscopic size. The question arises as to how the lowest possible energy depends on the size or, more precisely, on the (macroscopic) number of particles in the object. Stability of matter in its precise mathematical formulation is the requirement that the lowest possible energy depends at most linearly on the number of particles. Put differently, the lowest possible energy calculated per particle cannot be arbitrarily negative as the number of particles increases. This is often referred to as "stability of the second kind." If stability of the second kind does not hold, one would be able to extract an arbitrarily large amount of energy by adding a single atomic particle to a sufficiently large macroscopic object.

A perhaps more intuitive notion of stability is related to the volume occupied by a macroscopic object. More precisely, the volume of the object, when its total energy is close to the lowest possible energy, grows at least linearly in the number of particles. This volume dependence is a fairly simple consequence of stability of matter as formulated above.

The first mention of stability of the second kind for a charged system is perhaps by Onsager (1939), who studied a system of charged classical particles with a hard core and proved the stability of the second kind. The proof of stability of matter by Dyson and Lenard, which does not rely on any hard-core assumption, but rather on the properties of fermionic quantum particles, used results from Onsager's paper.

The real relevance of the notion of stability of the second kind was first realized by Fisher and Ruelle (1966) in an attempt to understand the thermodynamic properties of matter and to give meaning to thermodynamic quantities such as the energy density (energy per volume). Stability of matter is a necessary ingredient in explaining the existence of thermodynamics, that is, that the energy per volume has a well-defined limit as the volume and number of particles tend to infinity, with the ratio (i.e., the density of particles) kept fixed. The existence of this limit is, however, not just a simple consequence of stability of matter. The existence of the thermodynamic limit for ordinary charged matter was proved rigorously by Lieb and Lebowitz (1972) using the result on stability of matter as an input.

After the original proof of stability of matter by Dyson and Lenard, several other proofs were given (see, e.g., reviews by Lieb (1976, 1990, 2004) for detailed references). Lieb and Thirring (1975) in particular presented an elegant and simple proof relying on an uncertainty principle for fermions. As explained in a later section, the best mathematical formulation of the usual uncertainty principle is in terms of a Sobolev inequality. The method of Lieb and Thirring is related to a Sobolev type inequality for antisymmetric functions. The Lieb–Thirring inequality is discussed later. The proof by Dyson

and Lenard gave a very poor bound on the lowest possible energy per particle. The proof by Lieb and Thirring gave a much more realistic bound on this quantity (see below). Two proofs of stability of matter will be sketched here. Both proofs rely on the Lieb–Thirring inequality. The first proof described is mathematically simple to explain, whereas the second proof (Lieb–Thirring) is based on the Thomas–Fermi theory. It is mathematically somewhat more involved but, from a physical point of view, more intuitive.

As in the case of white dwarfs, stability of matter relies on the fermionic property of electrons. Dyson (1967) proved that the stability of the second kind fails if we ignore the Pauli exclusion principle. In physics textbooks, the importance of the Pauli exclusion principle for the stability of white dwarfs is often emphasized. Its importance for the stability of everything around us is usually ignored.

As mentioned above the result on stability of matter appeared from the beginning as a completely rigorously proved theorem. In contrast, the stability of white dwarfs was only derived rigorously by Lieb and Thirring (1984) and Lieb and Yau (1987) over 50 years after the original work of Chandrasekhar.

The original formulation of stability of matter, which is given in the next section, dealt with charged matter consisting of electrons and nuclei interacting only through electrostatic interactions and being described by nonrelativistic quantum mechanics. Over the years, many generalizations of stability of matter have been derived in order to include relativistic effects and electromagnetic interactions. Some of these generalizations will be discussed in this article. A complete understanding of stability of matter in quantum electrodynamics (QED) does not exist as yet, which is intimately related to the fact that this theory still awaits a mathematically satisfactory formulation.

## The Formulation of Stability of Matter

Consider $K$ nuclei with nuclear charges $z_1, \ldots, z_K > 0$ at positions $r_1, \ldots, r_K \in \mathbb{R}^3$, and $N$ electrons with charges –1 (this amounts to a choice of units) at positions $x_1, \ldots, x_N \in \mathbb{R}^3$. In order to discuss stability, it turns out that one can consider the nuclei as fixed in space, whereas the electrons are dynamic. More precisely, this means that the kinetic energy of the nuclei is ignored. It is important to realize that if stability holds for static nuclei, it also holds for dynamic nuclei. This is simply because the kinetic energy is positive, so that the effect of ignoring it is to lower the total energy.

Since we consider only electrostatic interactions, the quantum Hamiltonian describing this system is

$$H_N = \sum_{i=1}^{N} T_i - \sum_{k=1}^{K}\sum_{i=1}^{N} \frac{z_k}{|x_i - r_k|} + \sum_{1\le i<j\le N} \frac{1}{|x_i - x_j|} + \sum_{1\le k<\ell\le K} \frac{z_k z_\ell}{|r_k - r_\ell|} \quad [1]$$

The kinetic energy operator $T_i$ is (half) the Laplacian in the variable $x_i$, i.e., $T_i = -(1/2)\Delta_i$. Atomic units are used, where not only the electron charge is –1, but the mass of the electron is also 1 and $\hbar = 1$. The unit of energy is then 2 Ry.

The Hamiltonian $H_N$ depends on the parameters $\boldsymbol{z} = (z_1, \ldots, z_K)$ and $\boldsymbol{r} = (r_1, \ldots, r_K)$. It acts on the Hilbert space of fermionic, that is, antisymmetric wave functions. More precisely, the fermionic Hilbert space is

$$\mathcal{H}_N^{\mathrm{F}} = \bigwedge^{N} L^2(\mathbb{R}^3; \mathbb{C}^2)$$

Here the target space is $\mathbb{C}^2$, in order to describe spin-1/2 particles. One can, of course, also consider the Hamiltonian $H_N$ on the full Hilbert space,

$$\mathcal{H}_N = \bigotimes^{N} L^2(\mathbb{R}^3; \mathbb{C}^2) = L^2(\mathbb{R}^{3N}; \mathbb{C}^{2^N})$$

of which $\mathcal{H}_N^{\mathrm{F}}$ is a subspace.

The quantity of interest is the ground-state energy

$$\begin{aligned} E^{\mathrm{F}}(\boldsymbol{z}, N, K) &= \inf_{\boldsymbol{r}} \inf \operatorname{spec}_{\mathcal{H}_N^{\mathrm{F}}} H_N \\ &= \inf_{\boldsymbol{r}} \inf \Big\{ (\Psi, H_N \Psi) \mid \Psi \\ &\qquad \in \mathcal{H}_N^{\mathrm{F}} \cap C^\infty(\mathbb{R}^{3N}; \mathbb{C}^{2^N}), \|\Psi\| = 1 \Big\} \end{aligned} \quad [2]$$

and likewise for the ground-state energy $E(\boldsymbol{z}, N, K)$ on the full space $\mathcal{H}_N$. Clearly, $E^{\mathrm{F}}(\boldsymbol{z}, N, K) \ge E(\boldsymbol{z}, N, K)$. It turns out that the energy $E(\boldsymbol{z}, N, K)$ is the same as one would get by restricting to symmetric functions instead of antisymmetric ones. Therefore, the energy $E(\boldsymbol{z}, N, K)$ is often referred to as the lowest possible energy for bosonic particles.

The Hamiltonian $H_N$ is an unbounded operator and we must discuss its domain to be able to talk about its spectrum. Also, it should be self-adjoint. It turns out that these questions are intimately related to stability. The operator $H_N$ is well defined on smooth (i.e., $C^\infty$) functions. Thus, the last definition of $E^{\mathrm{F}}(\boldsymbol{z}, N, K)$ in [2] is meaningful. If this ground-state energy is finite (i.e., not $-\infty$), then the Hamiltonian has an extension, the Friedrichs' extension, to a

self-adjoint operator with the property that the second equality in [2] holds.

In the definition of $E^{\mathrm{F}}$, we have minimized over all the positions $\boldsymbol{r}$ of the nuclei. Even though the nuclear dynamics is not considered, one is still interested in finding the lowest possible energy independent of where they are located.

**Theorem 1** (Stability of the first kind). *For all* $N$, $K$, *and* $z$, *we have*

$$E(z, N, K) > -\infty$$

**Theorem 2** (Stability of matter). *There exists a constant* $C_{|z|} > 0$ *depending only on* $|z| = \max\{z_1, \ldots, z_k\}$ *such that*

$$E^{\mathrm{F}}(z, N, K) \geq -C_{|z|}(N + K)$$

The constant $C_{|z|}$ bounds the binding energy per particle. In the case of hydrogen atoms, when $|z| = 1$, Dyson and Lenard arrived at a bound with $C_1 \approx 10^{14}$ Ry. Lieb and Thirring arrive at $C_1 \approx 5 = 10$ Ry. Since the binding energy of a single hydrogen atom is 1 Ry, it is easy to see that one must have $C_1 \geq 1/4$. Over the years, there have been some improvements on the estimated value of this constant in the theory of stability of matter.

That the Pauli exclusion principle, that is, the fermionic character of the electrons, is necessary for stability of matter is a consequence of the next theorem.

**Theorem 3** (the $N^{5/3}$ law for bosons). *If* $N = K$ *and* $z_1 = \cdots = z_K = z > 0$, *then there exist constants* $C_\pm > 0$ *depending on* $z$ *such that*

$$-C_- N^{5/3} < E(z, N, N) < -C_+ N^{5/3}$$

It is the superlinear (exponent 5/3) behavior in $N$ of the upper bound that violates stability of matter. This upper bound was proved by Lieb (1979) by a fairly simple variational argument. The lower bound above, which shows that the exponent 5/3 is optimal, was proved by Dyson and Lenard (1968) in their original paper on stability of matter.

This theorem leaves open the possibility that the stability of matter could be recovered by introducing finite nuclear masses. That this, indeed, is not the case was proved by Dyson (1967) by a complicated variational argument based on the Bogolubov pair theory for superfluid helium. We now add the kinetic energy $\sum_{k=1}^{K} -(1/2)\Delta_{r_k}$ of the nuclei (assuming, for simplicity, that they have the same mass as the electrons) to the Hamiltonian $H_N$ and consider the case where $z_1 = z_2 = \cdots = z_K = 1$. We denote the ground-state energy over the space $L^2(\mathbb{R}^{3(N+K)})$ (ignoring spin) by $\widetilde{E}(N,K)$. Then, Dyson proved that

$$\min_{N+K=M} \widetilde{E}(N, K) \leq -CM^{7/5}$$

for some constant $C > 0$. It was later shown by Conlon *et al.* (1988) that the exponent 7/5 is indeed optimal. Dyson (1967) made a conjecture for the precise asymptotic behavior of this energy. This conjecture, which was proved by Lieb and Solovej (2005) and Solovej (2004), is given in the next theorem.

**Theorem 4** (Dyson's 7/5-law for the charged Bose gas).

$$\lim_{M\to\infty} \min_{N+K=M} \frac{\widetilde{E}(N, K)}{M^{7/5}} = \inf\left\{\frac{1}{2}\int |\nabla\phi|^2 - J\int \phi^{5/2} \,|\, \phi \geq 0, \int \phi^2 = 1\right\} \quad [3]$$

*where*

$$J = \left(\frac{4}{\pi}\right)^{3/4} \frac{\Gamma(1/2)\Gamma(3/4)}{5\Gamma(5/4)}$$

## Generalizations of Stability of Matter

Over the years, generalizations of stability of matter including relativistic effects and interactions with the electromagnetic field have been attempted. Since the relativistic Dirac operator is not bounded below, we cannot simply replace the standard nonrelativistic kinetic energy operator $T_j = -(1/2)\Delta_j$ by the free Dirac operator.

Relativistic effects have been included by considering the (pseudo) relativistic kinetic energy

$$T_j^{\mathrm{Rel}} = \sqrt{-c^2\Delta_j + c^4} - c^2$$

In the units used in this article, the physical value of the speed of light $c$ is approximately 137 or, more precisely, the reciprocal of the fine-structure constant $\alpha$.

For this relativistic kinetic energy, Lieb and Yau (1988) proved that stability of matter holds in the sense formulated in Theorem 2 if $\alpha(=c^{-1})$ is small enough and $\max_j\{z_j\}\alpha \leq 2/\pi$. It is known here that the value $2/\pi$ is the best possible, since it is so for the one-atom case. The one-atom case had been studied by Herbst. The corresponding case of a one-electron molecule was studied by Lieb and Daubechies. Less optimal results on the stability of matter with relativistic kinetic energy had been

obtained prior to the work of Lieb and Yau by Conlon and later by Fefferman and de la Llave. References to these works can be found in the work of Lieb and Yau (1988).

The relativistic kinetic energy $T_j^{\text{Rel}}$ agrees with the free Dirac operator on the positive spectral subspace of the free Dirac operator (i.e., a subspace of $L^2(\mathbb{R}^3;\mathbb{C}^4)$). Therefore, the stability of matter follows if $T_j$ is replaced by the free Dirac operator and if one restricts to the Hilbert space obtained as in [2] but with $L^2(\mathbb{R}^3;\mathbb{C}^2)$ replaced by the positive spectral subspace of the free Dirac operator. This formulation is often referred to as the "no-pair" model. In the usual Dirac picture, the negative spectral subspace, the Dirac sea, is occupied. As long as one ignores pair creation, only the positive spectral subspace is available.

Magnetic fields may be included by considering the "magnetic kinetic energy"

$$T_j^{\text{Mag}} = \tfrac{1}{2}\left(-\mathrm{i}\nabla_j - c^{-1}\boldsymbol{A}(x_j)\right)^2$$

It turns out that the stability of matter theorem (Theorem 2) holds for all magnetic vector potentials $\boldsymbol{A}:\mathbb{R}^3 \to \mathbb{R}^3$ with a constant $C_{|z|}$ independent of $\boldsymbol{A}$. This is, therefore, also the case if we consider the magnetic field (or rather the vector potential) as a dynamic variable and add the (positive) field energy

$$\mathcal{U} = \frac{1}{8\pi}\int_{\mathbb{R}^3} |\nabla \times \boldsymbol{A}(x)|^2\,\mathrm{d}x \qquad [4]$$

to the Hamiltonian. The resulting Hamiltonian describes a charged spinless particle interacting with a classical electromagnetic field.

A more complicated situation is described by the "magnetic Pauli kinetic energy"

$$T_j^{\text{Pauli}} = \tfrac{1}{2}((-\mathrm{i}\nabla_j - c^{-1}\boldsymbol{A}(x_j))\cdot\boldsymbol{\sigma}_j)^2$$

where the coupling of the spin to the magnetic field is included through the vector of $2\times 2$ Pauli matrices acting on the spin components of particle $j$, that is, $\boldsymbol{\sigma} = (\sigma_1, \sigma_2, \sigma_3)$, with

$$\sigma_1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \sigma_2 = \begin{pmatrix} 0 & -\mathrm{i} \\ \mathrm{i} & 0 \end{pmatrix}, \quad \sigma_3 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$$

For the Pauli kinetic energy, stability of matter will not hold independently of the magnetic field (or even for a fixed unbounded magnetic field) unless the field energy $\mathcal{U}$ in [4] is included in the Hamiltonian. If the field energy is included, stability of matter holds independently of the magnetic field, that is, even if one minimizes over the dynamic variable $\boldsymbol{A}$, if $\alpha(=c^{-1})$ and $\max_j\{z_j\}\alpha^2$ are small enough. This was proved by Fefferman (1997) and by Lieb *et al.* (1995). The latter result includes the physical value of $\alpha$. The fact that a bound on $\alpha$ is needed had been proved by Loss and Yau. Stability for a one-electron atom had been proved in this model by Fröhlich, Lieb, and Loss. The many-electron atom and the one-electron molecule had been studied by Lieb and Loss. Most relevant references may be found in the work of Lieb *et al.* (1995).

The possibility of quantizing the magnetic field has also been studied. In this case, one must introduce an ultraviolet cutoff in the momentum modes of the vector potential. Stability of matter in the resulting model of (ultraviolet cutoff) QED coupled to non-relativistic matter was proved by Fefferman *et al.* improving results of Bugliaro, Fröhlich, and Graf.

Finally, one may include both relativistic effects and electromagnetic interactions. Let us first discuss the case of classical electromagnetic fields. If instead of the Pauli kinetic energy one uses the Dirac operator with a magnetic vector potential then there would be no lower bound on the energy. But, as previously described, one can study a no-pair formulation of relativistic particles coupled to electromagnetic fields. The question arises which subspace of $L^2(\mathbb{R}^3;\mathbb{C}^4)$ one should restrict to (i.e., which subspace is filled and which one is available). There are two obvious choices. Either one should, as before, restrict to the positive spectral subspace of the free Dirac operator or one should restrict to the positive spectral subspace of the magnetic Dirac operator. It is proved by Lieb *et al.* (1997) that the former choice leads to instability, whereas stability of matter holds for the latter choice under some conditions on $\alpha$ and $\max_j\{z_j\}$. Stability requires that the field energy $\mathcal{U}$ is included in the Hamiltonian. It then holds independently of the magnetic field.

This final stability result also holds if the magnetic field is quantized with an ultraviolet cutoff as proved by Lieb and Loss (2002).

The no-pair model even with the ultraviolet cutoff quantized field is not fully relativistically invariant. As mentioned above, there is still no mathematical formulation of QED, a fully relativistically invariant model for quantum particles interacting with electromagnetic fields.

## The Proof of Stability of the First Kind

The proof of stability of the first kind will now be sketched for charged quantum systems.

As mentioned in the introduction, stability of the first kind is a consequence of the uncertainty principle. Contrary to what is often stated in physics textbooks, stability does not follow from the Heisenberg formulation of the uncertainty principle.

A mathematically more flexible formulation is provided by the classical Sobolev inequality, which states that for all square-integrable functions $\psi \in L^2(\mathbb{R}^3)$, one has

$$\int |\nabla\psi|^2 \geq C_S \left(\int |\psi|^6\right)^{1/3} \qquad [5]$$

for $C_S > 0$. It follows from this inequality that for any attractive potential $V$, there is a lower bound on the energy expectation

$$\begin{aligned}&\left(\psi, \left(-\frac{1}{2}\Delta - V\right)\psi\right)\\ &\quad = \frac{1}{2}\int |\nabla\psi|^2 - \int V|\psi|^2 \geq \frac{1}{2} C_S \left(\int \psi^6\right)^{1/3}\\ &\quad - \left(\int V^{5/2} \int |\psi|^2\right)^{2/5} \left(\int |\psi|^6\right)^{1/5}\\ &\quad \geq -C \int V^{5/2} \int |\psi|^2\end{aligned}$$

for some $C > 0$. Thus, the lowest possible energy of one particle moving in the potential $V$ is bounded below by $-C\int V^{5/2}$. For $N$ (noninteracting) particles, the lower bound is $-CN\int V^{5/2}$. This holds whether or not the particles have spin. If, more generally, the potential can be written as $V = U + W, U, W \geq 0$, where $\int U^{5/2} < \infty$ and $W$ is bounded $W \leq \|W\|_\infty$, then the energy of $N$ noninteracting particles moving in the potential $V$ is bounded below by

$$-NC \int U^{5/2} - N\|W\|_\infty \qquad [6]$$

For the Hamiltonian $H_N$ from [1], one can get a lower bound on the energy $E(z, N, K)$ by ignoring all the positive potential terms, that is, the last two sums in [1]. The remaining Hamiltonian describes $N$ independent particles moving in the potential

$$-V = -\sum_{k=1}^{K} \frac{z_k}{|x - r_k|} = -\sum_{k=1}^{K} (U_k + W_k)$$

where $U_k$ is the restriction of $z_k/|x - r_k|$ to the set $|x - r_k| < R$ for some $R > 0$ and $W_k$ is the restriction to the complementary set. Using [6], one can easily see that the energy expectation is bounded below by

$$\begin{aligned}&- C\,N\,K^{5/2} \max_k\{z_k\}^{5/2} R^{1/2} - N\,K \max_k\{z_k\} R^{-1}\\ &\quad = -C'\,N\,K^2 \max_k\{z_k\}^2\end{aligned}$$

where we have made the optimal choice for $R \sim (K \max_k \{z_k\})^{-1}$.

This finite lower bound on the energy proves the stability of the first kind, but it clearly does not have the form required for the stability of the second kind.

## The Proof of Stability of Matter

The proof of stability of the first kind presented in the previous section must be improved in two ways in order to conclude the stability of matter.

For fermions, it turns out that the lower bound in [6] can be improved in such a way that there is no factor $N$ in the first term. This is the content of the bound of Lieb and Thirring discussed in the introduction.

**Theorem 5** (Lieb–Thirring inequality 1975). *The sum of all the negative eigenvalues of the operator* $-(1/2)\Delta - V(x)$ *is bounded below by*

$$-L_{\mathrm{LT}} \int V^{5/2}$$

*for some constant* $L_{\mathrm{LT}} > 0$

For $N$ noninteracting fermions moving in the potential $V$, the lowest possible energy is given by the sum of the $N$ lowest eigenvalues of the operator in the above theorem. Thus, the theorem gives a lower bound on this energy independently of $N$.

The second point where the argument from the previous section has to be improved is the control of the electrostatic energy. In the above discussion, all repulsive terms have simply been ignored. For stability of matter, a much more delicate bound is needed. Many versions of such bounds have been given going back to the work of Onsager (1939). Here, a result of Baxter (1980) will be used.

**Theorem 6** (Baxter's correlation estimate). *For all positions* $x_i, \ldots, x_N, r_1, \ldots, r_K \in \mathbb{R}^3$ *and all charges* $z_1, \ldots, z_K > 0$, *we have the pointwise inequality*

$$\begin{aligned}&-\sum_{k=1}^{K}\sum_{i=1}^{N} \frac{z_k}{|x_i - r_k|} + \sum_{1 \leq i < j \leq N} \frac{1}{|x_i - x_j|}\\ &\quad + \sum_{1 \leq k < \ell \leq K} \frac{z_k z_\ell}{|r_k - r_\ell|} \geq -\sum_{i=1}^{N} V(x_i)\end{aligned}$$

*where* $V(x) = (1 + 2\max_k\{z_k\}) \max_k \{|x - r_k|^{-1}\}$.

This theorem simply states that, for a lower bound, one can replace the full electrostatic Coulomb energy by the energy of independent electrons moving in the potential where they always see only the closest nuclei (with a modified charge). Baxter (1980) used probabilistic techniques to prove the inequality. An improved version of the inequality was given by Lieb and Yau (1988), with an analytic proof.

Similarly to the argument in the previous section, one can write $V(x) = U(x) + W(x)$, where $U$ is the restriction of $V$ to the set where $\min_k \{|x - r_k|\} < R$ for some $R > 0$ and $W$ is the restriction to the complementary set. It then follows from Baxter's correlation estimate and the Lieb–Thirring inequality that the lowest eigenvalue of the Hamiltonian $H_N$ on the fermionic Hilbert space $\mathcal{H}_N^{\mathrm{F}}$ is bounded below by

$$\begin{aligned} &-L_{\mathrm{LT}} \int U^{5/2} - N(1 + 2\max_k\{z_k\})R^{-1} \\ &\geq -C(1 + 2\max_k\{z_k\})^{5/2} K R^{1/2} \\ &\quad - N(1 + 2\max_k\{z_k\})R^{-1} \\ &= -C'(1 + 2\max_k\{z_k\})^2 (N + K) \end{aligned}$$

where $R \sim (1 + 2\max_k\{z_k\})^{-1}$. This lower bound is linear in the total particle number $N + K$, as required by stability of matter.

## From Thomas–Fermi Theory to Stability of Matter

In this final section, the proof of stability of matter by Lieb and Thirring (1975), where they use the Thomas–Fermi theory, is discussed briefly. First note that there is a dual formulation of the Lieb–Thirring inequality theorem (Theorem 5), which makes the connection to the Sobolev inequality [5] much more transparent.

**Theorem 7** (Lieb–Thirring inequality as a kinetic energy bound). *For any normalized antisymmetric (fermionic) wave function $\Psi \in \mathcal{H}_N^{\mathrm{F}}$ we have with $C_{\mathrm{LT}} = \frac{3}{5}(\frac{2}{5}L_{\mathrm{LT}}^{-1})^{2/3}$ the following lower bound on the kinetic energy*:

$$\begin{aligned} &\sum_{i=1}^{N} \frac{1}{2} \int_{\mathbb{R}^{3N}} \|\nabla_i \Psi(x_1, \ldots, x_N)\|^2 \, \mathrm{d}x_1 \cdots \mathrm{d}x_N \\ &\quad \geq C_{\mathrm{LT}} \int_{\mathbb{R}^3} \rho(x)^{5/3} \, \mathrm{d}x \end{aligned}$$

*where $\|\cdot\|$ is the norm in spin space $(\mathbb{C}^{2^N})$ and the one-electron density is given by*

$$\rho(x) = N \int_{\mathbb{R}^{3(N-1)}} \|\Psi(x, x_2, \ldots, x_N)\|^2 \, \mathrm{d}x_2 \cdots \mathrm{d}x_N$$

This estimate follows immediately from Theorem 5, which implies that

$$\sum_{i=1}^{N} \frac{1}{2} \int \|\nabla_i \Psi\|^2 - \int \rho V \geq -L_{\mathrm{LT}} \int V^{5/2}$$

To arrive at Theorem 7, simply choose $V = ((2/5(L_{\mathrm{LT}}^{-1}\rho)^{2/3}$.

One should compare the Lieb–Thirring kinetic energy bound with the expression $(3/10)(3\pi^2)^{2/3}\rho^{5/3}$ for the (thermodynamic) energy density of a free Fermi gas. One of the yet unproven conjectures is that the Lieb–Thirring bound holds with $C_{\mathrm{LT}}$ replaced by the free Fermi constant $(3/10)(3\pi^2)^{2/3}$.

The idea in the Lieb–Thirring proof of stability of matter is to bound the energy below by an expression depending only on the one-electron density. Theorem 7 achieves this for the kinetic energy. What is missing is a lower bound on the electrostatic Coulomb energy depending only on the density. One can show (see Lieb (1976) or Lieb and Thirring (1975)) that, except for an error of the form "$-\mathrm{const} \times N$," the total energy expectation $(\Psi, H_N \Psi)$ may be bounded below by

$$\begin{aligned} &C_{\mathrm{LT}} \int \rho^{5/3} - \sum_{k=1}^{K} \int \rho(x) \frac{z_k}{|x - r_k|} \, \mathrm{d}x \\ &\quad + \frac{1}{2} \iint \frac{\rho(x)\rho(y)}{|x - y|} \, \mathrm{d}x \, \mathrm{d}y + \sum_{1 \leq k < \ell \leq K} \frac{z_k z_\ell}{|r_k - r_\ell|} \end{aligned} \qquad [7]$$

Here, as before, $\rho$ is the one-electron density of the $N$-body wave function $\Psi$. The expression [7] is the famous Thomas–Fermi energy functional. It has been studied rigorously by Lieb and Simon (1977). The Thomas–Fermi energy is the infimum of the expression (7) over all $\rho$ with $\int \rho = N$. One of the important results about the Thomas–Fermi energy is Teller's no-binding theorem (Lieb and Simon 1977). It states that in Thomas–Fermi theory atoms do not bind to form molecules. This means that the Thomas–Fermi energy is greater than the sum of the individual atomic energies (these energies in turn depend only on the nuclear charges).

The above Thomas–Fermi lower bound on the energy expectation $(\Psi, H_N \Psi)$ together with the no-binding theorem implies stability of matter.

The generalizations to stability of matter discussed earlier are proved in a way similar to the proof presented in the previous section.

# Stability of Minkowski Space

**S Klainerman**, Princeton University, Princeton, NJ, USA

## Introduction

The Minkowski space, which is the simplest solution of the Einstein field equations in vacuum, that is, in the absence of matter, plays a fundamental role in modern physics as it provides the natural mathematical background of the special theory of relativity. It is most reasonable to ask whether it is stable under small perturbations. In other words, can arbitrary small perturbations of flat initial conditions lead to developments which are radically different, in the large, from the flat Minkowski space? It turns out to be a highly nontrivial problem as the Einstein equations are of a quasilinear hyperbolic character. Typical systems of this type, in three space dimensions, do form singularities in finite time even for small disturbances of their trivial initial data. To avoid finite-time singularities, we must require that sufficiently small perturbations of Minkowski space are geodesically complete. This, however, is not enough; one should also insist that the corresponding spacetimes become flat along all possible directions, that is, globally asymptotically flat. This is measured by the decay of the curvature tensor to zero. The precise rate of decay is also of interest. One expects that various null-frame components of the curvature tensor decay at different rates along outgoing null hypersurfaces; this goes under the name of "peeling estimates." It turns out in fact that we cannot prove geodesic completeness without establishing at the same time sufficiently fast rates of decay to flatness corresponding to at least some peeling.

The problem of stability of Minkowski space is intimately related to that of describing the asymptotic properties of the gravitational field at large distances from an isolated, weakly radiating physical system. Precise laws of gravitational radiation can be deduced from the assumption that the spacetime $(\boldsymbol{M}, \boldsymbol{g})$ under consideration can be conformally compactified by adding a boundary $\mathcal{S}$, called skry, to $\boldsymbol{M}$ so that an appropriate conformal rescaling of $\boldsymbol{g}$ can be extended smoothly to the new manifold $(\hat{\boldsymbol{M}}, \hat{\boldsymbol{g}})$ with boundary. In reality, the compactified spacetime cannot be smooth at the particular point $i^0$ corresponding to spacelike infinity. A spacetime

$(\boldsymbol{M}, \boldsymbol{g})$ is called asymptotically simple (AS) if its conformal completion is smooth everywhere except $i^0$ and every null geodesic intersects $\mathcal{S}$ at precisely two endpoints. The AS assumption allows one to derive precise decay asymptotic for various curvature components of $(\boldsymbol{M}, \boldsymbol{g})$ along null geodesics which are referred to as strong peeling. The obvious questions raised by this procedure are: do there exist nontrivial AS spacetimes and, if so, do they contain a sufficiently large class of radiating spacetimes including those which appear in all relevant applications?

Clearly, the two problems mentioned above are related but not equivalent. Asymptotically simple spacetimes verify strong peeling, in particular they are globally asymptotically flat, that is, their curvature tensor tends to zero along all geodesics. Yet, it is perfectly possible that arbitrarily small perturbations of the Minkowski space are geodesically complete and globally asymptotically flat without being asymptotically simple.

The first global stability result of the Minkowski metric was proved by Christodoulou and Klainerman (1993). Their result proves sufficiently strong peeling estimates to allow one to derive the most important properties of gravitational radiation, such as the Bondi mass-law formula, but not as strong as those consistent with asymptotic simplicity. A companion result was proved by Klainerman and Nicolò (2003). Recently, Rodnianski and Lindblad (submitted) have obtained a surprising global stability of Minkowski result for the Einstein vacuum equations in the Lorentz gauge, which provides considerable weaker peeling than Christodoulou and Klainerman (1993) and Klainerman and Nicolò (1999) but is much easier to prove.

The goal of this article is to describe various results obtained since the early 1980s concerning both aspects of the problem of stability of Minkowski mentioned above.

## Initial Data Formulation

The proper mathematical context for the stability of Minkowski is that provided by the initial-value problem for vacuum solutions to the Einstein field equations, that is, Ricci flat spacetimes $(\boldsymbol{M}, \boldsymbol{g})$, $\boldsymbol{R}_{\mu\nu} = 0$. We recall the following simple definitions:

**Definition 1** An initial data set is a triplet $(\Sigma, g, k)$ consisting of a three-dimensional complete Riemannian manifold $(\Sigma, g)$ and a 2-covariant symmetric tensor $k$ on $\Sigma$ satisfying the constraint equations:

$$\nabla^j k_{ij} - \nabla_i \, tr_g \, k = 0, \qquad R - |k|^2 + (\mathrm{tr}\, k)^2 = 0$$

where $\nabla$ is the covariant derivative, $R$ the scalar curvature of $(\Sigma, g)$. An initial data set is said to be maximal if $\mathrm{tr}_g \, k = 0$. This is a gauge condition which can be imposed without loss of generality. For simplicity we shall assume, throughout this article, that all initial data sets we consider are maximal.

**Definition 2** An initial data set is said to be flat, or trivial, if it corresponds to a complete spacelike hypersurface in Minkowski space with its induced metric and second fundamental form. An initial data set is said to be asymptotically flat if there exists a system of coordinates $(x^1, x^2, x^3)$ defined in a neighborhood of infinity on $\Sigma$, with $r = \sqrt{(x^1)^2 + (x^2)^2 + (x_3)^2}$, relative to which the metric $g$ approaches the Euclidian metric and $k$ approaches zero as $r \to \infty$. We assume, for simplicity, that $\Sigma$ has only one end. A neighborhood of infinity means the complement of a sufficiently large compact set on $\Sigma$.

**Remark 1** Because of the constraint equations, the asymptotic behavior cannot be arbitrarily prescribed. A precise definition of asymptotic flatness has to involve the ADM mass of $(\Sigma, g)$. Taking the mass into account, we write

$$g_{ij} = \left(1 + \frac{2M}{r}\right)\delta_{ij} + o(r^{-1})$$

According to the positive-mass theorem, $M \geq 0$ and $M = 0$ implies that the initial data set is flat.

**Definition 3** We say that an initial data set is strongly asymptotically flat if, for some $\delta 1/2$, relative to the coordinate system mentioned above,

$$g_{ij} - \left(1 + \frac{2M}{r}\right)\delta_{ij} = O(r^{-1-\delta}), \quad k_{ij} = O(r^{-2-\delta})$$

as $r \to \infty$

Moreover, every derivative of $g - (1 + 2M/r)\delta$ and $k$ improves the asymptotics by one.

**Definition 4** A Cauchy development of an initial data set $(\Sigma, g, k)$ is a spacetime manifold $(\boldsymbol{M}, \boldsymbol{g})$ satisfying the Einstein equations together with an embedding $i: \Sigma \longrightarrow \boldsymbol{M}$ such that $i_*(g), i_*(k)$ are the first and second fundamental forms of $i(\Sigma)$ in $\boldsymbol{M}$. A development is required to be also globally hyperbolic (which means that $i(\Sigma)$ is a Cauchy hypersurface, i.e., each causal curve in $\boldsymbol{M}$ intersects $i(\Sigma)$ at precisely one point) in order to assure the unique dependence of solutions on the data. A future development of $(\Sigma, g, k)$ consists of a globally hyperbolic manifold $(\boldsymbol{M}, \boldsymbol{g})$ with boundary, satisfying the Einstein equations, and an embedding $i$ as before which identifies $\Sigma$ to the boundary of $\boldsymbol{M}$.

The most primitive question asked about the initial-value problem, solved in a satisfactory way, for very large classes of evolution equations, is that of local existence and uniqueness of solutions. For the Einstein equations, this type of result was first established by Bruhat (1952) with the help of wave coordinates which allowed her to cast the Einstein equations in the form of a system of nonlinear wave equations to which one can apply the standard theory of symmetric hyperbolic systems. A stronger result, due to Hughes *et al.* (1976), states the following:

**Theorem 1** *Let* $(\Sigma, g, k)$ *be an initial data set for the Einstein vacuum equations. Assume that* $\Sigma$ *can be covered by a locally finite system of coordinate charts* $U_\alpha$ *related to each other by* $\mathbf{C}^1$ *diffeomorphisms, such that* $(g,k) \in H^s_{\mathrm{loc}}(U_\alpha) \times H^{s-1}_{\mathrm{loc}}(U_\alpha)$ *with* $s > 5/2$. *Then there exists a unique (up to an isometry) globally hyperbolic, Hausdorff, development (***M***, g) for which* $\Sigma$ *is a Cauchy hypersurface.*

In Theorem 1, the uniqueness up to an isometry requires additional regularity, $s > (5/2) + 1$, on the data. One has uniqueness, however, without additional regularity for the reduced Einstein equations system in wave coordinates.

**Remark 2** In the case of nonlinear systems of differential equations, the local existence and uniqueness result leads, through a straightforward extension argument, to a global result. The formulation of the same type of result for the Einstein equations is a little more subtle; it was done by Bruhat and Geroch.

**Theorem 2** (Bruhat–Geroch). *For each smooth initial data set, there exists a unique maximal future development.*

Thus, any construction, obtained by an evolutionary approach from a specific initial data set, must be necessarily contained in its maximal development. This may be said to solve the problem of global existence and uniqueness in general relativity. This is of course misleading, for equations defined in a fixed background global is a solution which exists for all time. In general relativity, however, we have no such background as the spacetime itself is the unknown. The connection with the classical meaning of a global solution requires a special discussion concerning the proper time of timelike geodesics; all further questions may be said to concern the qualitative properties of the maximal development. The central issue is that of existence and character of singularities. First, we can define a regular maximal development as one which is complete in the sense that all future timelike and null geodesics can be indefinitely extended relative to their proper time (or affine parameter in the case of null geodesics). If the initial data set is sufficiently far off from the trivial one, the corresponding future development may not be regular. This is the content of the following well-known theorem of Penrose (1979).

**Theorem 3** *If the manifold support of an initial data set is noncompact and contains a closed trapped surface, the corresponding maximal development is incomplete.*

## Stability of Minkowski Space

At the opposite end of Penrose's trapped-surface condition, the problem of stability of Minkowski space concerns the development of asymptotically flat initial data sets which are sufficiently close to the trivial one. Although it may be reasonable to expect the existence of a sufficiently small neighborhood of the trivial initial data set, in an appropriate topology, such that all corresponding developments are geodesically complete and globally asymptotically flat, such a result was by no means preordained. First, all known explicit asymptotically flat solutions of the Einstein vacuum equations, that is, the Kerr family, are singular. The attempts to construct nonexplicit, dynamic, solutions based on the conformal compactification method, due to Penrose (1962), were obstructed by the irregular behavior of initial data sets at $i^0$. (The problem is that the singularity at $i^0$ could propagate and thus destroy the expected smoothness of scry. This problem has been recently solved by constructing initial data sets which are precisely stationary at spacelike infinity.) Finally, the attempts, using partial differential equation hyperbolic methods, to extend the classical local result of Bruhat ran into the usual difficulties of establishing global in time existence to solutions of quasilinear hyperbolic systems. Indeed, as mentioned above, the wave coordinate gauge allows one to express the Einstein vacuum equations in the form of a system of nonlinear wave equations which does not satisfy Klainerman's null condition (the null condition (Klainerman 1983, 1986) identifies an important class of quasilinear systems of wave equations in four spacetime dimensions for which one can prove global in time existence of small solutions) and thus was sought to lead to formation of singularities. (The conjectured singular behavior of wave coordinates was sought, however, to reflect only the instability of the specific choice of gauge condition and not a true singularity of the equations.) According to Bruhat (personal communication),

Einstein himself had reasons to believe that the Minkowski space may not be stable. The problem of stability of the Minkowski space was first settled by Christodoulou and Klainerman (1990).

**Theorem 4** (Global stability of Minkowski). *Any asymptotically flat initial data set which is sufficiently close to the trivial one has a complete maximal future development.*

A related result (Theorem 5) proved recently by Klainerman and Nicolò (2003a), solves the problem of radiation for arbitrary asymptotically flat initial data sets: a proof the result below can also be derived, indirectly, from Christodoulou and Klainerman (1993). The proof of Klainerman and Nicolò (2003a) avoids, however, a great deal of the technical complications of this proof.

**Theorem 5** *For any, suitably defined, asymptotically flat initial data set* $(\Sigma, g, k)$ *with maximal future development* $(\mathbf{M}, \mathbf{g})$, *one can find a suitable domain* $\Omega_0 \subset \Sigma$ *with compact closure in* $\Sigma$ *such that the boundary* $\mathcal{D}_0^+$ *of its domain of influence* $\mathcal{C}^+(\Omega_0)$, *or causal future of* $\Omega$, *in* $\mathbf{M}$ *has complete null geodesic generators with respect to the corresponding affine parameters.*

Both the results of Christodoulou–Klainerman and Klainerman–Nicolò prove in fact a lot more than stated above. They provide a wealth of information concerning the behavior of null hypersurfaces as well as the rate at which various components of the Riemann curvature tensor approach zero along timelike and null geodesics. Here are more precise versions for Theorems 4 and 5.

**Theorem 4** (Expanded version). *Assume that* $(\Sigma, g, k)$ *is maximal and strong asymptotically flat,* $g - (1 + 2M/r)\delta = 0(r^{-3/2})$, $k = 0(r^{-5/2})$ *plus an appropriate global smallness assumption. We can construct complete spacetime* $(M, g)$ *together with a maximal foliation* $\Sigma_t$ *given by the level hypersurfaces of a time function t and null foliation* $C_u$, *given by the level hypersurfaces of an outgoing optical function u such that relative to an adapted null frame* $e_4 = L$, $e_3 = \underline{L}$, *and* $(e_a)_{a=1,2}$ *we have, along the null hypersurfaces* $C_u$ *the weak peeling decay,*

$$\begin{aligned} \alpha_{ab} &= R(L, e_a, L, e_b) = O(r^{-7/2}) \\ 2\beta_a &= R(L, \underline{L}, L, e_a) = O(r^{-7/2}) \\ 4\rho &= R(L, \underline{L}, L, \underline{L}) = O(r^{-3}) \\ 4\sigma &= {}^{*}R(L, \underline{L}, L, \underline{L}) = O(r^{-3}) \\ 2\underline{\beta}_a &= R(L, \underline{L}, L, e_a) = O(r^{-2}) \\ \underline{\alpha}_{ab} &= R(\underline{L}, e_a, \underline{L}, e_b) = O(r^{-1}) \end{aligned} \quad [1]$$

*as* $r \to \infty$ *with* $4\pi r^2 = \mathrm{Area}(S_{t,u} = \Sigma_t \cap C_u)$. *Also,* $\rho - \bar{\rho}, \sigma = O(r^{-7/2})$, *with* $\bar{\rho}$ *the average of* $\rho$ *over the compact 2-surfaces* $S_{t,u} = \Sigma_t \cap C_u$.

Three points are noteworthy. (1) The outgoing optical solution refers to the solution of the Eikonal equation $\mathbf{g}^{\alpha\beta}\partial_a u \partial_\beta u = 0$ whose level hypersurfaces $C_u$ intersect $\Sigma_t$ in expanding wave fronts for increasing $t$; (2) the generators $L$ and $\underline{L}$ are given by: $L = -\mathbf{g}^{\alpha\beta}\partial_\beta u \partial_\alpha$, the null geodesic generator of $C_u$; $\underline{L}$ is then the null conjugate of $L$, perpendicular to $S_{t,u} = C_u \cap \Sigma_t$; and (3) $e_a$ is an orthonormal frame on $S_{t,u}$.

**Theorem 5** (Expanded version). *For any asymptotically flat initial data sets* $(\Sigma, g, k)$, *verifying the same asymptotically flat conditions as in Theorem 4 one can find a suitable domain* $\Omega_0 \subset \Sigma$ *with compact closure in* $\Sigma$ *such that its future domain of influence* $\mathcal{C}^+(\Omega_0)$ *can be foliated by two null foliations; one outgoing* $C(u)$ *whose leaves are complete towards the future and the second one* $\underline{C}(\underline{u})$ *which is incoming. Let* $S(u, \underline{u}) = C(u) \cap \underline{C}(\underline{u})$ *denote the compact 2-surfaces of intersection between the outgoing and incoming null hypersurfaces, whose area is denoted by* $4\pi r^2$, *and consider an adapted null frame (that is, L is a the geodesic null generator of* $C(u)$, $\underline{L}$ *its null conjugate perpendicular to* $S(u, \underline{u})$, *and* $e_a$ *an orthonormal frame on* $S(u, \underline{u})$) $L, \underline{L}, (e_a)_{a=1,2}$ *at every point along an outgoing null cone* $C(u)$. *Then, denoting by* $\alpha, \beta, \rho, \sigma, \underline{\beta}, \underline{\alpha}$ *the null components of the curvature tensor, as in Theorem 5, we have, along* $C(u)$ *as* $r \to \infty$,

$$\begin{aligned} &\alpha, \beta, \rho - \bar{\rho}, \sigma = O(r^{-7/2}), \quad \underline{\beta} = O(r^{-2}), \\ &\underline{\alpha} = O(r^{-1}) \end{aligned} \quad [2]$$

Observe that the rates of decay in [1] and [2] are the same. This will be referred to as weak peeling to distinguish from the rates of decay compatible with asymptotic simplicity, that is,

$$\begin{aligned} &\alpha = O(r^{-5}), \quad \beta = O(r^{-4}) \\ &\rho, \sigma = O(r^{-3}), \quad \underline{\beta} = O(r^{-2}), \quad \underline{\alpha} = O(r^{-1}) \end{aligned} \quad [3]$$

to which we shall refer as strong peeling. We shall discuss more about these in the next section, following a review, of a recent result of Lindblad–Rodnianski.

Even the expanded forms of Theorems 4 and 5 stated here do not exhaust, all the information provided by global stability results in Christodoulou and Klainerman (1993) and Klainerman and Nicolò (2003a). Of particular interest are the main asymptotic conclusions which can be derived with the help of these information, the most

important being the Bondi mass-law formula which calculates the gravitational energy radiated at null infinity.

The simplest gauge condition in which the hyperbolic character of the Einstein field equations are easiest to exhibit is the wave coordinate condition; that is, one solves the Einstein vacuum equations relative to a special system of coordinates $x^\alpha$ which satisfy the equation $\Box \mathbf{g} x^\alpha = 0$. Then, denoting by $h_{\alpha\beta} = \mathbf{g}_{\alpha\beta} - \mathbf{m}_{\alpha\beta}$ with $\mathbf{m}$ the standard Minkowski metric, we obtain the following system of quasilinear wave equations in $h$,

$$g^{\mu\nu}\partial_\mu\partial_\nu h = N(h, \partial h) \qquad [4]$$

with $N(h, \partial h)$ a nonlinear term, quadratic in $\partial h$, which can be exhibited explicitly. This form of the Einstein field equations, called the wave coordinates reduced Einstein equations, is precisely the one which allowed Bruhat (1952) to prove the first local existence result. Later, she also pointed out that the first nontrivial iterate of [4] behaves like $t^{-1}\log t$ rather than $t^{-1}$ as expected from the decay properties of solutions to $\Box h = 0$ in Minkowski space. This seems to indicate that the wave coordinates may not be suitable to study the long-time behavior of solutions to the Einstein field equations. This negative conclusion is also consistent with the fact that the eqns [4] do not verify Klainerman's null condition. (Klainerman's null condition (Klainerman 1983) is an algebraic condition on systems of nonlinear wave equations in $(1+3)$ dimensions, similar to [4], which allows one to extend all local solutions, corresponding to small initial data, for all time. Moreover, these solutions decay at the rate of $t^{-1}$ as $t \to \infty$ consistent to the decay of free waves.) Lindblad and Rodnianski (2003) were able to isolate a new condition, which they call the weak null condition, verified by the wave coordinates reduced Einstein eqns [4], for which one can prove a small data global existence result consistent with the weaker decay rates suggested by the linear asymptotic analysis of Bruhat. Although the new result provides far weaker peeling information than [1], it is much simpler to prove than both Theorems 4 and 5. Moreover, the result seems to apply to a broader class of initial data than in Theorems 4 and 5. It remains an intriguing open problem whether the result of Lindblad–Rodnianski can be used as a stepping stone towards the more complete results of Theorems 4 and 5; that it is once a complete solution, with limited peeling, is known to exist whether one can improve, using the more precise techniques employed in Theorems 4 and 5 minus an important part of their technical complications, the weak peeling properties of [1].

## Strong Peeling

The weak peeling properties [1] derived in Theorems 4 and 5 are consistent, from a scaling point of view, with the SAF condition. To derive strong peeling, see [3], one needs stronger asymptotic conditions. Recently, Corvino–Schoen and Chruściel and Delay (2002) have proved the existence of a large class of asymptotically flat initial data sets $(\Sigma, g, k)$ which are precisely stationary (here $g_{\text{kerr}}, k_{\text{kerr}}$ are the initial data of the a Kerr solution in standard coordinates) $g = g_{\text{kerr}}, k = k_{\text{kerr}}$ outside a sufficiently large compact set. Moreover, they have proved the existence of sufficiently small solutions in this class which satisfy the requirements needed in Friedrich's conformal compactification method (see Friedrich (2002) and the references within) to produce asymptotically simple spacetimes, that is, spacetimes satisfying Penrose's regular compactification condition (Penrose 1962). Simultaneously, Klainerman and Nicolò (1999) were able to refine the methods used in the proof of Theorem 5 to prove the following:

**Theorem 6** *Assume that the initial data set* $(\Sigma, g, k)$ *of Theorem 5 satisfies the stronger assumption,*

$$g - g_S = O(r^{-(3/2+\gamma)}), \qquad k = (r^{-(5/2+\gamma)}) \qquad [5]$$

*for some* $\gamma > 3/2$. *Here*

$$g_S = \left(1 - 2\frac{M}{r}\right)^{-1} dr^2 + r^2(d\theta^2 + \sin^2\theta\, d\phi^2)$$

*denotes the restriction of the Schwarzschild to* $t = 0$ *in standard polar coordinates. Then, in addition to the results reported in Theorem 5, we have the strong peeling estimates,*

$$\alpha = O(r^{-5}), \qquad \beta = O(r^{-4})$$

*as* $r \to \infty$ *along the outgoing null leaves* $C(u)$. *Moreover, the same conclusions hold true if [5] is replaced by*

$$g - g_{\text{kerr}} = O(r^{-(3/2+\gamma)}), \qquad k - k_{\text{kerr}} = (r^{-(5/2+\gamma)}) \qquad [6]$$

*for some* $\gamma > 5/2$.

The first part of the theorem was proved in Klainerman and Nicolò (2003b). The second part is work in progress by Klainerman and Nicolò. The existence of initial conditions of the type required in Theorem 6 was established in the works of Corvino (2000) and Chruściel and Delay (2002).

## Open Problems

**Problem 1** *Extend results of Theorems 5 and 6 to the whole domain of dependence, for small data sets.*

The results of Theorems 5 and 6 give a satisfactory description of gravitational radiation of general classes of asymptotically flat initial data sets outside the domain of dependence of a sufficiently large compact set. It would be desirable to extend these results to the whole domain of dependence of initial data sets which satisfy an additional global smallness assumption similar to that of Theorem 4.

**Problem 2** *Is strong peeling (and implicitly asymptotic simplicity) consistent with physically relevant data? If not, is weak peeling a good substitute?*

Damour and Christodoulou (2000) have given conclusive evidence that under no-incoming-radiation condition the future null infinity cannot be smooth. In fact, $\beta = O(r^{-4} \log r)$ as $r \to \infty$.

**Problem 3** *Can one weaken the AF conditions to include, for example, initial data sets with infinite ADM angular momentum?*

It is reasonable to expect a global stability of Minkowski result for small initial data sets which verify, for arbitrarily small $\epsilon$,

$$g - \left(1 + 2\frac{M}{r}\right)\delta = 0(r^{-1-c}), \qquad k = 0(r^{-2-c})$$

One expects in this case that the top null components $\alpha$ and $\beta$ decay only like $O(r^{-3})$ as $r \to \infty$ along the null hypersurfaces $C(u)$. It seems that the methods of Lindblad–Rodnianski can treat this case but can only give decay estimates for $\alpha, \beta$ of the form $O(r^{-3+c})$.

**Problem 4** *Is the Kerr solution in the exterior of the black hole stable?*

The problem remains wide open.

# Stability Problems in Celestial Mechanics

**A Celletti**, Università di Roma “Tor Vergata,” Rome, Italy

## Introduction

The long-term stability of planets and satellites might be desumed by the regular dynamics that we constantly observe. However, the ultimate fate of the solar system is an intriguing question, which has puzzled scientists since antiquity. In the past centuries, the common belief of a regular motion of the main planets was strengthened by the discovery of a simple law, due to J D Titius and J E Bode (eighteenth century), which provides a recipe to compute the approximate distances of the planets from the Sun. Adopting astronomical units as a measure of the distance, the Titius–Bode law can be stated as

$$d_n = 0.4 + 0.3 \times 2^n \text{ AU} \qquad [1]$$

where the index $n$ must be selected as provided in Table 1, which compares the distances computed according to [1] with the observed values. Titius and Bode already noticed that it was necessary to skip one unit in $n$ from Mars to Jupiter; indeed, the quantity $d_3 = 2.8$ AU might correspond to an average distance of some minor bodies of the asteroid belt, which had been discovered since the beginning of the nineteenth century. The studies of the $N$-body problem, namely the dynamics of $N$ mutually attracting bodies (according to Newton’s law), inspired several mathematical and physical theories: from the development of perturbation methods to the discovery of chaotic systems, as attested by the masterly work of H Poincaré (1892). In particular, perturbation theory had relevant applications in celestial mechanics; for example, it led to the prediction of the existence of Neptune in the nineteenth century by J C Adams and U Leverrier and later to the discovery of Pluto by C Tombaugh, as a result of unexplained perturbations on Uranus and Neptune, respectively. Modern advances in perturbation theories have been provided by the Kolgomorov–Arnol’d–Moser (KAM) and Nekhoroshev theorems, which find broad applications in celestial mechanics insofar as simple model problems are concerned.

The stability of the solar system can also be approached through numerical investigations, which allow one to predict the motion of the celestial bodies using more realistic models. The results of the numerical integrations undermine in some cases the apparent regularity of the solar system: in the following sections, we shall review many examples of regular and chaotic motions in different contexts of celestial mechanics, from the $N$-body problem to the rotational dynamics.

**Table 1** Tititus–Bode law and observed data

| | *Index n* (*of* [1]) | *Distance computed from* [1] | *Observed distance* (AU) |
|---|---|---|---|
| Mercury | $-\infty$ | 0.4 | 0.39 |
| Venus | 0 | 0.7 | 0.72 |
| Earth | 1 | 1 | 1 |
| Mars | 2 | 1.6 | 1.52 |
| Jupiter | 4 | 5.2 | 5.2 |
| Saturn | 5 | 10 | 9.54 |
| Uranus | 6 | 19.6 | 19.19 |

## The Restricted Three-Body Problem

Let $P_1, \ldots, P_N$ be $N$ bodies with masses $m_1, \ldots, m_N$, which interact through Newton’s law. Let $u^{(i)} \in \boldsymbol{R}^3, i = 1, 2, \ldots, N$, denote the position of the bodies in an inertial reference frame. Normalizing the gravitational constant to 1, the equations of motion of the $N$-body problem have the form

$$\frac{\mathrm{d}^2 u^{(i)}}{\mathrm{d}t^2} = -\sum_{j=1, j\neq i}^{N} \frac{m_j (u^{(i)} - u^{(j)})}{|u^{(i)} - u^{(j)}|^3}, \quad i = 1, \ldots, N \qquad [2]$$

In the case $N = 2$, one reduces to the two-body problem, which can be explicitly solved by means of Kepler’s laws as follows. Consider, for example, the Earth–Sun case: for negative values of the energy, the trajectory of the Earth is an ellipse with one focus coinciding with the barycenter, which can practically be identified with the Sun; the Earth–Sun radius vector describes equal areas in equal times; the cube of the semimajor axis is proportional to the square of the period of revolution.

Consider now an extension to the study of three bodies such that in the Keplerian approximation $P_2$ and $P_3$ move around $P_1$ and such that the semimajor axis of $P_2$ is greater than that of $P_3$ (an example is obtained identifying $P_1$ with the Sun, $P_2$ with the Jupiter, and $P_3$ with an asteroid of the main belt). The three-body problem is described by [2] setting $N = 3$; a special case is given by the restricted three-body problem, which describes the evolution of a “zero-mass” body under the gravitational attraction exerted by an assigned two-body system. Setting $N = 3$ and $m_3 = 0$ in [2], the

equations governing the restricted three-body problem are given by

$$\frac{d^2u^{(1)}}{dt^2} = -\frac{m_2(u^{(1)} - u^{(2)})}{|u^{(1)} - u^{(2)}|^3}$$
$$\frac{d^2u^{(2)}}{dt^2} = -\frac{m_1(u^{(2)} - u^{(1)})}{|u^{(2)} - u^{(1)}|^3}$$
$$\frac{d^2u^{(3)}}{dt^2} = -\frac{m_1(u^{(3)} - u^{(1)})}{|u^{(3)} - u^{(1)}|^3} - \frac{m_2(u^{(3)} - u^{(2)})}{|u^{(3)} - u^{(2)}|^3}$$

The first two equations concern the motion of the primaries $P_1$ and $P_2$ and they correspond to a Keplerian two-body problem, whose solution can be inserted in the equation for $u^{(3)}$, which becomes a periodically forced second-order equation. The restricted three-body problem can be conveniently described in terms of suitable action-angle coordinates, known as Delaunay variables. The present discussion is restricted to the planar case, namely we assume that the motion of the three bodies takes place on the same plane. The corresponding Delaunay variables, say $(L, G, \ell, \gamma) \in \boldsymbol{R}^2 \times \boldsymbol{T}^2$, are defined as follows (Szebehely 1967). Let $a$ and $e$ be, respectively, the semimajor axis and the eccentricity of the osculating orbit of $P_3$ and let $\mu = 1/m_1^{2/3}$; then Delaunay's action variables are given by

$$L = \mu\sqrt{m_1 a}, \qquad G = L\sqrt{1-e^2}$$

Next, introduce the angle variables: we denote by $\lambda$ and $\varphi$ the longitudes of Jupiter and of the asteroid; let $\gamma$ be the argument of perihelion, namely the angle formed by the periapsis direction with a preassigned reference line, and let $u$ denote the eccentric anomaly, which can be defined through

$$\tan\frac{\varphi-\gamma}{2} = \sqrt{\frac{1+e}{1-e}}\tan\frac{u}{2} \qquad [3]$$

Let $\ell$ be the mean anomaly, which is related to the eccentric anomaly by means of Kepler's equation

$$\ell = u - e\sin u \qquad [4]$$

Delaunay's angle variables are represented by the mean anomaly $\ell$ and by the argument of perihelion $\gamma$. For completeness, it should be remarked that the distance $r$ between the minor body $P_3$ and the primary $P_1$ is related to the longitude and to the eccentric anomaly by means of the relations

$$r = \frac{a(1-e^2)}{1+e\cos(\varphi-\gamma)} = a(1-e\cos u) \qquad [5]$$

In a reference frame centered at one of the primaries, say $P_1$, let $H = H(L, G, \ell, \gamma, \lambda)$ denote the Hamiltonian function describing the planar problem; notice that $H(L, G, \ell, \gamma, \lambda)$ has two degrees of freedom and an explicit time dependence through the longitude $\lambda$ of $P_2$. If the primaries are assumed to move in circular orbits around their common center of mass, the Hamiltonian function reduces to two degrees of freedom, where a new variable $g$ is introduced as the difference between the argument of perihelion $\gamma$ and the longitude $\lambda$ of the primary. Normalizing the units of measure so that the distance between the primaries and the sum of their masses is unity, the Hamiltonian function $H$ describing the circular, planar, restricted three-body problem is given by

$$H(L, G, \ell, g) = -\frac{1}{2L^2} - G + \varepsilon F(L, G, \ell, g) \qquad [6]$$

where $\varepsilon = \mu m_2$. The perturbing function takes the form

$$F = r\cos(f+g) - \frac{1}{\sqrt{1+r^2-2r\cos(f+g)}}$$

where $f = \varphi - \gamma$ represents the true anomaly, namely the angle formed by the instantaneous orbital radius with the periapsis line. Notice that the quantities $r$ and $f$ are functions of the Delaunay variables through the relations [3]–[5]. As a consequence, one can expand the perturbing function in the form (Delaunay 1860)

$$F(L, G, \ell, g) = \sum_{j,k\geq 0} F_{jk}(\ell, g)e^j a^k$$

where $F_{jk}$ are cosine terms with arguments given by a linear combination of the variables $\ell$ and $g$. For example, the first few terms of the series development are given by the following expression:

$$\begin{aligned} F(L, G, \ell, g) = & -1 - \frac{L^4}{4} - \frac{9}{64}L^8 + \frac{L^4 e}{2}\cos\ell \\ & - \left(\frac{3}{8}L^6 + \frac{15}{64}L^{10}\right)\cos(\ell+g) \\ & + \frac{9}{4}L^4 e\cos(\ell+2g) \\ & - \left(\frac{3}{4}L^4 + \frac{5}{16}L^8\right)\cos(2\ell+2g) \\ & - \frac{3}{4}L^4 e\cos(3\ell+2g) \\ & - \left(\frac{5}{8}L^6 + \frac{35}{128}L^{10}\right)\cos(3\ell+3g) \\ & - \frac{35}{64}L^8\cos(4\ell+4g) \\ & - \frac{63}{128}L^{10}\cos(5\ell+5g) + \cdots \end{aligned} \qquad [7]$$

where the eccentricity is a function of the actions through $e = \sqrt{1 - G^2/L^2}$. We remark that the Hamiltonian [6] is nearly integrable with perturbing parameter $\varepsilon$; indeed, for $\varepsilon = 0$ one recovers the two-body problem describing the interaction between $P_1$ and $P_3$, which can be explicitly solved according to Kepler's laws.

### KAM Stability

Classical perturbation theory, as developed by Laplace, Lagrange, Delaunay, Poincaré, etc., does not allow investigation of the stability of the $N$-body problem, since the series defining the solution are generally divergent. In order to justify this statement, let us start by rewriting the unperturbed Hamiltonian in [6] as

$$h(L, G) = -\frac{1}{2L^2} - G \qquad [8]$$

so that [6] becomes $H(L, G, \ell, g) = h(L, G) + \varepsilon F(L, G, \ell, g)$. In order to remove the perturbation to the second order in the perturbing parameter, one looks for a change of variables $(L, G, \ell, g) \to (L', G', \ell', g')$ close to the identity, that is,

$$\begin{aligned} L &= L' + \varepsilon \frac{\partial \Phi}{\partial \ell}(L', G', \ell, g) \\ G &= G' + \varepsilon \frac{\partial \Phi}{\partial g}(L', G', \ell, g) \\ \ell' &= \ell + \varepsilon \frac{\partial \Phi}{\partial L'}(L', G', \ell, g) \\ g' &= g + \varepsilon \frac{\partial \Phi}{\partial G'}(L', G', \ell, g) \end{aligned}$$

where $\Phi(L', G', \ell, g)$ is the generating function of the transformation. Let

$$\frac{\partial h}{\partial L}(L, G) = \frac{1}{L^3} \equiv \omega(L)$$

In order to perform a first-order perturbation theory, we look for a generating function $\Phi(L', G', \ell, g)$, such that the transformed Hamiltonian is integrable up to $O(\varepsilon^2)$, namely

$$\begin{aligned} &h\left(L' + \varepsilon \frac{\partial \Phi}{\partial \ell}(L', G', \ell, g), G' + \varepsilon \frac{\partial \Phi}{\partial g}(L', G', \ell, g)\right) \\ &\quad + \varepsilon F\left(L' + \varepsilon \frac{\partial \Phi}{\partial \ell}(L', G', \ell, g), G' \right. \\ &\quad \left. + \varepsilon \frac{\partial \Phi}{\partial g}(L', G', \ell, g), \ell, g\right) \\ &= h_1(L', G') + \varepsilon\left[\omega(L') \frac{\partial \Phi}{\partial \ell}(L', G', \ell', g') \right. \\ &\quad \left. - \frac{\partial \Phi}{\partial g}(L', G', \ell', g') + F(L', G', \ell', g')\right] + O(\varepsilon^2) \end{aligned}$$

where $h_1(L', G')$ is the new unperturbed Hamiltonian. If we denote by $F_0(L', G')$ the average of the perturbing function over the angle variables, the new unperturbed Hamiltonian takes the form

$$h_1(L', G') = h(L', G') + \varepsilon F_0(L', G')$$

Expanding $F$ in Fourier series as $F(L, G, \ell, g) = \sum_{n, m \in \mathbf{Z}} F_{nm}(L, G) e^{i(n\ell + mg)}$, the generating function is given by the following expression:

$$\Phi(L', G', \ell, g) = -i \sum_{n, m \in \mathbf{Z} \setminus \{0\}} \frac{F_{nm}(L', G')}{\omega(L')n - m} e^{i(n\ell + mg)}$$

The occurrence of small divisors of the form

$$\frac{1}{\omega(L)n - m}, \quad n, m \in \mathbf{Z}$$

might prevent the convergence of the series defining the generating function. In particular, we remark that zero divisors occur whenever $\omega(L) = m/n$. This situation, which is called an $m:n$ orbit–orbit resonance, implies that during a given interval of time the body $P_3$ makes $m$ revolutions, whereas $P_2$ makes exactly $n$ orbits about $P_1$.

The control of the occurrence of the small divisors was obtained through a theorem by A N Kolmogorov, who made a major breakthrough in the study of nearly integrable systems. He proved, under general assumptions, that some regions of the phase space are almost filled by maximal invariant tori. The theorem provides a constructive algorithm to give estimates on the perturbing parameter, ensuring the existence of some invariant surfaces. Kolmogorov's theorem was later extended by V I Arnol'd and J Moser, giving rise to the so-called KAM theory. More precisely, the KAM theorem can be stated as follows (see, e.g., Arnol'd *et al.* (1997)): consider a real-analytic, nearly integrable Hamiltonian function and fix a rationally independent frequency vector $\omega$; if the unperturbed Hamiltonian is not degenerate and if the frequency satisfies a strong nonresonance assumption (called the diophantine condition), for sufficiently small values of the perturbing parameter, there exists an invariant torus on which a quasiperiodic motion with frequency $\omega$ takes place. A preliminary investigation of the stability of the $N$-body problem by means of KAM theory (Arnol'd *et al.* 1997) leads to the existence of large regions filled by quasiperiodic motions, provided the masses of the planets are sufficiently small. Arnol'd's version of KAM theorem has been applied by J Laskar and P Robutel to the spatial three-body planetary problem (the planetary problem concerns the study of the

dynamics of two bodies with comparable masses, moving in the gravitational field of a larger primary) and the existence of quasiperiodic motions has been proved for values of the ratio of semimajor axis less than 0.8 and for inclinations up to $\sim 1°$.

Concrete estimates on the strength of the perturbation were given by M Hénon: in the context of the three-body problem, the application of the original version of Arnol'd's theorem allows one to prove the existence of invariant tori for values of the perturbing parameter (representing the Jupiter–Sun mass ratio) $\leq 10^{-333}$ while the implementation of Moser's theorem provides an estimate of $10^{-50}$. We remark that the astronomical value of the Jupiter–Sun mass ratio amounts to $\sim 10^{-3}$, showing a relevant discrepancy between KAM results and physical measurements. More recently, KAM estimates have been refined and adapted to the study of significant problems of celestial mechanics (Celletti and Chierchia 1995). Strong improvements have been obtained combining accurate estimates with a computer-assisted implementation, where the computer is used to perform long computations concerning the development of the perturbing series and the check of KAM estimates. The numerical errors are controlled through the implementation of a suitable technique, known as interval arithmetic. In the framework of the planar, circular, restricted three-body problem, the stability of some asteroids has been proved by A Celletti and L Chierchia for realistic values of the perturbing parameter (e.g., for $\varepsilon = 10^{-3}$). A suitable approximation of the disturbing function (namely, a finite truncation of the series development as in [7]) has been considered. The result relies on an implementation of a computer-assisted isoenergetic KAM theorem and on the following remark: in the four-dimensional phase space, on a fixed energy level the invariant two-dimensional surfaces separate the phase space, providing the stability of the actions for all motions trapped between any two invariant tori. Since the action variables are related to the semimajor axis and to the eccentricity of the orbit, one obtains that the elliptic elements remain close to their initial values.

A computer-assisted KAM theorem has been applied by A Giorgilli and U Locatelli to the planetary (Jupiter–Saturn) problem. Using a suitable secular approximation, it can be shown that this model admits two invariant tori, which bound the orbits corresponding to the initial data of Jupiter and Saturn.

#### Nekhoroshev Stability

A different approach in order to study the stability of nearly integrable systems is provided by Nekhoroshev's theorem (see, e.g., Arnol'd *et al.* (1997)), which guarantees, under smallness requirements, the stability of the motions on an open set of initial conditions for exponentially long times. Consider a Hamiltonian function of the form

$$H(y, x) = h(y) + \varepsilon f(y, x), \quad (y, x) \in B \times \boldsymbol{T}^n \qquad [9]$$

where $B$ is an open subset of $\boldsymbol{R}^n$. We assume that $h$ and $f$ are analytic functions and that the integrable Hamiltonian $h$ satisfies a geometric condition, called steepness. We remark that functions such as $h(L, G)$ in [8] satisfy the steepness condition. For sufficiently small values of $\varepsilon$, Nekhoroshev's theorem states that any motion $(y(t), x(t))$ satisfying Hamilton's equations associated with [9] is bounded for a finite (but exponentially long) time, that is,

$$\|y(t) - y(0)\| \leq y_0 \varepsilon^a, \quad \text{for } |t| \leq t_0 \mathrm{e}^{(\varepsilon_0/\varepsilon)^b}$$

where $y_0, t_0, \varepsilon_0, a$, and $b$ are suitable positive constants.

Nekhoroshev's theorem can be conveniently applied to the three-body problem, where it provides a confinement of the action variables, representing the semimajor axis and the eccentricity of the osculating orbit. Interesting applications of Nekhoroshev's theorem concern the investigation of the triangular Lagrangian points in the spatial, restricted three-body problem. (The Lagrangian points are five equilibrium positions of the planar, restricted three-body problem in a synodic reference frame, which rotates with the angular velocity of the primaries. Two of such positions are called triangular, since the configuration of the three bodies is an equilateral triangle in the orbital plane.) Effective estimates were developed by A Giorgilli and C Skokos, showing the existence of a stability region around the Lagrangian point $L_4$, large enough to include some known asteroids. In the same framework, the exponential stability was proven by G Benettin, F Fassó, and M Guzzo for all values of the mass-ratio parameter, except for a few values of the reduced mass $\mu$ up to $\mu \simeq 0.038$.

#### Numerical Results

The study of the stability of the $N$-body problem can be investigated by performing numerical integrations of the equations of motion. The dynamics of the outer planets of the solar system (from Jupiter to Pluto) has been explored by Sussman and Wisdom (1992) using a dedicated computer, the Digital Orrery. The integration of the equations of motion was performed over 845 million years; the results provided evidence of the stability of the major planets and a chaotic behavior of Pluto. An

alternative approach, based on an average of the equations of motion over fast angles, was adopted by Laskar (1995), where the perturbing function of the spatial problem was expanded up to the second order in the masses and up to the fifth powers of the eccentricity and the inclination. The dynamics of all planets (excluding Pluto) was investigated by means of frequency analysis over a time span ranging from −15 Gyr to +10 Gyr. The numerical integrations provided evidence of the regularity of the external planets (from Jupiter to Neptune), a moderate chaotic behavior of Venus and the Earth, and a marked chaotic dynamics of Mercury and Mars. The computations show that the inner solar system is chaotic, with a Lyapunov time of $\sim 5$ Myr, thus preventing any prediction of the evolution over 100 Myr.

## The Spin–Orbit Problem

The dynamics of the bodies of the solar system results from a combination of a revolutionary motion around a primary body and a rotation about an internal axis. A simple mathematical model describing the spin–orbit interaction can be introduced as follows. Let S be a triaxial ellipsoidal satellite, which moves about a central planet P. We denote by $T_{rev}$ and $T_{rot}$ the periods of revolution and rotation. A $p:q$ spin–orbit resonance occurs if

$$\frac{T_{rev}}{T_{rot}} = \frac{p}{q}, \quad \text{for } p, q \in \mathbf{N}, \ q \neq 0$$

Whenever $p = q = 1$, the satellite always points the same face to the host planet. Most of the evolved satellites or planets are trapped in a 1 : 1 resonance, with the only exception of Mercury, which is observed in a nearly 3 : 2 resonance. In order to introduce a simple mathematical model which describes the spin–orbit interaction, we assume that:

1. the satellite moves on a Keplerian orbit around the planet (with semimajor axis $a$ and eccentricity $e$);
2. the spin axis is perpendicular to the orbit plane;
3. the spin axis coincides with the shortest physical axis; and
4. dissipative effects as well as perturbations due to other planets or satellites are neglected.

We denote by $A < B < C$ the principal moments of inertia of the satellite and by $r$ and $f$, respectively, the instantaneous orbital radius and the true anomaly of the Keplerian orbit. Let $x$ be the angle between the longest axis of the ellipsoid and a preassigned reference line. From standard Euler's equations for rigid body, the equation of motion in normalized units (i.e., assuming that the period of revolution is $2\pi$) takes the form

$$\ddot{x} + \frac{\varepsilon}{r^3} \sin(2x - 2f) = 0 \qquad [10]$$

where $\varepsilon \equiv \frac{3}{2}(B - A)/C$. This equation is integrable whenever $A = B$ or in the case of zero orbital eccentricity. Due to the assumption of Keplerian motion, both $r$ and $f$ are known functions of the time. Therefore, we can expand [10] in Fourier series as

$$\ddot{x} + \varepsilon \sum_{m \neq 0,\, m=-\infty}^{\infty} W\left(\frac{m}{2}, e\right) \sin(2x - mt) = 0 \qquad [11]$$

where the coefficients $W(m/2, e)$ decay as $W(m/2, e) \propto e^{|m-2|}$. A further simplification of the model is obtained as follows. According to (4), we neglected the dissipative forces and perturbations due to other bodies. The most important contribution is due to the nonrigidity of the satellite, provoking a tidal torque caused by the internal friction. The size of the dissipative effects is significantly small compared to the gravitational terms. Therefore, we decide to retain in [11] only those terms which are of the same order or larger than the average effect of the tidal torque. The following equation results:

$$\ddot{x} + \varepsilon \sum_{m \neq 0,\, m=N_1}^{N_2} \tilde{W}\left(\frac{m}{2}, e\right) \sin(2x - mt) = 0 \qquad [12]$$

where $N_1$ and $N_2$ are suitable integers, which depend on the physical and orbital parameters of the satellite, while $\tilde{W}(m/2, e)$ are suitable truncations of the coefficients $W(m/2, e)$. We remark that eqn [12] can be derived from Hamilton's equations associated with a one-dimensional, time-dependent, nearly integrable Hamiltonian function with perturbing parameter $\varepsilon$ and a trigonometric disturbing function.

### Analytical Results

The phase space associated with [12] admits a Poincaré map showing a pendulum-like structure: the periodic orbits are surrounded by librational curves and the chaotic separatrix divides the librational regime from the region where rotational motions can take place. The three-dimensional phase space is separated by KAM rotational tori into invariant regions, providing a strong stability property for all motions confined between any pair of KAM rotational tori. Let us denote by $\mathcal{P}(p/q)$ a periodic orbit associated with the $p:q$ resonance; in the context of the model associated with [12], the

stability of the periodic orbit $\mathcal{P}(p/q)$ is obtained by showing the existence of two invariant tori $\mathcal{T}(\omega_1)$ and $\mathcal{T}(\omega_2)$ with $\omega_1 < p/q < \omega_2$. A refined computer-assisted KAM theorem has been implemented (Celletti 1990) with the aim of proving the existence of trapping invariant surfaces. Realistic estimates, in agreement with the physical values of the parameters (namely, the equatorial oblateness $\varepsilon$ and the eccentricity $e$), have been obtained in several examples of spin–orbit commensurabilities, like the 1 : 1 Moon–Earth interaction or the 3 : 2 Mercury–Sun resonance.

Concerning Nekhoroshev-type estimates, the classical D'Alembert problem has been studied by Biasco and Chierchia (2002). In particular, an equatorially symmetric oblate planet moving on a Keplerian orbit around a primary body has been investigated; the model does not assume any further constraint on the spin axis. Although the Hamiltonian describing this model is properly degenerate, it is shown that Nekhoroshev-like results apply to the D'Alembert problem in the proximity of a 1 : 1 resonance.

### Numerical Results

The model introduced in [10]–[12] often represents an unrealistic simplification of the spin–orbit dynamics. In particular, assumption (1) implies that secular perturbations of the orbital parameters are neglected, whereas the hypothesis (2) corresponds to disregarding the spin–orbit obliquity, namely the angle formed by the rotational axis with the normal to the orbital plane. Due to the presence of an equatorial bulge, the gravitational attraction of the other bodies of the solar system induces a torque, resulting in a precessional motion. It is also important to take into account the changes of the obliquity angle, whose variations might affect the climatic behavior.

A realistic model for the precession and the variation of the obliquity has been presented by Laskar (1995). The numerical simulations and the frequency-map analysis show that the Earth's obliquity is actually stable, although a large chaotic region is found in the interval between 60° and 90°. Since the present obliquity of the Earth amounts to ~23.3°, the Earth is outside the dangerous region. An interesting simulation was performed to evaluate the role played by the Moon. Without the Moon, the extent of the chaotic region would greatly increase, eventually preventing the birth of an evoluted life. Among the inner planets, Mars' obliquity shows larger chaotic extent, which drives to variations from 0° to 60° in a few million years. On the contrary, the external planets do not show significant chaotic regions and their obliquities are essentially stable.

## Introduction

A Hamiltonian system is a dynamical system whose equations of motions can be written in terms of a scalar function, called the Hamiltonian of the system: if one uses coordinates $(\boldsymbol{p}, \boldsymbol{q})$ in a domain (phase space) $\mathcal{D} \subset \boldsymbol{R}^{2N}$, where $N$ is the number of independent variables one needs to identify a configuration of the system (degrees of freedom), there is a function $\mathcal{H}(\boldsymbol{p}, \boldsymbol{q})$ such that $\dot{\boldsymbol{p}} = -\partial\mathcal{H}/\partial\boldsymbol{q}$ and $\dot{\boldsymbol{q}} = \partial\mathcal{H}/\partial\boldsymbol{p}$. An integrable (Hamiltonian) system is a Hamiltonian system which, in suitable coordinates $(\boldsymbol{A}, \boldsymbol{\alpha}) \in \mathcal{A} \times \boldsymbol{T}^N$, where $\mathcal{A}$ is an open subset of $\boldsymbol{R}^N$ and $\boldsymbol{T} = \boldsymbol{R}/2\pi\boldsymbol{Z}$ is the standard torus, can be described by a Hamiltonian $\mathcal{H}_0(\boldsymbol{A})$, that is, depending only on $\boldsymbol{A}$. The coordinates $(\boldsymbol{A}, \boldsymbol{\alpha})$ are called action-angle variables. In such a case the dynamics is trivial: any initial condition $(\boldsymbol{A}_0, \boldsymbol{\alpha}_0)$ evolves in such a way that the action variables are constants of motion (i.e., $\boldsymbol{A}(t) = \boldsymbol{A}_0$ for all $t \in \boldsymbol{R}$), while the angles grow linearly in time as $\boldsymbol{\alpha}(t) = \boldsymbol{\alpha}_0 + \boldsymbol{\omega}t$, where $\boldsymbol{\omega} = \boldsymbol{\omega}(\boldsymbol{A}_0) \equiv \partial_{\boldsymbol{A}}\mathcal{H}_0(\boldsymbol{A}_0)$ is called the rotation (or frequency) vector. An integrable system can be thought of as a collection of decoupled (i.e., independent) rotators: the entire phase space $\mathcal{A} \times \boldsymbol{T}^N$ is foliated into invariant tori and all motions are quasiperiodic. Integrable systems are stable, in the sense that nearby initial conditions separate at most linearly in time (in particular, the actions do not separate at all): mathematically, this is expressed by the fact that all the Lyapunov exponents are nonpositive.

An example of an integrable system is any one-dimensional conservative mechanical system, in any region of phase space in which motions are bounded. By increasing the number of degrees of freedom, exhibiting nontrivial integrable systems can become a difficult task. The problem of studying the effects of even small Hamiltonian perturbations on integrable systems and of understanding if the latter remain stable, in the aforementioned sense, was considered by Poincaré to be the fundamental problem of dynamics. For a long time, it was commonly thought that all motions could be reduced to superpositions of periodic motions, hence to quasiperiodic motions, but at the end of nineteenth century it was realized by Boltzmann and Poincaré that such a picture was too naive, and that in reality more complicated motions were possible. As a consequence of this, it became a widespread belief that, even when starting from an integrable system, the introduction of an arbitrarily small perturbation would break integrability.

This belief was strengthened by the work of Poincaré (1898), who showed that the series describing the solution in a perturbation theory approach are in general divergent. The source of divergence in perturbation series is the presence of small divisors, that is, of denominators of the kind of $\boldsymbol{\omega} \cdot \boldsymbol{\nu}$, where $\boldsymbol{\omega}$ is the rotation vector that should characterize the invariant torus (if existent) and $\boldsymbol{\nu}$ is any integer vector. Despite this, however, perturbation series (known as Lindstedt series) continued to be extensively used by astronomers in problems of celestial mechanics, such as the study of planetary motions, for the simple reason that they provided predictions in good agreement with the observations. But the feeling that the underlying mathematical tools were unsatisfactory persisted.

In fact, the well-known Fermi–Pasta–Ulam numerical experiment, in 1955, was originally conceived in the spirit of confirming that integrability would in general be easily lost. Consider a chain with $N$ harmonic oscillators, with, say, periodic boundary conditions, coupled with cubic and quartic two-body potentials, so that the Hamiltonian is

$$\begin{gathered} \mathcal{H}(\boldsymbol{p}, \boldsymbol{q}) = \sum_{i=1}^{N} \frac{1}{2} p_i^2 + W(q_{i+1} - q_i) \\ W(x) = \frac{1}{2}x^2 + \frac{\alpha}{3}x^3 + \frac{\beta}{4}x^4 \end{gathered} \qquad [1]$$

for $\alpha, \beta$ real parameters and $(\boldsymbol{p}, \boldsymbol{q}) \in \boldsymbol{R}^N \times \boldsymbol{R}^N$. One can introduce new variables such that the Hamiltonian, for $\alpha = \beta = 0$, can be written as

$$\mathcal{H}_0(\boldsymbol{A}) = \sum_{i=1}^{N} \frac{1}{2}\left(P_k^2 + \omega_k Q_k^2\right) = \boldsymbol{\omega} \cdot \boldsymbol{A} \qquad [2]$$

for a suitable rotation vector $\boldsymbol{\omega} = (\omega_1, \ldots, \omega_N) \in \boldsymbol{R}^N$ (an explicit computation gives $\omega_k = 2\sin(k\pi/N)$).

Consider an initial condition in which all the energy is confined to a few modes, that is, $A_k \neq 0$ at $t = 0$ only for a few values of $k$. For $\alpha = \beta = 0$, the system is integrable, so that $A_k(t) = 0$ for all $t \in \boldsymbol{R}$ and for all $k$ such that $A_k(0) = 0$. If the system ceases to be integrable when the perturbation is switched on, the energy is likely to start to be shared among the various modes, and after a long enough time has

elapsed, an equidistribution of the energy among all modes (thermalization) might be expected. At least this behavior was expected by Fermi, Pasta, and Ulam, but it was not what they found numerically: on the contrary, all the energy seemed to remain associated with the modes close to the few initially excited ones.

At about the same time, Kolmogorov (1954) published a breakthrough paper going exactly in the opposite direction: if one perturbs an integrable system, under some mild conditions on the integrable part, most of the tori are preserved, although slightly deformed. A more precise statement is the following.

**Theorem 1** *Let an N-degree-of-freedom Hamiltonian system be described by an analytic Hamiltonian of the form*

$$\mathcal{H}(\boldsymbol{A},\boldsymbol{\alpha}) = \mathcal{H}_0(\boldsymbol{A}) + \varepsilon f(\boldsymbol{A},\boldsymbol{\alpha}) \qquad [3]$$

*with $\varepsilon$ a real parameter (perturbation parameter), $f$ a $2\pi$-periodic function of each angle variable (potential or perturbation), and $\mathcal{H}_0(\boldsymbol{A})$ satisfying the nondegeneracy condition $\det \partial_{\boldsymbol{A}}^2 \mathcal{H}_0(\boldsymbol{A}) \neq 0$ (anisochrony condition). If $\boldsymbol{\omega} = \boldsymbol{\omega}(\boldsymbol{A}) \equiv \partial_{\boldsymbol{A}} \mathcal{H}_0(\boldsymbol{A})$ is fixed to satisfy the Diophantine condition*

$$|\boldsymbol{\omega}\cdot\boldsymbol{\nu}| > \frac{C_0}{|\boldsymbol{\nu}|^{\tau}} \quad \forall \boldsymbol{\nu} \in \boldsymbol{Z}^N \setminus \boldsymbol{0} \qquad [4]$$

*for some constants $C_0 > 0$ and $\tau > N-1$ (here $|\boldsymbol{\nu}| = |\nu_1| + \cdots + |\nu_N|$ and $\cdot$ denotes the standard inner product: $\boldsymbol{\omega}\cdot\boldsymbol{\nu} = \omega_1\nu_1 + \cdots + \omega_N\nu_N$), then there is an invariant torus with rotation vector $\boldsymbol{\omega}$ for $\varepsilon$ small enough, say for $\varepsilon$ smaller than some value $\varepsilon_0$ depending on $C_0$ and $\tau$ (and on the function $f$).*

By saying that there is an invariant torus with rotation vector $\boldsymbol{\omega}$, one means that there is an invariant surface in phase space on which, in suitable coordinates, the dynamics is the same as in the unperturbed case, and the conjugation (i.e., the change of variables which leads to such coordinates) is analytic in the angle variables and in the perturbation parameter. One also says that the torus of an integrable system ($\varepsilon = 0$) is preserved (or even persists) under a small perturbation.

Note that, *a posteriori*, this proves convergence of the perturbation series: however, a direct check of convergence was performed only recently by Eliasson (1996). Kolmogorov's proof was based on a completely different idea, that is, by performing iteratively a sequence of canonical transformations (which are changes of coordinates preserving the Hamiltonian structure of the equations of motion) such that at each step the size of the perturbation is reduced. Of course, on the basis of Poincaré's result, this iterative procedure cannot work for all initial conditions (e.g., when $\boldsymbol{\omega}$ does not satisfy [4]). The key point in Kolmogorov's scheme is to fix the rotation vector $\boldsymbol{\omega}$ of the torus one is looking for, in such a way that the small divisors are controlled through the Diophantine condition [4] and the exponentially fast convergence of the algorithm.

New proofs and extensions of Kolmogorov's theorem were given later by Arnol'd (1962) and by Moser (1962); hence, the acronym KAM to denote such a theorem. Arnol'd gave a more detailed (and slightly different) proof compared to the original one by Kolmogorov, and applied the result to the planar three-body problem, thus showing that physical applications of the theorem were possible. Moser, on the other hand, proposed a modified method using a technique introduced by Nash (which approximates smooth functions with analytical ones) to deal with the case of systems with finite smoothness.

For fixed small enough $\varepsilon$, the surviving invariant tori cover a large portion of the phase space, called the Kolmogorov set; the relative measure of the region of phase space which is not filled by such tori tends to zero at least as $\sqrt{\varepsilon}$ for $\varepsilon \to 0$. A system described by a Hamiltonian like [3] is then called a quasi-integrable Hamiltonian system.

The excluded region of phase space corresponds to the unperturbed tori which are destroyed by the perturbation: the rotation vectors of such tori are close to a resonance, that is, to a value $\boldsymbol{\omega}$ such that $\boldsymbol{\omega}\cdot\boldsymbol{\nu} = 0$ for some integer vector $\boldsymbol{\nu}$, and these are exactly the vectors which do not satisfy the Diophantine condition [4] for any value $C_0$. A subset of phase space of this kind is called a resonance region.

At first sight, this would seem to provide an explanation for the results found by Fermi, Pasta, and Ulam, but this is not quite the case. First, the threshold value $\varepsilon_0$ depends on $N$, and goes to zero very fast as $N \to \infty$ (in general as $N!^{-\alpha}$ for some $\alpha > 0$); however, the results of the numerical experiments apparently were insensitive to the number $N$ of oscillators. Second, the KAM theorem deals with maximal tori, that is, tori characterized by rotation vectors which have as many components as the number of degrees of freedom, while the rotation vectors of the numerical quasiperiodic solutions seem to involve just a small number of components.

Finally, as an extra problem, the validity of the nondegeneracy condition for the unperturbed

Hamiltonian is violated, because the unperturbed Hamiltonian is linear in the action variables (one says that the Hamiltonian is isochronous). Recently, Rink (2001), by continuing the work by Nishida, showed that in the Fermi–Pasta–Ulam problem it is possible to perform a canonical change of coordinates such that in the new variables the Hamiltonian becomes anisochronous: one uses part of the perturbation to remove isochrony. But the other two obstacles remain.

## Lower-Dimensional Tori

A natural question is what happens to the invariant tori corresponding to rotation vectors which are not rationally independent, that is, vectors satisfying $n$ resonance conditions, such as $\boldsymbol{\omega}\cdot\boldsymbol{\nu}_i=0$ for $n$ independent vectors $\boldsymbol{\nu}_1,\ldots,\boldsymbol{\nu}_n$, with $1\le n\le N-2$ (the case $n=N-1$ corresponds to periodic orbits and is comparatively easy); for instance, one can take $\boldsymbol{\omega}=(\omega_1,\ldots,\omega_n,0,\ldots,0)$ and, by a suitable linear change of coordinates, one can always make the reduction to a case of this kind. In particular, one can ask if a result analogous to the KAM theorem holds for these tori. Such a problem for the model [3] has not been studied very widely in the literature. What has usually been considered is a system of $n$ rotators coupled with a system with $s=N-n$ degrees of freedom near an equilibrium point: then one calls normal coordinates the coordinates describing the latter, and the role of the parameter $\varepsilon$ is played by the size of the normal coordinates (if their initial conditions are chosen near the equilibrium point). In the absence of perturbation (i.e., for $\varepsilon=0$), one has either hyperbolic or elliptic or, more generally, mixed tori, according to the nature of the equilibrium points: one refers to these tori as lower-dimensional tori, as they represent $n$-dimensional invariant surfaces in a system with $N$ degrees of freedom. Then one can study the preservation of such tori.

One can prove that, in such a case, at least if certain generic conditions are satisfied, in suitable coordinates, $n$ angles rotate with frequencies $\omega_1,\ldots,\omega_n$, respectively, while the remaining $N-n$ angles have to be fixed close to some values corresponding to the extremal points of the function obtained by averaging the potential over the rotating angles.

The case of hyperbolic tori is easier, as in the case of elliptic tori one has to exclude some values of $\varepsilon$ to avoid some further resonance conditions between the rotation vector $\boldsymbol{\omega}$ and the normal frequencies $\lambda_k$ (i.e., the eigenvalues of the linearized system corresponding to the normal coordinates), known as the first and second Mel'nikov conditions:

$$\begin{aligned}&|\boldsymbol{\omega}\cdot\boldsymbol{\nu}\pm\lambda_k|>\frac{C_0}{|\boldsymbol{\nu}|^\tau}\quad\forall\boldsymbol{\nu}\in\mathbf{Z}^N\setminus 0,\ \forall 1\le k\le s\\&|\boldsymbol{\omega}\cdot\boldsymbol{\nu}\pm\lambda_k\pm\lambda_{k'}|>\frac{C_0}{|\boldsymbol{\nu}|^\tau}\quad\forall\boldsymbol{\nu}\in\mathbf{Z}^N\setminus 0\\&\quad\forall 1\le k,k'\le s\end{aligned}\qquad[5]$$

Such conditions appear, with the values of the normal frequencies slightly modified by terms depending on $\varepsilon$, at each iterative step, and at the end only for values of $\varepsilon$ belonging to some Cantor set one can have elliptic lower-dimensional tori.

The second Mel'nikov conditions are not really necessary, and in fact they can be relaxed as Bourgain (1994) has shown; this is an important fact, as it allows degenerate normal frequencies, which were forbidden in the previous works by Kuksin (1987), Eliasson (1988), and Pöschel (1989).

Similar results also apply in the case of lower-dimensional tori for the model [3], which represents sort of a degenerate situation, as the normal frequencies vanish for $\varepsilon=0$. Again, one has to use part of the perturbation to remove the complete degeneracy of normal frequencies.

## Quasiperiodic Solutions in Partial Differential Equations

For explaining the Fermi–Pasta–Ulam experiment, one has to deal with systems with arbitrarily many degrees of freedom. Hence, it is natural to investigate systems which have *ab initio* infinitely many degrees of freedom, such as the nonlinear wave equation, $u_{tt}-u_{xx}+V(x)u=\varphi(u)$, the nonlinear Schrödinger equation, $\mathrm{i}u_t-u_{xx}+V(x)u=\varphi(u)$, the nonlinear Korteweg–de Vries equation $u_t+u_{xxx}-6u_xu=\varphi(u)$, and other systems of nonlinear partial differential equations (PDEs); the continuum limit of the Fermi–Pasta–Ulam model gives indeed a nonlinear Korteweg–de Vries equation, as shown by Zabuski and Kruskal (1965). Here $(t,x)\in\mathbf{R}\times[0,\pi]^d$, if $d$ is the space dimension, and either periodic $(u(0,t)=u(\pi,t))$ or Dirichlet $(u(0,t)=u(\pi,t)=0)$ boundary conditions can be considered; $\varphi(u)$ is a function analytic in $u$ and starting from orders strictly higher than one, while $V(x)$ is an analytic function of $x$, depending on extra parameters $\xi_1,\ldots,\xi_n$. Such a function is introduced essentially for technical reasons, as we shall see that the eigenvalues $\lambda_k$ of the Sturm–Liouville operator $-\partial_x^2+V(x)$ must satisfy some Diophantine conditions. If we set $V(x)=\mu\in\mathbf{R}$ in the nonlinear wave equation, we obtain the Klein–Gordon equation, which, in the particular case $\mu=0$,

reduces to the string equation. Again, the role of the perturbation parameter is played by the size of the solution itself.

Small-amplitude periodic and quasiperiodic solutions for PDE systems have been extensively studied, among others, by Kuksin, Wayne, Craig, Pöschel, and Bourgain. Results for such systems read as follows. Consider for concreteness the one-dimensional nonlinear wave equation with Dirichlet boundary conditions and with $\varphi(u) = u^3 + O(u^5)$. When the nonlinear function $\varphi(u)$ is absent, any solution of the linear wave equation $u_{tt} - u_{xx} + V(x)u = 0$ is a superposition of either finitely or infinitely many periodic solutions with frequencies $\lambda_k$ determined by the function $V(x)$. Let $u_0(\boldsymbol{\omega}t, x)$ be a quasiperiodic solution of the linear wave equation with rotation vector $\boldsymbol{\omega} \in \boldsymbol{R}^n$, where $\omega_k = \lambda_{m_k}$, for some $n$-tuple $\{m_1, \ldots, m_n\}$. Then for $\varepsilon$ small enough there exists a subset $\Xi_\varepsilon$ of the space of parameters with large Lebesgue measure (more precisely, with complementary Lebesgue measure which tends to zero when $\varepsilon \to 0$) such that for all $\boldsymbol{\xi} = (\xi_1, \ldots, \xi_n) \in \Xi_\varepsilon$ there is a solution $u_\varepsilon(t, x)$ of the nonlinear wave equation and a rotation vector $\boldsymbol{\omega}_\varepsilon$ satisfying the conditions

$$\begin{aligned} \left| u_\varepsilon(t, x) - \sqrt{\varepsilon} u_0(\boldsymbol{\omega}_\varepsilon t, x) \right| &\leq C\varepsilon \\ |\boldsymbol{\omega}_\varepsilon - \boldsymbol{\omega}| &< C\varepsilon \end{aligned} \qquad [6]$$

for some positive constant $C$.

The case $n = 1$ (periodic solutions) is not as easy as the finite-dimensional case, because there are infinitely many normal frequencies, so that there are small divisor problems which for finite-dimensional systems appear only for $n \geq 2$.

For the nonlinear wave equation and the Schrödinger equation, if $n \geq 1$, one can take $V(x) = \mu$, but one needs $\mu \neq 0$; for $n > 1$, one can take $V(x) = \mu$, as one can perform a preliminary transformation leading to an equation in which a function depending on parameters naturally appears, as shown by Kuksin and Pöschel (1996). For $n = 1$, the case $\mu = 0$ has been very recently solved by Gentile *et al.* (2005).

Statements for more general situations can also be obtained, while extensions to space dimensions $d \geq 2$ are not trivial and have been obtained only recently by Bourgain (1998). The above result also holds if the number of components of the rotation vector is less than the number of parameters: one uses such parameters because one needs to impose some Diophantine conditions such as [5], now for all the frequencies $\lambda_k = \omega_k, k \notin \{m_1, \ldots, m_n\}$. Again, the second Mel'nikov conditions were shown by Bourgain to be unnecessary, and this is an essential ingredient for the higher-dimensional case.

Even if systems of the type considered above have been widely studied, they remain significantly different from a discrete system such as the chain of oscillators [1] for $N$ large enough (also in the limit $N \to \infty$), so that the results which have been found for PDE systems do not really provide an explanation for the numerical findings.

Also in the case of lower-dimensional tori for finite-dimensional systems the main problem is that, even if such tori exist, it is not clear what relevance they can have for the dynamics (a case in which hyperbolic tori play a role is considered later). An important feature of maximal tori is that they fill most of the phase space, a property which certainly does not hold for lower-dimensional tori, which lie outside the Kolmogorov set.

In the Fermi–Pasta–Ulam experiment, one considers initial conditions close to lower-dimensional tori; hence, an interesting problem is to study their stability, that is, how fast the trajectories starting from such initial conditions drift away.

## Arnol'd Diffusion and Nekhoroshev's Theorem

Consider again the maximal tori. For $N = 2$, the preservation of most of the invariant tori prevents the possibility of diffusion in phase space: the tori represent two-dimensional surfaces in a three-dimensional space (as dynamics occur on the level surfaces of the energy in a four-dimensional space), so that, if an initial condition is trapped in a gap between two tori, the corresponding trajectory remains confined forever between them. The situation is quite different for $N \geq 3$: in such a case, the tori do not represent a topological obstruction to diffusion any more.

That mechanisms of diffusion are really possible was shown by Arnol'd (1963). Because of the perturbation, lower-dimensional hyperbolic tori appear inside the resonance regions, with their stable and unstable manifolds (whiskers). It is possible that these manifolds of the same torus intersect with a nonvanishing angle (homoclinic angle); as a consequence, the angles between the stable and unstable manifolds of nearby tori (heteroclinic angles) can also be different from zero, and one can find a set of hyperbolic lower-dimensional tori such that the unstable manifold of each of them intersects the stable manifold of the torus next to it: one says that such tori form a transition chain of heteroclinic connections. Then there can be trajectories moving along such connections, producing at the end a drift of order 1 (in $\varepsilon$) in the action variables. Such a phenomenon is referred to as Arnol'd diffusion.

Of course, diffusing trajectories should be located in the region of phase space where there are no invariant tori (hence, a very small region when $\varepsilon$ is small), but an important consequence is that, unlike what happens in the unperturbed case, not all motions are stable: in particular, the action variables can change by a large amount over long times.

Providing interesting examples of Hamiltonian systems in which Arnol'd diffusion can occur is not so easy: in fact, for the diffusion to really occur, one needs a lower bound on the homoclinic angles, and to evaluate these angles can be difficult. For instance, Arnold's (1963) original example, which describes a system near a resonance region, is a two-parameter system given by

$$\frac{1}{2}\left(A_1^2 + A_2^2\right) + A_3 + \mu(\cos\alpha_1 - 1) + \varepsilon\mu(\cos\alpha_1 - 1)(\sin\alpha_2 + \cos\alpha_3) \qquad [7]$$

and the angles can be proved to be bounded from below only by assuming that the perturbation parameter $\varepsilon$ is exponentially small with respect to the other parameter $\mu$, which in turn implies a situation not really convincing from a physical point of view. More generally, for all the examples which are discussed in literature, the relation with physics (as the d'Alembert problem on the possibility for a planet to change the inclination of the precession cone) is not obvious.

So the question naturally arises as to how fast can such a mechanism of diffusion be, and how relevant is it for practical purposes. A first answer is provided by a theorem of Nekhoroshev (1977), which states the following result.

**Theorem 2** *Suppose we have an N-degree-of-freedom quasi-integrable Hamiltonian system, where the unperturbed Hamiltonian satisfies some condition such as convexity (or a weaker one, known as steepness, which is rather involved, to state in a concise way); for concreteness consider a function $\mathcal{H}_0(\boldsymbol{A})$ in [2] which is quadratic in $\boldsymbol{A}$. Then there are two positive constants a and b such that for times t up to $O(\exp(\varepsilon^{-b}))$ the variations of the action variables cannot be larger than $O(\varepsilon^a)$.*

The constants $a$ and $b$ depend on $N$, and they tend to zero when $N \to \infty$; Lochak and Neĭshtadt (1992) and Pöschel (1993) found estimates $a = b = 1/2N$, which are probably in general optimal. Nekhoroshev's theorem is usually stated in the form above, but it provides more information than that explicitly written: the trajectories, when trapped into a resonance region, drift away and come close to some invariant torus, and then they behave like quasiperiodic motions, up to very small corrections, for a long time, until they enter some other resonance region, and so on. Of course, for initial conditions on some invariant torus, KAM theorem applies, but the new result concerns initial conditions which do not belong to any tori.

Nekhoroshev's theorem gives a lower bound for the diffusion time, that is, the time required for a drift of order 1 to occur in the action variables. But, of course, an upper bound would also be desirable. The diffusion times are related to the amplitude of the homoclinic angles, which are very small (and difficult to estimate as stated before). The strongest results in this direction have been obtained with variational methods, for instance, by Bessi, Bernard, Berti, and Bolle: at best, for the diffusion time, one finds an estimate $O(\mu^{-1}\log\mu^{-1})$, if $\mu$ is the amplitude of the homoclinic angles (which in turn are exponentially small in some power of $\epsilon$, as one can expect as a consequence of Nekhoroshev's theorem).

Then one can imagine that the results of the Fermi–Pasta–Ulam experiment can also be interpreted in the light of Nekhoroshev's theorem. The solutions one finds numerically certainly do not correspond to maximal tori, but one could expect that they could be solutions which appear to be quasiperiodic for long but finite times (e.g., moving near some lower-dimensional torus determined by the initial conditions), and that if one really insists on observing the time evolution for a very long time, then deviations from quasiperiodic behavior could be detected. This is an appealing interpretation, and the most recent numerical results make it plausible: Galgani and Giorgilli (2003) have found numerically that the energy, even if initially confined to the lower modes, tend to be shared among all the other modes, and higher the modes the longer is the time needed for the energy to flow to them. Of course, this does not settle the problem, as there is still the issue of the large number of degrees of freedom; furthermore, for large $N$ the spacing between the frequencies is small, and they become almost degenerate. Hence, the problem still has to be considered as open.

## Stability versus Chaos

The main problem in applying the KAM theorem seems to be related to the small value of the threshold $\epsilon_0$ which is required. In general, when the size of the perturbation parameter is very large, the region of phase space filled with invariant tori decreases (or even disappears), and chaotic motions appear. By the latter, one generally means motions which are highly sensitive to the initial conditions: a small variation of the initial conditions produces a catastrophic variation in the corresponding trajectories (this is due to the appearance of strictly positive Lyapunov exponents).

A natural question is then how such a result as the KAM theorem is meaningful in physical situations: in other words, for which systems the KAM theorem can really apply.

One of the main motivations to study such a problem was to explain astronomical observations and to study the stability of the solar system. In order to apply the KAM theorem to the solar system, one has to interpret the gravitational forces between the planets as perturbations of a collection of several decoupled two-body systems (each planet with the Sun). One can write the masses of the planets as $\varepsilon m_i$, and $\varepsilon$ plays the role of the perturbation parameter. The corresponding Hamiltonian (after suitable reductions and scalings) is

$$\sum_{i=1}^{N} \frac{p_i^2}{2\mu_i} - \sum_{i=1}^{N} \frac{m_i m_0}{|q_i|} + \varepsilon \sum_{1 \le i < j \le N} \frac{p_i \cdot p_j}{m_0} + \varepsilon \sum_{1 \le i < j \le N} \frac{m_i m_j}{|q_i - q_j|} \qquad [8]$$

where $i = 0$ corresponds to the Sun, while $i = 1, \ldots, N$ correspond to the planets (hence $N = 9$), $m_0$ is the mass of the Sun, and $\varepsilon\mu_i$ are the reduced masses ($\mu_i^{-1} = m_i^{-1} + \varepsilon m_0^{-1}$); here $(q_i, p_i) \in \boldsymbol{R}^3 \times \boldsymbol{R}^3, i = 0, \ldots, N$, the inner product in $p_i \cdot p_j$ is in $\boldsymbol{R}^3$, and the norm $|\cdot|$ is the Euclidean one.

A first difficulty is that the solar system is a properly degenerate system; that is, the unperturbed Hamiltonian does not depend on all the action variables. But such a degeneracy can be removed by performing a canonical change of coordinates which produces a new Hamiltonian in which the integrable part contains new terms of order $\varepsilon$ depending on all action variables and is nondegenerate, while the perturbation becomes of order $\varepsilon^2$: the angle variables corresponding to the actions not originally appearing in the unperturbed Hamiltonian are called the slow variables, while the others are called the fast variables.

However, a naive implementation of the KAM theorem, in general, even for simplified but still realistic systems, would provide a preposterously small value of the threshold $\varepsilon_0$. The problem could be just a computational one: in principle, a very refined estimate of the threshold could give a better value, so that it is very difficult to decide analytically if the real values of the planetary masses allow the solar system to fall inside the regime of applicability of the KAM theorem. Results in this direction have been obtained, but only for special situations: for instance, by considering the restricted planar circular three-body problem (which provides a simplified description of the system "Sun + Jupiter + asteroid"), Celletti and Chierchia (1997) found analytical bounds on the perturbation parameters comparable with the physical values. Of course, this is not at all conclusive for the general situation in which all planets (with their satellites and the asteroids) are considered together; in particular, it does not shed light on the problem of the stability of the entire solar system.

On the contrary, extensive numerical simulations performed by Laskar (starting from 1989) seem to suggest that the solar system is unstable. Deflections from the current orbits could be produced to such an extent that collisions between planets could not be avoided: Mercury could collide with Venus and be ejected from the solar system. An important issue is to consider the times over which such phenomena can occur. Laskar's numerical simulations show that such times are less than the estimated age of the solar system, and that one can make accurate predictions for the planetary motions only for a finite amount of time (~100 Myr). Furthermore, the assumed partial instability of the solar system has also been used by Laskar (2004) to explain some observed phenomena such as the evolution of the obliquity (which is the angle between equator and orbital plane) of some planets. Of course, these simulations have been carried out with several approximations, as that of averaging over the fast variables, which allows one to use a large integration step in the numerical integration of the equations of motion for the resulting system. This is the so-called secular system introduced by Lagrange: instead of the fast motion of the planets, one describes the slow deformations of the planetary orbits (imagining the planets as regions of mass spread along their orbits).

# Standard Model of Particle Physics

**G Altarelli**, CERN, Geneva, Switzerland

## Introduction

The standard model (SM) is a consistent, finite, and – within the limitations of our present technical ability – computable theory of fundamental microscopic interactions that successfully explains most of the known phenomena in elementary particle physics. The SM describes strong, electromagnetic, and weak interactions. All microscopic phenomena observed to date can be attributed to one or the other of these interactions. For example, the forces that hold together the protons and the neutrons in the atomic nuclei are due to strong interactions; the binding of electrons to nuclei in atoms or of atoms in molecules is caused by electromagnetism; and the energy production in the Sun and the other stars occurs through nuclear reactions induced by weak interactions. In principle, gravitational forces should also be included in the list of fundamental interactions but their impact on fundamental particle processes at accessible energies is totally negligible.

The structure of the SM is a generalization of that of quantum electrodynamics (QED), in the sense that it is a renormalizable field theory based on a local symmetry (i.e., separately valid at each spacetime point $x$) that extends the gauge invariance of electrodynamics to a larger set of

conserved currents and charges. There are eight strong charges, called "color" charges and four electroweak charges (which, in particular, include the electric charge). The commutators of these charges form the $SU(3) \otimes SU(2) \otimes U(1)$ algebra. In QED, the interaction between two matter particles with electric charges (e.g., two electrons) is mediated by the exchange of one (or more) photons emitted by one electron and reabsorbed by the second. In the SM the matter fields, all of spin 1/2, are the quarks, the constituents of protons, neutrons, and all hadrons, endowed with both color and electroweak charges, and the leptons (the electron $e^-$, the muon $\mu^-$, the tauon $\tau^-$, plus the three associated neutrinos $\nu_e$, $\nu_\mu$, and $\nu_\tau$) with no color but with electroweak charges. The matter fermions come in three generations or families with identical quantum numbers but different masses. The pattern is as follows:

$$\begin{bmatrix} u & u & u & \nu_e \\ d & d & d & e \end{bmatrix}, \quad \begin{bmatrix} c & c & c & \nu_\mu \\ s & s & s & \mu \end{bmatrix}, \quad \begin{bmatrix} t & t & t & \nu_\tau \\ b & b & b & \tau \end{bmatrix} \qquad [1]$$

Each family contains a weakly charged doublet of quarks, in three color replicas, and a colorless weakly charged doublet with a neutrino and a charged lepton. At present, there is no explanation for this triple repetition of fermion families. The force carriers, of spin 1, are the photon $\gamma$, the weak interaction gauge bosons $W^+$, $W^-$, and $Z_0$ and the eight gluons $g$ that mediate the strong interactions. The photon and the gluons have zero masses as a consequence of the exact conservation of the corresponding symmetry generators, the electric charge and the eight color charges. The weak bosons $W^+$, $W^-$, and $Z_0$ have large masses ($m_W \sim 80.4$ GeV, $m_Z = 91.2$ GeV), signaling that the corresponding symmetries are badly broken. In the SM, the spontaneous breaking of the electroweak gauge symmetry is induced by the Higgs mechanism, which predicts the presence of one (or more) spin 0 particles in the physical spectrum, the Higgs boson(s), not yet experimentally observed. A tremendous experimental effort is underway or planned to reveal the Higgs sector as the last crucial missing link in the SM verification.

## Quantum Chromodynamics

The statement that quantum chromodynamics (QCD) is a renormalizable gauge theory based on the group SU(3) with color triplet quark matter fields fixes the QCD Lagrangian density to be

$$\mathcal{L} = -\frac{1}{4}\sum_{A=1}^{8} F^{A\mu\nu}F^{A}_{\mu\nu} + \sum_{j=1}^{n_f} \bar{q}_j(\mathrm{i}\not{D} - m_j)q_j \qquad [2]$$

Here $q_j$ are the quark fields (of $n_f$ different flavors) with mass $m_j$; $\not{D} = D_\mu\gamma^\mu$, where $\gamma^\mu$ are the Dirac matrices and $D_\mu$ is the covariant derivative

$$D_\mu = \partial_\mu - \mathrm{i}e_s \sum_A t^A g^A_\mu \qquad [3]$$

$e_s$ is the gauge coupling (in analogy with QED,

$$\alpha_s = \frac{e_s^2}{4\pi} \qquad [4]$$

here and throughout this article natural units, $\hbar = c = 1$, are used); $g^A_\mu$, $A = 1, \ldots, 8$, are the gluon fields, and $t^A$ are the SU(3) group generators in the triplet representation of quarks (i.e., $t_A$ are $3 \times 3$ matrices acting on $q$); the generators obey the commutation relations $[t^A, t^B] = \mathrm{i}C_{ABC}t^C$, where $C_{ABC}$ are the complete antisymmetric structure constants of SU(3) (the normalization of $C_{ABC}$ and of $e_s$ is specified by $tr[t^A t^B] = 1/2\delta^{AB}$);

$$F^A_{\mu\nu} = \partial_\mu g^A_\nu - \partial_\nu g^A_\mu - e_s C_{ABC} g^B_\mu g^C_\nu \qquad [5]$$

The physical vertices in QCD include the gluon–quark–antiquark vertex, analogous to the QED photon–fermion–antifermion coupling, but also the three-gluon and four-gluon vertices, of order $e_s$ and $e_s^2$, respectively, which have no analog in an abelian theory like QED. In QED, the photon (a neutral particle) is coupled to all electrically charged particles. In QCD, the gluons are colored, hence self-coupled. This is reflected in the fact that in QED $F_{\mu\nu}$ is linear in the gauge field, so that the term $F^2_{\mu\nu}$ in the Lagrangian is a pure kinetic term, while in QCD $F^A_{\mu\nu}$ is quadratic in the gauge field, so that in $F^{A2}_{\mu\nu}$ we find cubic and quartic vertices beyond the kinetic term.

The QCD Lagrangian in eqn [2] has a simple structure but a very rich dynamical content, including the observed complex spectroscopy with a large number of hadrons. The most prominent properties of QCD are asymptotic freedom and confinement. In field theory, the effective coupling of a given interaction vertex is modified by the interaction. As a result, the measured intensity of the force depends on the transferred (four)momentum squared, $Q^2$, among the participants. In QCD, the relevant coupling parameter that appears in physical processes is $\alpha_s$ (see eqn [4]). Asymptotic freedom means that the effective coupling becomes a function of

$Q^2$: $\alpha_s(Q^2)$ decreases for increasing $Q^2$ and vanishes asymptotically. Thus, the QCD interaction becomes very weak in processes with large $Q^2$, called hard processes or deep inelastic processes (i.e., with a final-state distribution of momenta and a particle content very different from that in the initial state). One can prove that in four spacetime dimensions all gauge theories based on a noncommuting group of symmetry are asymptotically free, and conversely. The effective coupling decreases very slowly at large momenta with the inverse logarithm of $Q^2$: $\alpha_s(Q^2) = 1/b \log Q^2/\Lambda^2$, where $b$ is a known constant and $\Lambda$ is an energy of the order of a few hundred MeV. Since in quantum mechanics large momenta imply short wavelengths, the result is that at short distances the potential between two color charges is similar to the Coulomb potential, that is, proportional to $\alpha_s(r)/r$, with an effective color charge which is small at short distances. On the contrary the interaction strength becomes large at large distances or small transferred momenta, of order $Q \lesssim \Lambda$. In fact, the observed hadrons are tightly bound composite states of quarks, with compensating color charges so that they are overall neutral in color. The property of confinement is the impossibility of separating color charges, like individual quarks and gluons. This is because in QCD the interaction potential between color charges increases, at long distances, linearly in $r$. When we try to separate the quark and the antiquark that form a color-neutral meson the interaction energy grows until pairs of quarks and antiquarks are created from the vacuum and new neutral mesons are coalesced instead of free quarks. For example, consider the process $e^+e^- \to q\bar{q}$ at large center-of-mass energies. The final-state quark and antiquark have large energies, so they separate in opposite directions very fast. But the color-confinement forces create new pairs in between them. Two back-to-back jets of colorless hadrons are observed with a number of slow pions that make the exact separation of the two jets impossible. In some cases, a third well-separated jet of hadrons is also observed: these events correspond to the radiation of an energetic gluon from the parent quark–antiquark pair.

## Electroweak Interactions

We split the electroweak Lagrangian into two parts by separating the Higgs boson couplings:

$$\mathcal{L} = \mathcal{L}_{\text{symm}} + \mathcal{L}_{\text{Higgs}} \qquad [6]$$

We start by specifying $\mathcal{L}_{\text{symm}}$, which involves only gauge bosons and fermions (a sum over all flavors of quarks and leptons, generally indicated by $\psi$ is understood):

$$\mathcal{L}_{\text{symm}} = -\frac{1}{4}\sum_{A=1}^{3} F^A_{\mu\nu}F^{A\mu\nu} - \frac{1}{4}B_{\mu\nu}B^{\mu\nu} + \bar{\psi}_{\text{L}} \text{i}\gamma^\mu D_\mu \psi_{\text{L}} + \bar{\psi}_{\text{R}} \text{i}\gamma^\mu D_\mu \psi_{\text{R}} \qquad [7]$$

This is the Yang–Mills Lagrangian for the gauge group SU(2) $\otimes$ U(1) with fermion matter fields. Here

$$\begin{aligned} B_{\mu\nu} &= \partial_\mu B_\nu - \partial_\nu B_\mu \\ F^A_{\mu\nu} &= \partial_\mu W^A_\nu - \partial_\nu W^A_\mu - g\epsilon_{ABC} W^B_\mu W^C_\nu \end{aligned} \qquad [8]$$

are the gauge antisymmetric tensors constructed out of the gauge field $B_\mu$ associated with U(1), and $W^A_\mu$ corresponding to the three SU(2) generators; $\epsilon_{ABC}$ are the group structure constants (see eqn [11]), which, for SU(2), coincide with the totally antisymmetric Levi-Civita tensor (recall the familiar angular-momentum commutators).

The fermion fields are described through their left- and right-hand components:

$$\psi_{\text{L,R}} = [(1 \mp \gamma_5)/2]\psi, \qquad \bar{\psi}_{\text{L,R}} = \bar{\psi}[(1 \pm \gamma_5)/2] \qquad [9]$$

Note that, as given in eqn [9],

$$\begin{aligned} \bar{\psi}_{\text{L}} &= \psi^\dagger_{\text{L}}\gamma_0 = \psi^\dagger[(1-\gamma_5)/2]\gamma_0 \\ &= \bar{\psi}[\gamma_0(1-\gamma_5)/2]\gamma_0 = \bar{\psi}[(1+\gamma_5)/2] \end{aligned}$$

The matrices $P_\pm = (1 \pm \gamma_5)/2$ are projectors. They satisfy the relations $P_\pm P_\pm = P_\pm, P_\pm P_\mp = 0$, $P_+ + P_- = 1$.

The standard electroweak theory is a chiral theory, in the sense that $\psi_{\text{L}}$ and $\psi_{\text{R}}$ behave differently under the gauge group. In particular, all $\psi_{\text{R}}$ are singlets and all $\psi_{\text{L}}$ are doublets in the minimal SM (MSM). Thus, mass terms for fermions (of the form $\bar{\psi}_{\text{L}}\psi_{\text{R}}$ + h.c.) are forbidden in the symmetric limit. Fermion masses are introduced, together with $W^\pm$ and $Z$ masses, by the mechanism of symmetry breaking. The covariant derivatives $D_\mu\psi_{\text{L,R}}$ are explicitly given by

$$D_\mu\psi_{\text{L,R}} = \left[\partial_\mu + \text{i}g\sum_{A=1}^{3} t^A_{\text{L,R}} W^A_\mu + \text{i}g'\frac{1}{2}Y_{\text{L,R}}B_\mu\right]\psi_{\text{L,R}} \qquad [10]$$

where $t^A_{\text{L,R}}$ and $1/2Y_{\text{L,R}}$ are the SU(2) and U(1) generators, respectively, in the reducible representations $\psi_{\text{L,R}}$. The commutation relations of the SU(2) generators are given by

$$[t^A_{\text{L}}, t^B_{\text{L}}] = \text{i}\epsilon_{ABC}t^C_{\text{L}} \quad \text{and} \quad [t^A_{\text{R}}, t^B_{\text{R}}] = \text{i}\epsilon_{ABC}t^C_{\text{R}} \qquad [11]$$

We use the normalization $\text{tr}[t^At^B] = 1/2\delta^{AB}$ in the fundamental representation of SU(2). The electric

charge generator $Q$ (in units of $e$, the positron charge) is given by

$$Q = t_{\mathrm{L}}^3 + 1/2\, Y_{\mathrm{L}} = t_{\mathrm{R}}^3 + 1/2\, Y_{\mathrm{R}} \qquad [12]$$

All fermion couplings to the gauge bosons can be derived directly from eqns [7] and [10]. The charged-current (CC) couplings are the simplest. From

$$\begin{aligned} g\left(t^1 W_\mu^1 + t^2 W_\mu^2\right) &= g\left\{\left[\left(t^1 + \mathrm{i}t^2\right)/\sqrt{2}\right]\right. \\ &\quad \times \left.\left[\left(W_\mu^1 - \mathrm{i}W_\mu^2\right)/\sqrt{2}\right] + \text{h.c.}\right\} \\ &= g\left\{\left[\left(t^+ W_\mu^-\right)/\sqrt{2}\right] + \text{h.c.}\right\} \end{aligned} \qquad [13]$$

where $t^\pm = t^1 \pm \mathrm{i}t^2$ and $W^\pm = (W^1 \pm \mathrm{i}W^2)/\sqrt{2}$, we obtain the vertex

$$\begin{aligned} V_{\bar\psi\psi W} &= g\bar\psi\gamma_\mu\left[\left(t_{\mathrm{L}}^+/\sqrt{2}\right)(1-\gamma_5)/2 + \left(t_{\mathrm{R}}^+/\sqrt{2}\right)\right. \\ &\quad \times \left.(1+\gamma_5)/2\right]\psi W_\mu^- + \text{h.c.} \end{aligned} \qquad [14]$$

In the neutral-current (NC) sector, the photon $A_\mu$ and the mediator $Z_\mu$ of the weak NC are orthogonal and normalized linear combinations of $B_\mu$ and $W_\mu^3$:

$$\begin{aligned} A_\mu &= \cos\theta_{\mathrm{W}} B_\mu + \sin\theta_{\mathrm{W}} W_\mu^3 \\ Z_\mu &= -\sin\theta_{\mathrm{W}} B_\mu + \cos\theta_{\mathrm{W}} W_\mu^3 \end{aligned} \qquad [15]$$

Equations [15] define the weak mixing angle $\theta_{\mathrm{W}}$. The photon is characterized by equal couplings to left and right fermions with a strength equal to the electric charge. Recalling eqn [12] for the charge matrix $Q$, we immediately obtain

$$g\sin\theta_{\mathrm{W}} = g'\cos\theta_{\mathrm{W}} = e \qquad [16]$$

or, equivalently,

$$\tan\theta_{\mathrm{W}} = g'/g \qquad [17]$$

Once $\theta_{\mathrm{W}}$ has been fixed by the photon couplings, it is a simple matter of algebra to derive the $Z$ couplings, with the result

$$\begin{aligned} \Gamma_{\bar\psi\psi Z} &= g/(2\cos\theta_{\mathrm{W}})\bar\psi\gamma_\mu\left[t_{\mathrm{L}}^3(1-\gamma_5) + t_{\mathrm{R}}^3(1+\gamma_5)\right. \\ &\quad \left.-2Q\sin^2\theta_{\mathrm{W}}\right]\psi Z^\mu \end{aligned} \qquad [18]$$

where $\Gamma_{\bar\psi\psi Z}$ is a notation for the vertex. In the MSM, $t_{\mathrm{R}}^3 = 0$ and $t_{\mathrm{L}}^3 = \pm 1/2$. Note that the CC and NC weak couplings do not conserve P (parity) and C (charge conjugation).

In order to derive the effective four-fermion interactions that are equivalent, at low energies, to the CC and NC couplings given in eqns [14] and [18], we anticipate that large masses, as experimentally observed, are provided for $W^\pm$ and $Z$ by $\mathcal{L}_{\mathrm{Higgs}}$. For left–left CC couplings, when the momentum transfer squared can be neglected with respect to $m_{\mathrm{W}}^2$ in the propagator of Born diagrams with single $W$ exchange, from eqn [14], we can write

$$\begin{aligned} \mathcal{L}_{\mathrm{eff}}^{\mathrm{CC}} &\simeq \left(g^2/8m_{\mathrm{W}}^2\right)\left[\bar\psi\gamma_\mu(1-\gamma_5)t_{\mathrm{L}}^+\psi\right] \\ &\quad \times \left[\bar\psi\gamma^\mu(1-\gamma_5)t_{\mathrm{L}}^-\psi\right] \end{aligned} \qquad [19]$$

By specializing further in the case of doublet fields such as $\nu_e - e^-$ or $\nu_\mu - \mu^-$, we obtain the tree-level relation of $g$ with the Fermi coupling constant $G_{\mathrm{F}}$ measured from $\mu$ decay ($G_{\mathrm{F}} = 1.16639(2) \times 10^{-5}\,\mathrm{GeV}^{-2}$):

$$G_{\mathrm{F}}/\sqrt{2} = g^2/8m_{\mathrm{W}}^2 \qquad [20]$$

By recalling that $g\sin\theta_{\mathrm{W}} = e$, we can also cast this relation in the form

$$m_{\mathrm{W}} = \mu_{\mathrm{Born}}/\sin\theta_{\mathrm{W}} \qquad [21]$$

with

$$\mu_{\mathrm{Born}} = \left(\pi\alpha/\sqrt{2}G_{\mathrm{F}}\right)^{1/2} \simeq 37.2802\,\mathrm{GeV} \qquad [22]$$

where $\alpha$ is the fine-structure constant of QED ($\alpha \equiv e^2/4\pi = 1/137.036$).

In the same way, for neutral currents we obtain, in Born approximation, from eqn [18], the effective four-fermion interaction given by

$$\mathcal{L}_{\mathrm{eff}}^{\mathrm{NC}} \simeq \sqrt{2}G_{\mathrm{F}}\rho_0\bar\psi\gamma_\mu[\ldots]\psi\bar\psi\gamma^\mu[\ldots]\psi \qquad [23]$$

where

$$[\ldots] \equiv t_{\mathrm{L}}^3(1-\gamma_5) + t_{\mathrm{R}}^3(1+\gamma_5) - 2Q\sin^2\theta_{\mathrm{W}} \qquad [24]$$

and

$$\rho_0 = m_{\mathrm{W}}^2/m_{\mathrm{Z}}^2\cos^2\theta_{\mathrm{W}} \qquad [25]$$

All couplings given in this section are obtained at tree level and are modified in higher orders of perturbation theory. In particular, the relations between $m_{\mathrm{W}}$ and $\sin\theta_{\mathrm{W}}$ (eqns [21] and [22]) and the observed values of $\rho$ ($\rho = \rho_0$ at tree level) in different NC processes are altered by computable small electroweak radiative corrections.

The gauge-boson self-interactions can be derived from the $F_{\mu\nu}$ term in $\mathcal{L}_{\mathrm{symm}}$, by using eqn [15] and $W^\pm = (W^1 \pm \mathrm{i}W^2)/\sqrt{2}$. For the three-gauge-boson vertex $W^+W^-V$ with $V = Z, \gamma$, we obtain

$$\begin{aligned} \Gamma_{W^-W^+V} &= \mathrm{i}g_{W^-W^+V}\left[g_{\mu\nu}(q-p)_\lambda + g_{\mu\lambda}(p-r)_\nu\right. \\ &\quad \left.+ g_{\nu\lambda}(r-q)_\mu\right] \end{aligned} \qquad [26]$$

with

$$\begin{aligned} g_{W^-W^+\gamma} &= g\sin\theta_{\mathrm{W}} = e \quad \text{and} \\ g_{W^-W^+Z} &= g\cos\theta_{\mathrm{W}} \end{aligned} \qquad [27]$$

This form of the triple gauge vertex is very special: in general, there could be departures from the above SM expression, even restricting us to $SU(2) \otimes U(1)$ gauge symmetric and C and P invariant couplings. In fact, some small corrections are already induced by the radiative corrections. The SM form of the triple gauge vertex has been experimentally confirmed by measuring the cross section $e^+e^- \rightarrow W^+W^-$ at LEP.

We now turn to the Higgs sector of the electroweak Lagrangian. The Higgs Lagrangian is specified by the gauge principle and the requirement of renormalizability to be

$$\mathcal{L}_{\text{Higgs}} = \left(D_\mu \phi\right)^\dagger \left(D^\mu \phi\right) - V\left(\phi^\dagger \phi\right) - \bar{\psi}_{\text{L}} \Gamma \psi_{\text{R}} \phi - \bar{\psi}_{\text{R}} \Gamma^\dagger \psi_{\text{L}} \phi^\dagger \qquad [28]$$

where $\phi$ is a column vector including all Higgs scalar fields; it transforms as a reducible representation of the gauge group. The quantities $\Gamma$ (which include all coupling constants) are matrices that make the Yukawa couplings invariant under the Lorentz and gauge groups. The potential $V(\phi^\dagger\phi)$, symmetric under $SU(2) \otimes U(1)$, contains, at most, quartic terms in $\phi$ so that the theory is renormalizable:

$$V\left(\phi^\dagger \phi\right) = -\tfrac{1}{2}\mu^2 \phi^\dagger \phi + \tfrac{1}{4}\lambda\left(\phi^\dagger \phi\right)^2 \qquad [29]$$

Spontaneous symmetry breaking is induced if the minimum of $V$, which is the classical analog of the quantum-mechanical vacuum state (both are the states of minimum energy) is obtained for nonvanishing $\phi$ values. This occurs because we have taken $\mu^2$ and $\lambda$ positive in $V$ (note the "wrong" sign of the mass term). Precisely, we denote the vacuum expectation value (VEV) of $\phi$, that is, the position of the minimum, by $v$:

$$\langle 0|\phi(x)|0\rangle = v \neq 0 \qquad [30]$$

The fermion mass matrix is obtained from the Yukawa couplings by replacing $\phi(x)$ by $v$:

$$M = \bar{\psi}_{\text{L}} \mathcal{M} \psi_{\text{R}} + \bar{\psi}_{\text{R}} \mathcal{M}^\dagger \psi_{\text{L}} \qquad [31]$$

with

$$\mathcal{M} = \Gamma \cdot v \qquad [32]$$

In the SM, where all left fermions, $\psi_{\text{L}}$, are doublets and all right fermions, $\psi_{\text{R}}$, are singlets, only Higgs doublets can contribute to fermion masses. There are enough free couplings in $\Gamma$, so that one single complex Higgs doublet is indeed sufficient to generate the most general fermion mass matrix. It is important to observe that by a suitable change of basis we can always make the matrix $\mathcal{M}$ Hermitian, $\gamma_5$-free and diagonal. In fact, we can make separate unitary transformations on $\psi_{\text{L}}$ and $\psi_{\text{R}}$ according to

$$\psi'_{\text{L}} = U\psi_{\text{L}}, \qquad \psi'_{\text{R}} = V\psi_{\text{R}} \qquad [33]$$

and consequently

$$\mathcal{M} \rightarrow \mathcal{M}' = U^\dagger \mathcal{M} V \qquad [34]$$

This transformation does not alter the general structure of the fermion couplings in $\mathcal{L}_{\text{symm}}$.

If only one Higgs doublet is present, the change of basis that makes $\mathcal{M}$ diagonal will at the same time diagonalize also the fermion–Higgs Yukawa couplings. Thus, in this case, no flavor-changing neutral Higgs exchanges are present. This is not true, in general, when there are several Higgs doublets. But one Higgs doublet for each electric charge sector, that is, one doublet coupled only to $u$-type quarks, one doublet to $d$-type quarks, one doublet to charged leptons would also be satisfactory, because the mass matrices of fermions with different charges are diagonalized separately. In fact, at the moment, the simplest model with only one Higgs doublet seems adequate for describing all observed phenomena.

Weak charged currents are the only tree-level interactions in the SM that change flavor: by emission of a $W$, a $u$-type quark is turned into a $d$-type quark, or a $\nu_l$ neutrino is turned into an $l^-$ charged lepton (all fermions are left-handed). If we start from a $u$-type quark that is a mass eigenstate, emission of a $W$ turns it into a $d$-type quark state $d'$ (the weak isospin partner of $u$) that in general is not a mass eigenstate. In general, the mass eigenstates and the weak eigenstates do not coincide and a unitary transformation connects the two sets:

$$\begin{pmatrix} d' \\ s' \\ b' \end{pmatrix} = V \begin{pmatrix} d \\ s \\ b \end{pmatrix} \qquad [35]$$

or, in shorthand, $D' = VD$, where $V$ is the Cabibbo–Kobayashi–Maskawa (CKM) matrix. Thus, in terms of mass eigenstates the charged weak current of quarks is of the form

$$J^+_\mu \propto \bar{u}\gamma_\mu(1 - \gamma_5)VD \qquad [36]$$

Since $V$ is unitary (i.e., $VV^\dagger = V^\dagger V = 1$) and commutes with $T^2$, $T_3$, and Q (because all $d$-type quarks have the same isospin and charge) the neutral current couplings are diagonal both in the primed and unprimed basis (if the $Z$ $d$-type quark current is abbreviated as $\bar{D}'\Gamma D'$ then by changing basis we get $\bar{D}V^\dagger\Gamma VD$ and $V$ and $\Gamma$ commute because, as seen from eqn [24], $\Gamma$ is made of Dirac matrices and $T_3$ and Q generator matrices). It follows that $\bar{D}'\Gamma D' = \bar{D}\Gamma D$. This is the Glashow–Iliopoulos–Maiani (GIM)

mechanism that ensures natural flavor conservation of the neutral current couplings at the tree level. For three generations of quarks, the CKM matrix depends on four physical parameters: three mixing angles and one phase. This phase is the unique source of CP violation in the SM.

We now consider the gauge-boson masses and their couplings to the Higgs. These effects are induced by the $(D_\mu\phi)^\dagger(D^\mu\phi)$ term in $\mathcal{L}_{\text{Higgs}}$ (eqn [28]), where

$$D_\mu\phi = \left[\partial_\mu + \mathrm{i}g\sum_{A=1}^{3} t^A W_\mu^A + \mathrm{i}g'(Y/2)B_\mu\right]\phi \qquad [37]$$

Here $t^A$ and $1/2Y$ are the $\mathrm{SU}(2)\otimes\mathrm{U}(1)$ generators in the reducible representation spanned by $\phi$. Not only doublets but all non-singlet Higgs representations can contribute to gauge-boson masses. The condition that the photon remains massless is equivalent to the condition that the vacuum is electrically neutral:

$$Q|v\rangle = \left(t^3 + \tfrac{1}{2}Y\right)|v\rangle = 0 \qquad [38]$$

The charged $W$ mass is given by the quadratic terms in the $W$ field arising from $\mathcal{L}_{\text{Higgs}}$, when $\phi(x)$ is replaced by $v$. We obtain

$$m_{\mathrm{W}}^2 W_\mu^+ W^{-\mu} = g^2\left|\left(t^+ v/\sqrt{2}\right)\right|^2 W_\mu^+ W^{-\mu} \qquad [39]$$

whilst for the $Z$ mass we get (recalling eqn [15])

$$\tfrac{1}{2}m_{\mathrm{Z}}^2 Z_\mu Z^\mu = \left|\left[g\cos\theta_{\mathrm{W}} t^3 - g'\sin\theta_{\mathrm{W}}(Y/2)\right]v\right|^2 Z_\mu Z^\mu \qquad [40]$$

where the factor of 1/2 on the left-hand side is the correct normalization for the definition of the mass of a neutral field. For Higgs doublets

$$\phi = \begin{pmatrix}\phi^+\\ \phi^0\end{pmatrix}, \qquad v = \begin{pmatrix}0\\ v\end{pmatrix} \qquad [41]$$

we obtain

$$m_{\mathrm{W}}^2 = 1/2g^2v^2, \qquad m_{\mathrm{Z}}^2 = 1/2g^2v^2/\cos^2\theta_{\mathrm{W}} \qquad [42]$$

Note that by using eqn [20] we obtain

$$v = 2^{-3/4}G_{\mathrm{F}}^{-1/2} = 174.1\,\mathrm{GeV} \qquad [43]$$

It is also evident that for Higgs doublets

$$\rho_0 = m_{\mathrm{W}}^2/m_{\mathrm{Z}}^2\cos^2\theta_{\mathrm{W}} = 1 \qquad [44]$$

This relation is typical of one or more Higgs doublets and would be spoiled by the existence of, for example, Higgs triplets. This result is valid at the tree level and is modified by calculable small electroweak radiative corrections. The $\rho_0$ parameter has been measured from the intensity of NC interactions (recall eqn [25]) and confirmed to be close to unity at a few per milli level.

In MSM only one Higgs doublet is present. Then the fermion–Higgs couplings are in proportion to the fermion masses. In fact, from the Yukawa couplings $g_{\phi\bar{f}f}(\bar{f}_{\mathrm{L}}\phi f_{\mathrm{R}} + \mathrm{h.c.})$, the mass $m_f$ is obtained by replacing $\phi$ by $v$, so that $m_f = g_{\phi\bar{f}f}v$. In MSM, three out of the four Hermitian fields are removed from the physical spectrum by the Higgs mechanism and become the longitudinal modes of $W^+, W^-$, and $Z$ which acquire a mass. The fourth neutral Higgs is physical and should be found. If more doublets are present, two more charged and two more neutral Higgs scalars should be around for each additional doublet.

The couplings of the physical Higgs $H$ to the gauge bosons can be simply obtained from $\mathcal{L}_{\text{Higgs}}$, by the replacement

$$\phi(x) = \begin{pmatrix}\phi^+(x)\\ \phi^0(x)\end{pmatrix} \rightarrow \begin{pmatrix}0\\ v + (H/\sqrt{2})\end{pmatrix} \qquad [45]$$

(so that $(D_\mu\phi)^\dagger(D^\mu\phi) = 1/2(\partial_\mu H)^2 + \cdots$), with the result

$$\begin{aligned}\mathcal{L}[H, W, Z] &= g^2\left(v/\sqrt{2}\right)W_\mu^+W^{-\mu}H + \left(g^2/4\right)W_\mu^+W^{-\mu}H^2\\ &\quad + \left[\left(g^2vZ_\mu Z^\mu\right)/\left(2\sqrt{2}\cos^2\theta_{\mathrm{W}}\right)\right]H\\ &\quad + \left[g^2/\left(8\cos^2\theta_{\mathrm{W}}\right)\right]Z_\mu Z^\mu H^2\end{aligned}$$

In MSM, the Higgs mass $m_{\mathrm{H}}^2 \sim \lambda v^2$ is of order of the weak scale $v$ but cannot be predicted because the value of $\lambda$ is not fixed. The dominant decay mode of the Higgs is in the $b\bar{b}$ channel below the $WW$ threshold, while the $W^+W^-$ channel is dominant for sufficiently large $m_{\mathrm{H}}$. The width is small below the $WW$ threshold, not exceeding a few MeV, but increases steeply beyond the threshold, reaching the asymptotic value of $\Gamma \sim 1/2m_{\mathrm{H}}^3$ at large $m_{\mathrm{H}}$, where all energies and masses are in TeV.

A central role in the experimental verification of the standard electroweak theory has been played by CERN, the European Laboratory for Particle Physics, located near Geneva, between France and Switzerland. The indirect effects of the $Z_0$, that is, the occurrence of weak processes induced by the neutral current, were first observed in 1974 at CERN by the Collaboration Gargamelle (the name of the bubble chamber used in the experiment). Later, in 1982, the $W^\pm$ and the $Z_0$ were, for the first time, directly produced and observed in proton–antiproton collisions by the UA1 and UA2 collaborations and then further studied with the same technique both at CERN and subsequently at the Tevatron of Fermilab near Chicago. Starting from 1989 LEP, the large $e^+e^-$ collider was functioning at CERN till 2000. In the LEP circular ring of circumference $\sim$27 km, electrons and

positrons were accelerated in opposite directions to an equal energy in the range between 45 and 103 GeV. The beams were made to cross and collide in correspondence of four experimental areas where the ALEPH, DELPHI, L3, and OPAL detectors were located to study the final states produced in the collisions. In its first phase, called LEP1, from 1989 to 1995 the LEP operation had been completely dedicated to a precise study of the $Z_0$ properties, mass, lifetime, and decay modes in order to accurately test the predictions of the SM. The main lessons of the precision tests of the standard electroweak theory can be summarized as follows. It has been checked that the couplings of quarks and leptons to the weak gauge bosons $W^{\pm}$ and $Z$ are indeed precisely those prescribed by the gauge symmetry. The accuracy of a few tenths of 1% for these tests implies that, not only the tree level, but also the structure of quantum corrections has been verified. Then, since the end of 1995, the energy of LEP was increased and the phase of LEP2 was started. The total energy was gradually increased up to 206 GeV. The main physics goals of LEP2 were the search for the Higgs and for possible new particles, the precise measurement of $m_W$ and the experimental study of the triple gauge vertices $WW\gamma$ and $WWZ_0$. The Higgs particle of the SM could in principle be produced at LEP2 in the reaction $e+e^- \to Z_0 H$, which proceeds by $Z_0$ exchange. The nonobservation of the Higgs particle at LEP2 has allowed to establish a lower limit on its mass: $m_{\rm H} \gtrsim 114$ GeV. Indirect indications on the Higgs mass were also obtained from the precision tests of the SM, as the radiative effects depend logarithmically on $m_{\rm H}$. The indication is that the Higgs mass cannot be too heavy if the SM is valid: $m_{\rm H} \lesssim 219$ GeV at 95% c.l. In 2001, LEP was dismantled and, in its tunnel, a new double ring of superconducting magnets is being installed. The new accelerator, the LHC (Large Hadron Collider), will be a proton–proton collider of total center-of-mass energy 14 TeV. Two large experiments ATLAS and CMS will continue to search for the Higgs starting in the year 2007. The sensitivity of LHC experiments to the SM Higgs will go up to masses $m_{\rm H}$ of $\sim$1 TeV.

# Stationary Black Holes

**R Beig**, Universität Wien, Vienna, Austria
**P T Chruściel**, Université de Tours, Tours, France

## Introduction

This article treats a specific class of stationary solutions to the Einstein field equations which read

$$R_{\mu\nu} - \frac{1}{2} g_{\mu\nu} R = \frac{8\pi G}{c^4} T_{\mu\nu} \qquad [1]$$

Here $R_{\mu\nu}$ and $R = g^{\mu\nu} R_{\mu\nu}$ are, respectively, the Ricci tensor and the Ricci scalar of the spacetime metric $g_{\mu\nu}$, $G$ the Newton constant, and $c$ the speed of light. The tensor $T_{\mu\nu}$ is the stress–energy tensor of matter. Spacetimes, or regions thereof, where $T_{\mu\nu} = 0$ are called vacuum.

Stationary solutions are of interest for a variety of reasons. As models for compact objects at rest, or in steady rotation, they play a key role in astrophysics. They are easier to study than nonstationary systems because stationary solutions are governed by elliptic rather than hyperbolic equations. Finally, like in any field theory, one expects that large classes of dynamical solutions approach ("settle down to") a stationary state in the final stages of their evolution.

The simplest stationary solutions describing compact isolated objects are the spherically symmetric

ones. In the vacuum region, these are all given by the Schwarzschild family. A theorem of Birkhoff shows that in the vacuum region any spherically symmetric metric, even without assuming stationarity, belongs to the family of Schwarzschild metrics, parametrized by a positive mass parameter $m$. Thus, regardless of possible motions of the matter, as long as they remain spherically symmetric, the exterior metric is the Schwarzschild one for some constant $m$. This has the following consequence for stellar dynamics: imagine following the collapse of a cloud of pressureless fluid ("dust"). Within Newtonian gravity, this dust cloud will, after finite time, contract to a point at which the density and the gravitational potential diverge. However, this result cannot be trusted as a sensible physical prediction because, even if one supposes that Newtonian gravity is still valid at very high densities, a matter model based on noninteracting point particles is certainly not. Consider, next, the same situation in the Einstein theory of gravity: here a new question arises, related to the form of the Schwarzschild metric outside of the spherically symmetric body:

$$
\begin{aligned}
g &= -V^2\,\mathrm{d}t^2 + V^{-2}\,\mathrm{d}r^2 + r^2\mathrm{d}\Omega^2,\\
V^2 &= 1 - \frac{2Gm}{rc^2},\\
t &\in \mathbb{R}, \quad r \in \left(\frac{2Gm}{c^2}, \infty\right)
\end{aligned}
\qquad [2]
$$

Here $\mathrm{d}\Omega^2$ is the line element of the standard 2-sphere. Since the metric [2] seems to be singular as $r = 2m$ is approached (from now on, we use units in which $G = c = 1$), there arises the need to understand what happens at the surface of the star when the radius $r = 2m$ is reached. One thus faces the need of a careful study of the geometry of the metric [2] when $r = 2m$ is approached, and crossed.

The first key feature of the metric [2] is its stationarity, of course, with Killing vector field $X$ given by $X = \partial_t$. A Killing field, by definition, is a vector field the local flow of which generates isometries. A spacetime (the term spacetime denotes a smooth, paracompact, connected, orientable, and time-orientable Lorentzian manifold) is called stationary if there exists a Killing vector field $X$ which approaches $\partial_t$ in the asymptotically flat region (where $r$ goes to $\infty$; see below for precise definitions) and generates a one-parameter group of isometries. A spacetime is called static if it is stationary and if the stationary Killing vector $X$ is hypersurface orthogonal, that is, $X^\flat \wedge \mathrm{d}X^\flat = 0$, where $X^\flat = X_\mu\,\mathrm{d}x^\mu = g_{\mu\nu}X^\nu\,\mathrm{d}x^\mu$. A spacetime is called axisymmetric if there exists a Killing vector field $Y$, which generates a one-parameter group of isometries and which behaves like a rotation in the asymptotically flat region, with all orbits $2\pi$-periodic. In asymptotically flat spacetimes, this implies that there exists an axis of symmetry, that is, a set on which the Killing vector vanishes. Killing vector fields which are a nontrivial linear combination of a time translation and of a rotation in the asymptotically flat region are called stationary rotating, or helical.

There exists a technique, due independently to Kruskal and Szekeres, of attaching together two regions $r > 2m$ and two regions $r < 2m$ of the Schwarzschild metric, as in Figure 1, to obtain a manifold with a metric which is smooth at $r = 2m$. In the extended spacetime, the hypersurface $\{r = 2m\}$ is a null hypersurface $\mathscr{E}$, the Schwarzschild event horizon. The stationary Killing vector $X = \partial_t$ extends to a Killing vector in the extended spacetime which becomes tangent to and null on $\mathscr{E}$. The global properties of the Kruskal–Szekeres extension of the exterior Schwarzschild spacetime make this spacetime a natural model for a nonrotating black hole. It is worth noting here that the exterior Schwarzschild spacetime [2] admits an infinite number of nonisometric vacuum extensions, even in the class of maximal, analytic, simply connected ones. The Kruskal–Szekeres extension is singled out by the properties that it is maximal, vacuum, analytic, simply connected, with all maximally extended geodesics either complete, or with the area $r$ of the orbits of the isometry groups tending to zero along them.

We can now come back to the problem of the contracting dust cloud according to the Einstein theory. For simplicity, we take the density of the dust to be uniform – the so-called Oppenheimer–Snyder solution. It then turns out that, in the course of collapse, the surface of the dust will eventually cross the Schwarzschild radius, leaving behind a Schwarzschild black hole. If one follows the dust cloud further, a singularity will eventually form, but will not be visible from the "outside region" where $r > 2m$. For a collapsing body of the mass of the Sun, say, one has $2m = 3\,\mathrm{km}$. Thus, standard phenomenological matter models such as that for dust can still be trusted, so that the previous objection to the Newtonian scenario does not apply.

There is a rotating generalization of the Schwarzschild metric, namely the two-parameter family of exterior Kerr metrics, which in Boyer–Lindquist coordinates takes the form

$$
\begin{aligned}
g = &-\frac{\Delta - a^2\sin^2\theta}{\Sigma}\,\mathrm{d}t^2 - \frac{2a\sin^2\theta(r^2 + a^2 - \Delta)}{\Sigma}\,\mathrm{d}t\,\mathrm{d}\varphi\\
&+ \frac{(r^2 + a^2)^2 - \Delta a^2\sin^2\theta}{\Sigma}\sin^2\theta\,\mathrm{d}\varphi^2\\
&+ \frac{\Sigma}{\Delta}\,\mathrm{d}r^2 + \Sigma\,\mathrm{d}\theta^2
\end{aligned}
\qquad [3]
$$

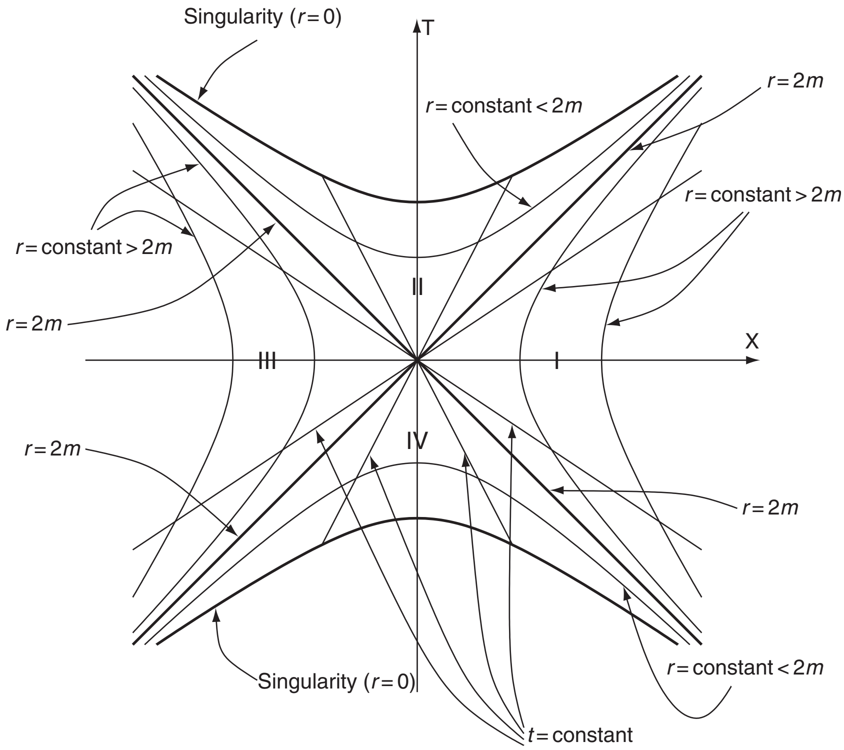

**Figure 1** The Kruskal–Szekeres extension of the Schwarzschild solution. (Adapted with permission from Nicolas J-P (2002) Dirac fields on asymptotically flat space-times. *Dissertationes Mathematicae* 408: 1–85.)

with $0 \leq a < m$. Here $\Sigma = r^2 + a^2 \cos^2\theta, \Delta = r^2 + a^2 - 2mr$ and $r_+ < r < \infty$ where $r_+ = m + (m^2 - a^2)^{1/2}$. When $a = 0$, the Kerr metric reduces to the Schwarzschild metric. The Kerr metric is again a vacuum solution, and it is stationary with $X = \partial_t$ the asymptotic time translation, as well as axisymmetric with $Y = \partial_\varphi$ the generator of rotations. Similarly to the Schwarzschild case, it turns out that the metric can be smoothly extended across $r = r_+$, with $\{r = r_+\}$ being a smooth null hypersurface $\mathscr{E}$ in the extension. The null generator $K$ of $\mathscr{E}$ is the limit of the stationary-rotating Killing field $X + \omega Y$, where $\omega = a/(2mr_+)$. On the other hand, the Killing vector $X$ is timelike only outside the hypersurface $\{r = m + (m^2 - a^2 \cos^2\theta)^{1/2}\}$, on which $X$ becomes null. In the region between $r_+$ and $r = m + (m^2 - a^2\cos^2\theta)^{1/2}$, which is called the ergoregion, $X$ is spacelike. It is also spacelike on and tangent to $\mathscr{E}$, except where the axis of rotation meets $\mathscr{E}$, where $X$ is null. Based on the above properties, the Kerr family provides natural models for rotating black holes.

Unfortunately, as opposed to the spherically symmetric case, there are no known explicit collapsing solutions with rotating matter, in particular no known solutions having the Kerr metric as final state.

The aim of the theory outlined below is to understand the general geometrical features of stationary black holes, and to give a classification of models satisfying the field equations.

## Model-Independent Concepts

Some of the notions used informally in the introductory section will now be made more precise. The mathematical notion of black hole is meant to capture the idea of a region of spacetime which cannot be seen by "outside observers." Thus, at the outset, one assumes that there exists a family of physically preferred observers in the spacetime under consideration. When considering isolated physical systems, it is natural to define the "exterior observers" as observers which are "very far" away from the system under consideration. The standard way of making this mathematically precise is by using conformal completions, discussed in more detail in the article about asymptotic structure in this encyclopedia: a pair $(\tilde{\mathscr{M}}, \tilde{g})$ is called a conformal completion at infinity, or simply conformal completion, of $(\mathscr{M}, g)$ if $\tilde{\mathscr{M}}$ is a manifold with boundary such that:

1. $\mathscr{M}$ is the interior of $\tilde{\mathscr{M}}$;
2. there exists a function $\Omega$, with the property that the metric $\tilde{g}$, defined as $\Omega^2 g$ on $\mathscr{M}$, extends by continuity to the boundary of $\tilde{\mathscr{M}}$, with the

extended metric remaining of Lorentzian signature; and

3. $\Omega$ is positive on $\mathscr{M}$, differentiable on $\tilde{\mathscr{M}}$, vanishes on the boundary

$$\mathscr{I} := \tilde{\mathscr{M}} \setminus \mathscr{M}$$

with $d\Omega$ nowhere vanishing on $\mathscr{I}$.

The boundary $\mathscr{I}$ of $\tilde{\mathscr{M}}$ is called Scri, a phonic shortcut for "script I." The idea here is the following: forcing $\Omega$ to vanish on $\mathscr{I}$ ensures that $\mathscr{I}$ lies infinitely far away from any physical object – a mathematical way of capturing the notion "very far away." The condition that $d\Omega$ does not vanish is a convenient technical condition which ensures that $\mathscr{I}$ is a smooth three-dimensional hypersurface, instead of some, say, one- or two-dimensional object, or of a set with singularities here and there. Thus, $\mathscr{I}$ is an idealized description of a family of observers at infinity.

To distinguish between various points of $\mathscr{I}$, one sets

$$\mathscr{I}^+ = \{\text{points in } \mathscr{I} \text{ which are to the future of the physical spacetime}\}$$

$$\mathscr{I}^- = \{\text{points in } \mathscr{I} \text{ which are to the past of the physical spacetime}\}$$

(Recall that a point $q$ is to the future, respectively to the past, of $p$ if there exists a future directed, respectively past directed, causal curve from $p$ to $q$. Causal curves are curves $\gamma$ such that their tangent vector $\dot{\gamma}$ is causal everywhere, $g(\dot{\gamma}, \dot{\gamma}) \leq 0$.) One then defines the black hole region $\mathscr{B}$ as

$$\mathscr{B} := \{\text{points in } \mathscr{M} \text{ which are not in the past of } \mathscr{I}^+\} \qquad [4]$$

By definition, points in the black hole region cannot thus send information to $\mathscr{I}^+$; equivalently, observers on $\mathscr{I}^+$ cannot see points in $\mathscr{B}$. The white-hole region $\mathscr{W}$ is defined by changing the time orientation in [4]. A key notion related to the concept of a black hole is that of future ($\mathscr{E}^+$) and past ($\mathscr{E}^-$) event horizons,

$$\mathscr{E}^+ := \partial\mathscr{B}, \qquad \mathscr{E}^- := \partial\mathscr{W} \qquad [5]$$

Under mild assumptions, event horizons in stationary spacetimes with matter satisfying the null-energy condition,

$$T_{\mu\nu}\ell^\mu\ell^\nu \geq 0 \quad \text{for all null vectors } \ell^\mu \qquad [6]$$

are smooth null hypersurfaces, analytic if the metric is analytic.

In order to develop a reasonable theory, one also needs a regularity condition for the interior of spacetime. This has to be a condition which does not exclude singularities (otherwise the Schwarzschild and Kerr black holes would be excluded), but which nevertheless guarantees a well-behaved exterior region. One such condition, assumed in all the results described below, is the existence in $\mathscr{M}$ of an asymptotically flat spacelike hypersurface $\mathscr{S}$ with compact interior. Further, either $\mathscr{S}$ has no boundary or the boundary of $\mathscr{S}$ lies on $\overline{\mathscr{E}^+ \cup \mathscr{E}^-}$. To make things precise, for any spacelike hypersurface let $g_{ij}$ be the induced metric, and let $K_{ij}$ denote its extrinsic curvature. A spacelike hypersurface $\mathscr{S}_{\text{ext}}$ diffeomorphic to $\mathbb{R}^3$ minus a ball will be called asymptotically flat if the fields $(g_{ij}, K_{ij})$ satisfy the fall-off conditions

$$|g_{ij} - \delta_{ij}| + r|\partial_\ell g_{ij}| + \cdots + r^k|\partial_{\ell_1\cdots\ell_k} g_{ij}| + r|K_{ij}| + \cdots + r^k|\partial_{\ell_1\cdots\ell_{k-1}} K_{ij}| \leq Cr^{-1} \qquad [7]$$

for some constants $C, k \geq 1$. A hypersurface $\mathscr{S}$ (with or without boundary) will be said to be asymptotically flat with compact interior if $\mathscr{S}$ is of the form $\mathscr{S}_{\text{int}} \cup \mathscr{S}_{\text{ext}}$, with $\mathscr{S}_{\text{int}}$ compact and $\mathscr{S}_{\text{ext}}$ asymptotically flat.

There exists a canonical way of constructing a conformal completion with good global properties for stationary spacetimes which are asymptotically flat in the sense of [7], and which are vacuum sufficiently far out in the asymptotic region. This conformal completion is referred to as the standard completion and will be assumed from now on.

Returning to the event horizon $\mathscr{E} = \mathscr{E}^+ \cup \mathscr{E}^-$, it is not very difficult to show that every Killing vector field $X$ is necessarily tangent to $\mathscr{E}$. Since the latter set is a null Lipschitz hypersurface, it follows that $X$ is either null or spacelike on $\mathscr{E}$. This leads to a preferred class of event horizons, called Killing horizons. By definition, a Killing horizon associated with a Killing vector $K$ is a null hypersurface which coincides with a connected component of the set

$$\mathcal{H}(K) := \{p \in \mathscr{M}\colon\ g(K,K)(p) = 0,\ K(p) \neq 0\} \qquad [8]$$

A simple example is provided by the "boost Killing vector field" $K = z\partial_t + t\partial_z$ in Minkowski spacetime: $\mathcal{H}(K)$ has four connected components,

$$\mathcal{H}_{\epsilon\delta} := \{t = \epsilon z, \delta t > 0\}, \quad \epsilon, \delta \in \{\pm 1\}$$

The closure $\bar{\mathcal{H}}$ of $\mathcal{H}$ is the set $\{|t| = |z|\}$, which is not a manifold, because of the crossing of the null hyperplanes $\{t = \pm z\}$ at $t = z = 0$. Horizons of this type are referred to as bifurcate Killing horizons, with the set $\{K(p) = 0\}$ being called the bifurcation surface of $\mathcal{H}(K)$. The bifurcate horizon structure in the Kruszkal–Szekeres–Schwarzschild spacetime can be clearly seen in **Figures 1** and **2**.

The Vishveshwara–Carter lemma shows that if a Killing vector $K$ is hypersurface orthogonal, $K^\flat \wedge dK^\flat = 0$, then the set $\mathcal{H}(K)$ defined in [8] is a union of smooth null hypersurfaces, with $K$ being tangent to the null geodesics threading $\mathcal{H}$ ("$\mathcal{H}$ is generated by $K$"), and so is indeed a Killing horizon. It has been shown by Carter that the same conclusion can be reached if the hypothesis of hypersurface orthogonality is replaced by that of existence of two linearly independent Killing vector fields.

In stationary-axisymmetric spacetimes, a Killing vector $K$ tangent to the generators of a Killing horizon $\mathcal{H}$ can be normalized so that $K = X + \omega Y$, where $X$ is the Killing vector field which asymptotes to a time translation in the asymptotic region, and $Y$ is the Killing vector field which generates rotations in the asymptotic region. The constant $\omega$ is called the angular velocity of the Killing horizon $\mathcal{H}$.

On a Killing horizon $\mathcal{H}(K)$, one necessarily has

$$\nabla^\mu (K^\nu K_\nu) = -2\kappa K^\mu \qquad [9]$$

Assuming the so-called dominant-energy condition on $T_{\mu\nu}$ (*see* Positive Energy Theorem and Other Inequalities in GR), it can be shown that $\kappa$ is constant (recall that Killing horizons are always connected in the terminology used in this article); it is called the surface gravity of $\mathcal{H}$. A Killing horizon is called degenerate when $\kappa = 0$, and nondegenerate otherwise; by an abuse of terminology, one similarly talks of degenerate black holes, etc. In Kerr spacetimes we have $\kappa = 0$ if and only if $m = a$. A fundamental theorem of Boyer shows that degenerate horizons are closed. This implies that a horizon $\mathcal{H}(K)$ such that $K$ has zeros in $\bar{\mathcal{H}}$ is nondegenerate, and is of bifurcate type, as described above. Further, a nondegenerate Killing horizon with complete geodesic generators always contains zeros of $K$ in its closure. However, it is not true that existence of a nondegenerate horizon implies that of zeros of $K$: take the Killing vector field $z\partial_t + t\partial_z$ in Minkowski spacetime from which the 2-plane $\{z = t = 0\}$ has been removed. The universal cover of that last spacetime provides a spacetime in which one cannot restore the points which have been artificially removed, without violating the manifold property.

The domain of outer communications (DOC) of a black hole spacetime is defined as

$$\langle\langle \mathscr{M} \rangle\rangle := \mathscr{M} \setminus \{\mathscr{B} \cup \mathscr{W}\} \qquad [10]$$

Thus, $\langle\langle \mathscr{M} \rangle\rangle$ is the region lying outside of the white-hole region and outside of the black hole region; it is the region which can both be seen by the outside observers and influenced by those.

The subset of $\langle\langle \mathscr{M} \rangle\rangle$ where $X$ is spacelike is called the ergoregion. In the Schwarzschild spacetime, $\omega = 0$ and the ergoregion is empty, but neither of these is true in Kerr with $a \neq 0$.

A very convenient method for visualizing the global structure of spacetimes is provided by the Carter–Penrose diagrams. An example of such a diagram is given in Figure 2.

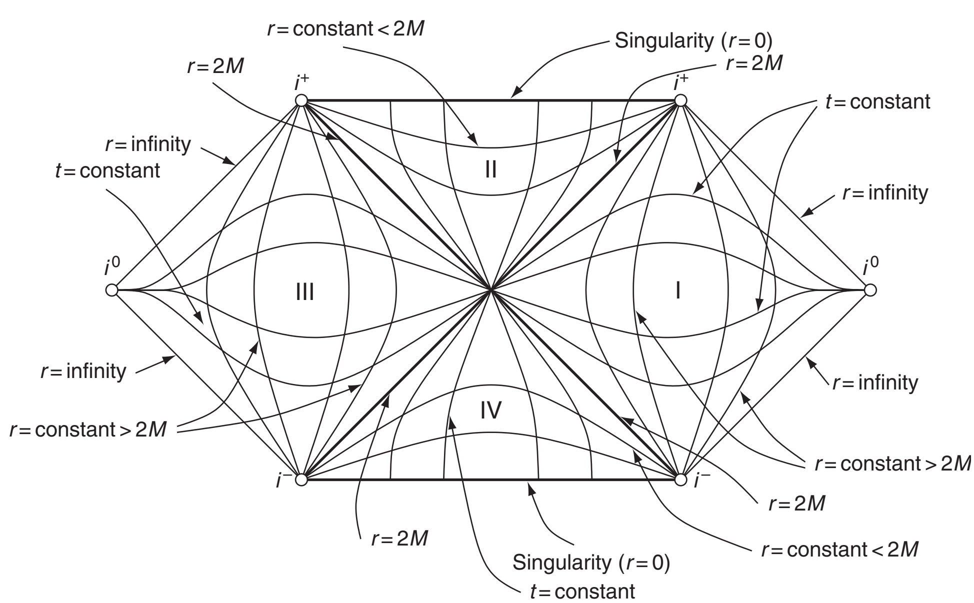

**Figure 2** The Carter–Penrose diagram for the Kruskal–Szekeres spacetime. There are actually two asymptotically flat regions, with corresponding $\mathscr{I}^\pm$ and $\mathscr{E}^\pm$ defined with respect to the second region, but not indicated on this diagram. Each point in this diagram represents a two-dimensional sphere, and coordinates are chosen so that light cones have slopes ±1. Regions are numbered as in Figure 1. (Adapted with permission from Nicolas J-P (2002) Dirac fields on asymptotically flat space-times. *Dissertationes Mathematicae* 408: 1–85.)

A corollary of the topological censorship theorem of Friedman, Schleich, and Witt is that DOCs of regular black hole spacetimes satisfying the dominant-energy condition are simply connected. This implies that connected components of event horizons in stationary spacetimes have $\mathbb{R} \times S^2$ topology.

The discussion of the concepts associated with stationary-black hole spacetimes can be concluded by summarizing the properties of the Schwarzschild and Kerr geometries: the extended Kerr spacetime with $m > a$ is a black hole spacetime with the hypersurface $\{r = r_+\}$ forming a nondegenerate, bifurcate Killing horizon generated by the vector field $X + \omega Y$ and surface gravity given by

$$\kappa = \frac{(m^2 - a^2)^{1/2}}{2m[m + (m^2 - a^2)^{1/2}]}$$

In the case $a = 0$, where the angular velocity $\omega$ vanishes, $X$ is hypersurface orthogonal and becomes the generator of $\mathcal{H}$. The bifurcation surface in this case is the totally geodesic 2-sphere, along which the four regions in **Figure 1** are joined.

## Classification of Stationary Solutions ("No-Hair Theorems")

We confine attention to the "outside region" of black holes, the DOC. (Except for the degenerate case discussed later, the "inside"(black hole) region is not stationary, so that this restriction already follows from the requirement of stationarity.) For reasons of space, we only consider vacuum solutions; there exists a similar theory for electro-vacuum black holes. (There is a somewhat less developed theory for black hole spacetimes in the presence of nonabelian gauge fields.) In connection with a collapse scenario, the vacuum condition begs the question: collapse of what? The answer is twofold: first, there are large classes of solutions of Einstein equations describing pure gravitational waves. It is believed that sufficiently strong such solutions will form black holes. (Whether or not they will do that is related to the cosmic censorship conjecture, *see* Spacetime Toplogy, Casual Structure and Singularities.) Consider, next, a dynamical situation in which matter is initially present. The conditions imposed in this section correspond then to a final state in which matter has either been radiated away to infinity, or has been swallowed by the black hole (as in the spherically symmetric Oppenheimer–Snyder collapse described above).

Based on the facts below, it is expected that the DOCs of appropriately regular, stationary, vacuum black holes are isometrically diffeomorphic to those of Kerr black holes:

1. *The rigidity theorem* (Hawking). Event horizons in regular, nondegenerate, stationary, analytic vacuum black holes are either Killing horizons for $X$, or there exists a second Killing vector in $\langle\langle \mathscr{M} \rangle\rangle$.
2. *The Killing horizons theorem* (Sudarsky–Wald). Nondegenerate stationary vacuum black holes such that the event horizon is the union of Killing horizons of $X$ are static.
3. The Schwarzschild black holes exhaust the family of static regular vacuum black holes (Israel, Bunting – Masood-ul-Alam, Chruściel).
4. The Kerr black holes satisfying

$$m^2 > a^2 \qquad [11]$$

exhaust the family of nondegenerate, stationary-axisymmetric, vacuum, connected black holes. Here $m$ is the total Arnowitt–Deser–Misner (ADM) mass, while the product $am$ is the total ADM angular momentum. (Of course, these quantities generalize the constants $a$ and $m$ appearing in the Kerr metric.) The framework for the proof has been set up by Carter, and the statement above is due to Robinson.

The above results are collectively known under the name of no-hair theorems, and they have not provided the final answer to the problem so far. There are no *a priori* reasons known for the analyticity hypothesis in the rigidity theorem. Further, degenerate horizons have been completely understood in the static case only.

Yet another key open question is that of the existence of nonconnected regular stationary-axisymmetric vacuum black holes. The following result is due to Weinstein: let $\partial\mathscr{S}_a$, $a = 1, \ldots, N$, be the connected components of $\partial\mathscr{S}$. Let $X^\flat = g_{\mu\nu} X^\mu \, dx^\nu$, where $X^\mu$ is the Killing vector field which asymptotically approaches the unit normal to $\mathscr{S}_{\text{ext}}$. Similarly, set $Y^\flat = g_{\mu\nu} Y^\mu dx^\nu$, $Y^\mu$ being the Killing vector field associated with rotations. On each $\partial\mathscr{S}_a$, there exists a constant $\omega_a$ such that the vector $X + \omega_a Y$ is tangent to the generators of the Killing horizon intersecting $\partial\mathscr{S}_a$. The constant $\omega_a$ is called the angular velocity of the associated Killing horizon. Define

$$m_a = -\frac{1}{8\pi} \int_{\partial\mathscr{S}_a} *dX^\flat \qquad [12]$$

$$L_a = -\frac{1}{4\pi} \int_{\partial\mathscr{S}_a} *dY^\flat \qquad [13]$$

Such integrals are called Komar integrals. One usually thinks of $L_a$ as the angular momentum of each connected component of the black hole. Set

$$\mu_a = m_a - 2\omega_a L_a \tag{14}$$

Weinstein shows that one necessarily has $\mu_a > 0$. The problem at hand can be reduced to a harmonic-map equation, also known as the Ernst equation, involving a singular map from $\mathbb{R}^3$ with Euclidean metric $\delta$ to the two-dimensional hyperbolic space. Let $r_a > 0$, $a = 1, \ldots, N-1$, be the distance in $\mathbb{R}^3$ along the axis between neighboring black holes as measured with respect to the (unphysical) metric $\delta$. Weinstein proved that for nondegenerate regular black holes the inequality [11] holds, and that the metric on $\langle\langle \mathscr{M} \rangle\rangle$ is determined up to isometry by the $3N-1$ parameters

$$(\mu_1, \ldots, \mu_N, L_1, \ldots, L_N, r_1, \ldots, r_{N-1}) \tag{15}$$

just described, with $r_a, \mu_a > 0$. These results by Weinstein contain the no-hair theorem of Carter and Robinson as a special case. Weinstein also shows that, for every $N \geq 2$ and for every set of parameters [15] with $\mu_a, r_a > 0$, there exists a solution of the problem at hand. It is known that for some sets of parameters [15] the solutions will have "strut singularities" between some pairs of neighboring black holes, but the existence of the "struts" for all sets of parameters as above is not known, and is one of the main open problems in our understanding of stationary-axisymmetric electro-vacuum black holes. The existence and uniqueness results of Weinstein remain valid when strut singularities are allowed in the metric at the outset, although such solutions do not fall into the category of regular black holes discussed here.

# Stationary Phase Approximation

**J J Duistermaat**, Universiteit Utrecht, Utrecht, The Netherlands

## Introduction

An oscillatory integral is an integral of the form

$$I(\omega) = \int e^{i\omega\varphi(\theta)} a(\theta) d\theta \tag{1}$$

Here the integration is over a smooth $k$-dimensional manifold $\Theta$ which is provided with a smooth density $d\theta$. The real variable $\omega$ plays the role of a frequency variable, whereas the real-valued smooth function $\varphi$ on $\Theta$ is called the phase function. The amplitude function $a$ is assumed to be a compactly supported complex (vector-) valued smooth function on $\Theta$. The topic of this article is the asymptotic behavior of the oscillatory integral $I(\omega)$ as the frequency $\omega$ tends to infinity.

When the manifold $\Theta$ is not compact and the amplitude function is not compactly supported, then a smooth cutoff function may be used to write the integral as the sum of an integral with a compactly supported amplitude and one with an amplitude which is equal to zero in a large compact subset of $\Theta$. The

latter integral can be studied if suitable assumptions are made about the asymptotic behavior of the phase function and the amplitude at infinity, but this is not the subject of this article. The use of the exponential function with purely imaginary argument instead of the sine and the cosine is just a matter of convenience.

The first observation about oscillatory integrals in the next section is the principle of stationary phase, which states that the contributions to the integral which are not rapidly decreasing as $\omega \to \infty$ only come from the stationary points of $\varphi$, the points $\theta \in \Theta$ where the total derivative $\mathrm{d}\varphi(\theta)$ of $\varphi$ is equal to zero. This principle is closely related to the observation that a superposition of waves is maximal at points where the waves are in phase, an observation which goes back to Huygens (1690).

Assume that $\theta_0$ is a nondegenerate stationary point of $\varphi$. That is, $\mathrm{d}\varphi(\theta_0) = 0$ and the Hessian $\mathrm{D}^2\varphi(\theta_0)$ of $\varphi$ at $\theta_0$ is nondegenerate. Then $\theta_0$ is an isolated stationary point of $\varphi$, and the contribution to $I(\omega)$ of a neighborhood of $\theta_0$ has an asymptotic expansion of the form

$$I(\omega) \sim \mathrm{e}^{\mathrm{i}\omega\varphi(\theta_0)} \sum_{r=0}^{\infty} c_r\, \omega^{-k/2-r}, \quad r \to \infty$$

Here the leading coefficient $c_0$ is the product of $a(\theta_0)$ with a nonzero constant which only depends on $\mathrm{D}^2\varphi(\theta_0)$ and the density $\mathrm{d}\theta$ at $\theta_0$. For increasing $r$ the coefficients $c_r$ depend on the derivatives of $\varphi$ and $a$ at $\theta_0$ of increasing order (see the section "The method of stationary phase").

Usually, even if all the objects are analytic in a neighborhood of $\theta_0$, the asymptotic power series does not converge. However, there are exceptional cases where the stationary phase approximation is exact. Assume, for instance, that $\Theta$ is a compact manifold provided with a symplectic form $\sigma, \varphi$ is the Hamiltonian function of a Hamiltonian circle action on $\Theta$ with isolated fixed points, and $a(\theta)\,\mathrm{d}\theta = \sigma^k/k!$. Then the stationary points of $\varphi$ are the fixed points of the circle action, each stationary point of $\varphi$ is nondegenerate and $I(\omega)$ is equal to the sum over the finitely many stationary points of only the leading terms of the asymptotic expansions at the stationary points. This Duistermaat–Heckman formula is a consequence of a more general localization formula in equivariant cohomology (see the section "Exact stationary phase").

For the purpose of applications, but also in the analysis of oscillatory integrals, it is worthwhile to allow complex-valued phase functions, but with a local minimum for the imaginary part at the stationary point $\theta_0$ of the real parts. That is, the real part of the exponent $\mathrm{i}\omega\varphi(\theta)$ has a local maximum at $\theta_0$. An extreme case occurs when $\varphi(\theta) = \mathrm{i}\psi(\theta)$ for a real-valued function $\psi$ which has a nondegenerate local minimum at $\theta_0$, in which case the integrand is a sharply peaking Gaussian density at $\theta_0$. When $\varphi$ and $a$ are analytic near $\theta_0$, then the method of steepest descent consists of deforming the path of integration in the complex domain in such a way that the integrand becomes such a sharply peaking Gaussian density. During the deformation, the integral does not change because of Cauchy's integral theorem.

An important extension of the theory occurs if the real-valued phase function and the amplitude are allowed to depend smoothly on additional parameters $x$, which vary in an $n$-dimensional smooth manifold $M$. The amplitude is also allowed to depend on $\omega$, with an asymptotic expansion of the form

$$a(x,\theta,\omega) \sim \sum_{r=0}^{\infty} a_r(x,\theta)\omega^{m+(k/2)-r} \quad \text{as } \omega \to \infty \qquad [2]$$

The expansion is supposed to be locally uniformly in $(x,\theta)$ and to allow termwise differentiations of any order with respect to the variables $(x,\theta)$. Then the integral

$$I(x,\omega) = \int \mathrm{e}^{\mathrm{i}\omega\varphi(x,\theta)} a(x,\theta,\omega)\,\mathrm{d}\theta$$

is called an oscillatory integral of order $m$. Here the function $x \mapsto I(x,\omega)$ is viewed as a continuous superposition of the $\theta$-dependent family of oscillatory functions $x \mapsto \mathrm{e}^{\mathrm{i}\omega\varphi(x,\theta)}a(x,\theta)$.

The example which formed the point of departure of Airy (1838) is that $\mathrm{e}^{\mathrm{i}\omega\varphi(x,\theta)}a(x,\theta,\omega)$ is the wave which arrives at the points $x$ in spacetime which is sent out by a point $\theta$ on a reflecting mirror. That is, at $x$ one collects (= integrates over $\Theta$) all the waves sent out by the various points $\theta$ of the mirror $\Theta$. The main point of the theory, however, is that in great generality the solutions of linear partial differential equations, such as classical wave equations or quantum mechanical Schrödinger equations, can be represented, as functions of $x$, as oscillatory integrals. This construction has led to decisive progress in the general theory of linear partial differential equations with smoothly varying coefficients.

According to the principle of stationary phase, the main asymptotic contributions to the integral come from the points $\theta$ such that $\partial\varphi(x,\theta)/\partial\theta = 0$. The phase function $\varphi \in \mathrm{C}^\infty(M \times \Theta)$ is called nondegenerate if the $(n+k) \times k$-matrix

$$\frac{\partial^2\varphi(x,\theta)}{\partial(x,\theta)\partial\theta} \text{ has rank } k \text{ when } \frac{\partial\varphi(x,\theta)}{\partial\theta} = 0 \qquad [3]$$

This is the natural condition to ensure that the set

$$S_\varphi := \left\{ (x, \theta) \in M \times \Theta \middle| \frac{\partial \varphi(x, \theta)}{\partial \theta} = 0 \right\}$$

is a smooth $n$-dimensional submanifold of $M \times \Theta$. The condition [3], moreover, implies that the mapping

$$\iota_\varphi : S_\varphi \ni (x, \theta) \mapsto \left( x, \frac{\partial \varphi(x, \theta)}{\partial x} \right) \in \mathrm{T}^* M$$

is a smooth immersion from $S_\varphi$ into the cotangent bundle $\mathrm{T}^*M$ of $M$. Note that $\xi = \partial\varphi(x,\theta)/\partial x$ is coordinate invariantly defined as a linear form on the tangent space $\mathrm{T}_xM$ of $M$ at the point $x$. That is, $\xi \in (\mathrm{T}_xM)^*$ = the dual space of $\mathrm{T}_xM$, and $(\mathrm{T}_xM)^*$ is the fiber of $\mathrm{T}^*M$ over $x$. In classical mechanics, $\mathrm{T}^*M$ is the phase space of the position space $M$, and a linear form $\xi$ on $\mathrm{T}_xM$ is called a momentum vector at the position $x$. If $\sigma$ denotes the canonical symplectic form on $\mathrm{T}^*M$, then $\iota_\varphi^*\sigma = 0$. The immersion $\iota_\varphi$ locally embeds $S_\varphi$ onto a smooth $n$-dimensional submanifold $\Lambda_\varphi$ of $M$, which is a Lagrangian manifold in $\mathrm{T}^*M$, which by definition means that $\iota_\varphi^*\sigma = 0$.

Oscillatory integrals with very different phase functions and amplitudes can define the same $\omega$-dependent functions on $M$. The theory of Hörmander (1971, section 3.1) says that the germs of the Lagrangian manifolds $\Lambda_\varphi$ and $\Lambda_\psi$ are the same if and only if $\varphi$ and $\psi$ define the same class of oscillatory integrals. Moreover, every Lagrangian submanifold $\Lambda$ of $\mathrm{T}^*M$ is locally of the form $\Lambda_\varphi$ for some nondegenerate phase function $\varphi$. In this way, the mapping $\varphi \mapsto \Lambda_\varphi$ defines a bijection between the set of equivalence classes of germs of nondegenerate phase functions and the set of germs of Lagrangian submanifolds of $\mathrm{T}^*M$. Let $\Lambda$ be an immersed Lagrangian submanifold of $\mathrm{T}^*M$. A global oscillatory integral of order $m$ on $M$, defined by $\Lambda$, is a locally finite sum $u(x,\omega)$ of oscillatory integrals of order $m$ with nondegenerate phase functions $\varphi$ such that $\Lambda_\varphi \subset \Lambda$. The leading terms of the amplitudes correspond to a section $s$ of a canonically defined complex line bundle $\lambda$ over $\Lambda$, which is called the principal symbol of $u$ (see the section "The principal symbol on the Lagrangian manifold").

If $P$ is a linear partial differential operator, such as the wave operators, in which the coefficients may depend in a smooth way on $x$ and in a polynomial way on $\omega$, then the condition that $Pu$ is asymptotically small implies that $p = 0$ on $\Lambda$, in which $p$ is a smooth function on $\mathrm{T}^*M$, called the principal symbol of $P$. Because $\Lambda$ is a Lagrangian manifold, the equation $p = 0$ implies that $\Lambda$ is invariant under the flow of the Hamiltonian system with Hamilton function equal to $p$. Furthermore, the principal symbol $s$ of $u$ satisfies a homogeneous first-order ordinary differential equation along the solution curves of the Hamiltonian system. Conversely, these properties can be used to construct global oscillatory integrals $u$ which asymptotically satisfy $Pu = 0$ and have prescribed initial values. This theory, due to Maslov (1972), may be viewed as a far reaching generalization of the WKB method.

Let $\pi : \mathrm{T}^*M \to M : (x, \xi) \mapsto x$ denote the canonical projection from $\mathrm{T}^*M$ onto $M$. The projections into $M$ of the solution curves in a Lagrangian submanifold $\Lambda$ of $\mathrm{T}^*M$, of a Hamiltonian system which leaves $\Lambda$ invariant, are the ray bundles of geometrical optics. If $\Lambda$ is not transversal to the fiber of $\mathrm{T}^*M$ at $(x, \xi)$, then the ray bundle exhibits a caustic at the point $x \in M$, and the oscillatory integral is asymptotically of larger order than $\omega^m$ near $x$. Applying the theory of unfoldings of singularities to the phase function, one can determine the structurally stable caustics and obtain normal forms of the oscillatory integrals in the structurally stable cases (see the section "Caustics").

If we also integrate over the frequency variable $\omega$, then we obtain the Fourier integral distributions $u$ of Hörmander (1971, sections 1.2 and 3.2). In this case the corresponding Lagrangian manifold is conic in the sense that if $(x, \xi) \in \Lambda$, then $(x, \tau\xi) \in \Lambda$ for every $\tau > 0$. The wave front set of $u$, which is the microlocal singular locus of the distribution $u$, is contained in $\Lambda$, with equality if the principal symbol of $u$ is not equal to zero at the corresponding stationary points of the phase function. Fourier integral operators are defined as the linear operators acting on distributions, of which the distribution kernels are Fourier integral distributions. Under a suitable transversality condition for the Lagrangian manifolds of the distribution kernels, the composition of two Fourier integral operators is again a Fourier integral operator, and the principal symbol of the composition is a product of the principal symbols. The proof is an application of the method of stationary phase. Fourier integral operators are a very powerful tool in the analysis of linear partial differential operators with smoothly varying coefficients (see Hörmander (1985)).

## The Principle of Stationary Phase

The principle of stationary phase says that if the phase function $\varphi$ has no stationary points in the support of the amplitude function $a$, then the

oscillatory integral [1] is rapidly decreasing, in the sense that for every $N$ we have $I(\omega) = O(\omega^{-N})$ as $\omega \to \infty$. For the proof, one introduces a vector field $v$ on $\Theta$ such that $v\varphi = 1$ on a neighborhood of the support of $a$. Then $e^{i\omega\varphi} = (i\omega)^{-1} v(e^{i\omega\varphi})$, and an integration by parts in [1] yields that

$$I(\omega) = \frac{1}{i\omega} \int e^{i\omega\varphi(\theta)} ({}^{t}va)(\theta)\, d\theta$$

where ${}^{t}v$ denotes the transposed of the linear partial differential operator $v$. Iterating this, the rapid decrease of $I(\omega)$ follows.

Using cutoff functions, $I(\omega)$ is, modulo a rapidly decreasing function, equal to an oscillatory integral with phase function $\varphi$ and an amplitude which has support in an arbitrarily small neighborhood of the set of stationary points of $\varphi$. In this sense, the contributions to the integral which are not rapidly decreasing come only from the stationary points of $\varphi$.

## The Method of Stationary Phase

Assume that $\theta_0$ is a nondegenerate stationary point of $\varphi$. Then $\theta_0$ is an isolated stationary point of $\varphi$. Using local coordinates near $\theta_0$, the contribution to [1] from the neighborhood of $\theta_0$ can be written as an oscillatory integral with $\Theta = \boldsymbol{R}^k$ and a pase function $\varphi$ which has a nondegenerate stationary point at 0. Write $Q = D^2\varphi(0)$. According to the Morse lemma, there is smooth substitution of variables $\theta = T(y)$ such that $T(0) = 0, DT(0) = I$, and $\varphi(T(\mu)) = \varphi(0) + \langle Qy, y\rangle/2$ for all $y$ in a neighborhood of 0 in $\boldsymbol{R}^k$. Applying this substitution of variables to [1] we obtain

$$I(\omega) = e^{i\omega\varphi(0)} \int_{\boldsymbol{R}^k} e^{i\omega\langle Qy,y\rangle/2} b(y)\, dy$$

where $b$ is a compactly supported smooth function on $\boldsymbol{R}^k$ with $b(0) = a(0)$. Now the Fourier transform of the function $y \mapsto e^{i\omega\langle Qy,y\rangle/2}$ is equal to the function

$$\eta \mapsto \left(\det\left(\frac{\omega}{2\pi i} Q\right)\right)^{-1/2} e^{i\omega^{-1}\langle Q^{-1}\eta,\eta\rangle/2} \qquad [4]$$

Both in the definition of the square root of the determinant and in the proof one uses the analytic continuation to the domain of complex-valued symmetric bilinear forms $Q$ for which the imaginary part of $Q$ is positive definite. For purely imaginary $Q$ we have the familiar formula for the Fourier transform of a Gaussian density (see Hörmander (1990, theorem 7.6.1)). The Taylor expansion of the exponential factor in [4] then yields that

$$\begin{aligned}\int_{\boldsymbol{R}^k} & e^{i\omega\langle Qy,y\rangle/2} b(y)\, dy \\ & \sim \left(\det\left(\frac{\omega}{2\pi i} Q\right)\right)^{-1/2} \sum_{r=0}^{\infty} (-2i\omega)^{-r} \frac{1}{r!} \\ & \times \left\langle Q^{-1} \frac{\partial}{\partial y}, \frac{\partial}{\partial y} \right\rangle^{r} b(y)\bigg|_{y=0}\end{aligned}$$

as $\omega \to \infty$ (see Hörmander (1990, lemma 7.7.3)).

It is important for the applications that, if the phase function and amplitude depend smoothly on parameters, all the constructions can be made to depend smoothly on the parameters.

## Exact Stationary Phase

Suppose that we have given an action of a Lie group $G$ on the manifold $\Theta$. Let $\mathfrak{g}$ denote the Lie algebra of $G$. For any $g \in G$ and $X \in \mathfrak{g}$ the corresponding diffeomorphism of $\Theta$ and vector field on $\Theta$ is denoted by $g_\Theta$ and $X_\Theta$, respectively. If $\Omega(\Theta)$ denotes the algebra of smooth differential forms on $\Theta$, then we consider the algebra $S\mathfrak{g}^* \otimes \Omega(\Theta)$ of all $\Omega(\Theta)$-valued polynomials on $\mathfrak{g}$, where $S\mathfrak{g}^*$ denotes the algebra of all polynomial functions on $\mathfrak{g}$. On $S\mathfrak{g}^* \otimes \Omega(\Theta)$ we have the action of $g \in G$ which sends $\alpha$ to $X \mapsto g_\Theta^*(\alpha(\mathrm{Ad}\, g\, X))$. Let $A = (S\mathfrak{g}^* \otimes \Omega(\Theta))^G$ denote the subalgebra of all $G$-invariant elements of $S\mathfrak{g}^* \otimes \Omega(\Theta)$. The equivariant exterior derivative $D$ is defined by

$$(D\alpha)(X) = d(\alpha(X)) - i_{X_\Theta}(\alpha(X))$$

If $\alpha$ is homogeneous as a differential form of degree $p$ and homogeneous as a polynomial on $\mathfrak{g}$ of degree $q$, then $r = p + 2q$ is called the total degree of $\alpha$. Let $A^r$ denote the space of sums of such $\alpha \in A$ of total degree $r$. Then $D_r = D\colon A^r \to A^{r+1}$ and $D_r \circ D_{r-1} = 0$. The space $H_G^r(\Theta) := \ker D_r / \mathrm{Im}\, D_{r-1}$ is called the equivariant cohomology in degree $r$, in the model of Cartan (1950).

Assume that $\Theta$ is compact and oriented, and that the action of $G$ preserves the orientation. If $\alpha \in A$, then we denote by $\alpha(X)^{[k]}$ the volume part of the differential form $\alpha(X)$, and

$$\left(\int \alpha\right)(X) := \int_\Theta \alpha(X)^{[k]}, \quad X \in \mathfrak{g}$$

defines an Ad $G$-invariant function $\int\alpha$ on $\mathfrak{g}$. Now $\alpha = D\beta$ implies that $\alpha(X)^{[k]}$ id equal to the exterior derivative of $\beta(X)^{[k-1]}$, and therefore $\int\alpha = 0$, in view of Stokes' theorem. It follows that integration over $\Theta$ yields a linear mapping $\int$ from $H_G(\Theta)$ to $(S\mathfrak{g}^*)^{\mathrm{Ad}\, G}$, which is called integration in equivariant cohomology.

Now assume that also the Lie group $G$ is compact, and let $X \in \mathfrak{g}$. Then the zero-set $Z_X$ of $X_\Theta$ in $\Theta$ has finitely many connected components $F$, each of which is a smooth and compact submanifold of $\Theta$. In general, the $F$'s can have different dimensions. The linearization L$X$ of the vector field $X_\Theta$ along $F$ acts linearly on the normal bundle N$F$ of $F$. If $\Omega$ is the curvature form of N$F$, then

$$\varepsilon(X) := \det_C\left[\frac{\mathrm{i}}{2\pi}(\mathrm{L}X - \Omega)\right]$$

is called the equivariant Euler form of N$F$. $\varepsilon(X)$ is an invertible element in the algebra $\Omega^{\mathrm{even}}(F)$. The localization formula of Berline–Vergne (1982) and Atiyah–Bott (1984) now says that if $D\alpha = 0$ then

$$\left(\int\alpha\right)(X) = \sum_F \int_F \left(\mathrm{i}_F^*\alpha(X)/\varepsilon(X)\right)^{[\dim F]}$$

Assume that $\sigma$ is a symplectic form on $\Theta$, which implies that $k = 2l$ is even. Furthermore, assume that the infinitesimal action of $\mathfrak{g}$ on $\Theta$ is Hamiltonian, which means that there exists a $G$-equivariant smooth mapping $\mu : \Theta \to \mathfrak{g}^*$, called the momentum mapping, such that $\mathrm{i}_{X_\Theta}\sigma = -\mathrm{d}(\mu(X))$ for every $X \in \mathfrak{g}$. Here $\mu$ is viewed as an element of $(\mathfrak{g}^* \otimes \Omega^0(\Theta))^G \subset A$. Then $\widehat{\sigma}(X) := \sigma - \mu(X)$ defines an element $\widehat{\sigma} \in A$ such that $D\widehat{\sigma} = 0$. In turn, this implies that the form

$$\beta(X) := \mathrm{e}^{-\mathrm{i}\omega\widehat{\sigma}(X)} = \mathrm{e}^{\mathrm{i}\omega\mu(X)} \sum_{r=0}^{l} (-\mathrm{i}\omega\sigma)^r / r!$$

is equivariantly closed, and the localization formula of equivariant cohomology applied to this case yields the Duistermaat–Heckman (1982, 1983) formula. Because $\beta(X)^{[k]} = \mathrm{e}^{\mathrm{i}\omega\mu(X)}(-\mathrm{i}\omega\sigma)^l/l!$, its integral over $\Theta$ is an oscillatory integral with phase function $\mu(X)$. The stationary points of $\mu(X)$ are the zeros of $X_\Theta$ and the stationary points of $\mu(X)$ are nondegenerate if and only if the zeros of $X_\Theta$ are isolated. It follows that in this case the oscillatory integral is equal to the leading term in the stationary-phase approximation.

## The Principal Symbol on the Lagrangian Manifold

Let $u(x, \omega)$ be a global oscillatory integral of order $m$ defined by $\Lambda$, and let $(x_0, \xi_0) \in \Lambda$. One way to define the principal symbol of $u$ at $(x_0, \xi_0) \in \Lambda$ is to test $u$ with an oscillatory function of the form $\mathrm{e}^{-\mathrm{i}\omega\psi(x)}b(x)$, in which $\mathrm{d}\psi(x_0) = \xi_0$, the support of $b$ is contained in a small neighborhood of $x_0$, and $b(x_0) = 1$. If $u$ is locally represented by the phase function $\varphi$ and amplitude $a$, and $(x_0, \xi_0) = \iota_\varphi(x_0, \theta_0)$, then the phase function $\varphi(x, \theta) - \psi(x)$ in the oscillatory integral

$$\langle u, \mathrm{e}^{-\mathrm{i}\psi} b\rangle = \int_M \int_\Theta \mathrm{e}^{\mathrm{i}(\varphi(x,\theta) - \psi(x))} a(x, \theta) b(x)\, \mathrm{d}\theta\, \mathrm{d}x$$

has a stationary point at $(x_0, \theta_0)$, which means that $\Lambda$ and $\mathrm{d}\psi$ intersect at $(x_0, \xi_0)$. Here the 1-form $\mathrm{d}\psi$ on $M$, which is a section of $\pi : \mathrm{T}^*M \to M$, is viewed as a submanifold of $\mathrm{T}^*M$. Locally the Lagrangian submanifolds of $\mathrm{T}^*M$ which are transversal to the fibers of $\pi : \mathrm{T}^*M \to M$ are precisely the manifolds of the form $\mathrm{d}\psi$. The stationary point of $\varphi - \psi$ is nondegenerate if and only if $L := \mathrm{T}_{(x_0,\xi_0)}\Lambda$ and $L_\psi := \mathrm{T}_{(x_0,\xi_0)}(\mathrm{d}\psi)$ are transversal. In this case, the method of stationary phase can be applied in order to obtain an asymptotic expansion in terms of powers of $\omega$. The coefficient of the leading term of order $\omega^m$ depends only on the Lagrangian plane $L_\psi$, which is transversal to both $L$ and the tangent space of the fiber of $\mathrm{T}^*M$, and not on the other data of $\psi$ and $b$. If $\mathcal{L}$ denotes the set of all Lagrangian planes in $\mathrm{T}_{(x_0,\xi_0)}(\mathrm{T}^*M)$ which are transversal to both $L$ and the fiber, then the complex-valued functions on $\mathcal{L}$ which arise in this way form a one-dimensional complex vector space $L_{(x_0,\xi_0)}$. The $L_{(x_0,\xi_0)}$ for $(x_0, \xi_0) \in \Lambda$ form a complex line bundle $\lambda$ over $\Lambda$ which is canonically isomorphic to the tensor product of the line bundle of half-densities and the Maslov line bundle, a line bundle with structure group $\mathbf{Z}/4\mathbf{Z}$ (see Duistermaat (1974, section 1.2)). In this way, the principal symbol $s$ of $u$ can be viewed as a section of the line bundle $\lambda$ over $\Lambda$.

## Caustics

Let $(x_0, \xi_0)$ be a point in the Lagrangian submanifold $\Lambda$ of $\mathrm{T}^*M$. The restriction to $\Lambda$ of the projection $\pi : \mathrm{T}^*M \to M$ is a diffeomorphism from an open neighborhood of $(x_0, \xi_0)$ in $\Lambda$ onto an open neighborhood of $x_0$ in $M$, if and only if $\Lambda$ is transversal to the fiber of $\mathrm{T}^*M$ at $(x_0, \xi_0)$. If $\Lambda = \Lambda_\varphi$ for a nondegenerate phase function $\varphi, (x_0, \xi_0) \in S_\varphi$ and $(x_0, \xi_0) = \iota_\varphi(x_0, \theta_0)$, then this condition is in turn equivalent to the condition that $\theta_0$ is a nondegenerate stationary point of $\theta \mapsto \varphi(x_0, \theta)$. An application of the method of stationary phase shows that in this case the oscillatory integral is equal to a progressing wave of the form $\mathrm{e}^{\mathrm{i}\omega\psi(x)}b(x, \omega)$. Here $\psi(x) = \varphi(x, \theta(x))$, where $\theta(x)$ is the stationary point of $\theta \mapsto \varphi(x, \theta)$, and $b(x, \omega)$ has an asymptotic expansion as in [2] with $k = 0$.

If $\theta_0$ is a degenerate stationary point of $\theta \mapsto \varphi(x_0, \theta)$ and $a_0(x_0, \theta_0) \neq 0$, then the oscillatory integral is not of order $O(\omega^m)$. That is, it is of larger order than at points where we have a nondegenerate

stationary point. For this reason, the points $(x_0, \xi_0)$ at which $\Lambda$ is not transversal to the fibers of $\pi : \mathrm{T}^*M \to M$ are called the caustic points of $\Lambda$. Their projections $x_0 \in M$ form the caustic set in $M$.

In the theory of unfoldings of singularities, the germs of the families of functions $x \mapsto (\theta \mapsto \varphi(x, \theta))$ and $y \mapsto (\mu \mapsto \psi(y, \mu))$ are called equivalent if there exists a germ of a diffeomorphism of the form $H : (x, \theta) \mapsto (y(x), \mu(x, \theta))$ and a smooth function $\chi(x)$ such that $\psi(y(x), \mu(x, \theta)) = \varphi(x, \theta) + \chi(x)$. If $J(y, \omega)$ is an oscillatory integral with phase function $\psi$, integration variable $\mu$ and parameter $y$, then the substitution of variables $\mu = \mu(x, \theta)$ in the integral, followed by the substitution of variables $y = y(x)$ in the parameters, yields that $J(y, \omega) = \mathrm{e}^{\mathrm{i}\omega\chi(x)} I(x, \omega)$, in which $I(x, \omega)$ is an oscillatory integral with phase function $\varphi$ and an amplitude function of the same order as the amplitude function of $J$. The germ $\varphi$ is called stable if every nearby germ $\psi$ is equivalent to $\varphi$. The Morse lemma with parameters implies that this is the case if $\theta \mapsto \varphi(x_0, \theta)$ has a nondegenerate stationary point at $\theta_0$. However, the theory of unfoldings of singularities of Thom and Mather shows that there are many stable germs with degenerate critical points. Moreover, in dimension $n \leq 5$ the generic germ is stable, and is equivalent to a germ in a finite list of normal forms.

The simplest example of a normal form with degenerate critical points is $\varphi(x, \theta) = \theta^3 + x_1\theta$. Here we have taken $k = 1$, but still allowed an arbitrary dimension $n \geq 1$ of $M$. In this normal form, the stationary points correspond to $3\theta^2 + x_1 = 0$, which is a manifold which over the $x$-space folds over at $x_1 = 0$. The stationary point is degenerate if and only if $6\theta = 0$, hence $x_1 = 0$, which means that $x_1 = 0$ is the caustic set. If the amplitude is equal to 1, then the oscillatory integral is equal to $\omega^{-1/3}\,\mathrm{Ai}(\omega^{2/3} x_1)$, in which $\mathrm{Ai}(z)$ denotes the Airy function. If the amplitude is nonzero at a degenerate critical point, then the oscillatory integral near the corresponding caustic point is asymptotically of the same order as $\omega^{-1/3}\,\mathrm{Ai}(\omega^{2/3} x_1)$, which implies that the oscillatory integral is a factor $\omega^{1/6}$ larger at these caustic points than at the points away from the caustic set. In Airy (1838), where the Airy function was introduced, Airy considered light in a neighborhood of a caustic as an oscillatory integral. Then, under suitable genericity conditions, he brought the phase function into the normal form $\theta^3 + x_1\theta$. Even for stable normal forms in low dimensions, the interference patterns near the caustic points can be very intricate (see, e.g., Berry *et al.* (1979)). A survey of the application of the theory of unfoldings to caustics in oscillatory integrals can be found in Duistermaat (1974).

# Statistical Mechanics and Combinatorial Problems

**R Zecchina**, International Centre for Theoretical Physics (ICTP), Trieste, Italy

## Introduction

Equilibrium statistical mechanics and combinatorial optimization – which is viewed here as a branch of discrete mathematics and theoretical computer science – have common roots. Phase transition are mathematical phenomena which are not limited to physical systems but are typical of many combinatorial problems, one famous example being the percolation transition in random graphs. Similarly, the understanding of relevant physical problems, such as three-dimensional lattice statistics or two-dimensional quantum statistical mechanics problems, is strictly related to the question of purely combinatorial origin of solving counting problems over nonplanar lattices. Most of the tools and concepts which have allowed to solve problems in one field have a natural counterpart in the other. While the possibility of solving exactly physical models is always connected to the presence of some algebraic properties which guarantee integrability, in the combinatorial approach the emphasis is more on algorithms that can be applied to problem instances in which the symmetries behind intergrability might be absent. Also at the level of out-of-equilibrium phenomena, there exists a deep connection between physics and combinatorics: just like physical processes, local algorithms have to deal with an exponentially large set of possible configurations and their out-of-equilibrium analysis constitutes a theory of how problems are actually solved.

Computational complexity theory deals with classifying problems in terms of the computational resources, typically time, required for their solution. What can be measured (or computed) is the time that a particular algorithm uses to solve the problem. This time in turn depends on the implementation of the algorithm as well as on the computer the program is running on. The theory of computational complexity provides us with a notion of complexity that is largely independent of implementational details and the computer at hand. This is not surprising, since it is related to a highly nontrivial question, that is: what do we mean by saying that a combinatorial problem is solvable?

Problems which can be solved in polynomial time are considered to be tractable and compose the so-called polynomial (P) class. The harder problems are grouped in a larger class called NP, where NP stands for "nondeterministic polynomial time." These problems are such that a potential solution can be checked rapidly in polynomial time, while finding a solution may require exponential time in the worst case. In turn, the hardest problems in NP belong to a subclass called NP-complete: an efficient algorithm for solving one NP-complete problem could be easily modified to effectively solve any problem in NP. By now, a huge number of NP-complete problems has been identified, and the lack of such an algorithm corroborates the widespread conjecture $P \neq NP$, that is, that no such algorithm exists. However, NP-complete problems are not always hard: when their resolution complexity is measured with respect to some underlying probability distribution of problem instances, NP-complete problems are often easy to solve on average. To deepen the understanding of the average-case complexity (and of the huge variability of running times observed in numerical experiments), computer scientists, mathematicians, and physicists have focused their attention on the study of random instances of hard combinatorial problems, seeking for a link between the onset of exponential-time complexity and some intrinsic (i.e., algorithm independent) properties of the randomized NP-complete problems. These types of questions have merged combinatorial optimization with statistical physics of disordered systems.

Computational complexity theory can also be formulated for counting problems: similarly to optimization problems, equivalence classes can be defined which separate polynomially solvable counting problems with the hard ones – the so-called #P and #P-complete problems. Complexity theory for counting problems makes the connections with statistical mechanics even more direct in that counting solutions is nothing but a computation of a partition function.

Two simple theorems by Jerrum and Sinclair (1989) (which can be easily extended to many combinatorial problems) can help in clarifying these connections.

The first theorem tells us that any randomized algorithm (e.g., Monte Carlo) for approximating the partition function of a generic spin glass model – the so-called spin glass problem – could be used to solve all the other NP combinatorial problems. The second theorem tells us that an algorithm for evaluating exactly the partition function of the ferromagnetic Ising model over a general graph would again solve any other problem in the class #P, which, as mentioned above, is the generalization of

the NP class to counting problems and obviously contains the class NP as a particular case.

Let us consider the following sightly simplified definition of the Ising and the spin glass problems.

**Problem instance** A symmetric matrix $J_{ij}$ with entries in $\{-1, 0, 1\}$ and an inverse temperature $\beta$.

**Output** The partition function $Z = \sum_{\{\sigma_i\}} 2^{-\beta H(\boldsymbol{\sigma})}$, where $H(\boldsymbol{\sigma}) = -\sum_{i,j} J_{ij}\sigma_i\sigma_j$ with $\sigma_i = \pm 1$.

Moreover, let us define the fully polynomial randomized approximation scheme (FPRAS) for counting and decision problems. A FPRAS for a function *f* from problem instances to real numbers is a probabilistic algorithm that in polynomial time in the problem size *n* and in the relative error $\epsilon \in [0, 1]$, outputs with high probability a number which approximates $f(n)$ within a ratio $1 + \epsilon$. Given the above definitions, the theorems can be stated as follows:

**Theorem 1** *There can be no FPRAS for the spin glass problem unless* P = NP, *that is*, *all problems in* NP *turn out to be solvable in polynomial time*.

**Theorem 2** *The Ising problem is* #P-*complete even when the matrix* $J_{ij}$ *is non-negative*, *that is*, *an algorithm which outputs in polynomial time the exact Ising partition function for an arbitrary graph could be used to solve any other counting problem in* #P.

The above theorems hold for arbitrary graphs, in particular for those graph or lattice realizations which are particularly hard to analyze, the so-called worst cases. There exist no similar proofs of computational hardness for more restricted and realistic structures, such as, for instance, three-dimensional regular lattices for the Ising problem or finite connectivity random graphs for spin glasses.

As a final introductory remark, it is worth mentioning that the connections between worst-case complexity and the average case one is the building block of modern cryptography and communication theory. On the one hand, the so-called RSA cryptosystem is based on factoring large integers, a problem which is believed to be hard on average while it is not known to be so in the worst case. On the other hand, alternative cryptographic systems have been proposed which rely on a worst-case/average-case equivalence (see, e.g., the theorem of Ajtai (1996) concerning some hidden vector problems in high-dimensional lattices.)

As far as communication theory is concerned, average-case complexity is indeed crucial: while Shannon's theorem (1948) provides a very general result stating that many optimal codes do exist (in fact, random codes are optimal), the decoding problem is in general NP-complete and therefore potentially intractable. However, since the choice of the coding scheme is part of the design, what matters are the average-case behavior of the decoding algorithm (and its large deviations) and very efficient codes which can solve on average the decoding problem close to Shannon's bounds are known.

In what follows, we will limit the discussion to two basic examples of combinatorial and counting problems which are representative and central to both computer science and statistical physics.

## Constraint Satisfaction Problems

Combinatorial problems are usually written as constraint satisfaction problems (CSPs): *n* discrete variables are given which have to satisfy *m* constraints, all at the same time. Each constraint can take different forms depending on the problem under study: famous examples are the *K*-satisfiability (*K*-SAT) problem in which constraints are an "OR" function of *K* variables in the ensemble (or their negations) and the graph *Q*-coloring problem in which constraints simply enforce the condition that the endpoints of the edges in the graph must not have the same color (among the *Q* possible ones). Quite in general a generic CSP can be written as the problem of finding a zero-energy ground state of an appropriate energy function and its analysis amounts at performing a zero-temperature statistical physics study. Hard combinatorial problems are those which correspond to frustrated physical model systems.

Given an instance of a CSP, one wants to know whether there exists a solution, that is, an assignment of the variables which satisfies all the constraints (e.g., a proper coloring). When it exists, the instance is called SAT, and one wants to find a solution. Most of the interesting CSPs are NP-complete: in the worst case, the number of operations needed to decide whether an instance is SAT or not is expected to grow exponentially with the number of variables. But recent years have seen an upsurge of interest in the theory of typical-case complexity, where one tries to identify random ensembles of CSPs which are hard to solve, and the reason for this difficulty. As already mentioned, random ensembles of CSPs are also of great theoretical and practical importance in communication theory, since some of the best modern error-correcting codes (the so-called low-density parity check codes) are based on such constructions.

### Satisfiability and Spin Glass Models

The archetypical example of CSP is satisfiability (SAT). This is a core problem in computational complexity: it is the first one to have been shown NP-complete, and since then thousands of problems have been shown to be computationally equivalent to it. Yet it is not so easy to find difficult instances. The main ensemble which has been used for this goal is the random $K$-SAT ensemble (for $K > 2$, K-SAT is NP-complete).

The SAT problem is defined as follows. Given a vector of $\{0,1\}$ Boolean variables $\boldsymbol{x} = \{x_i\}_{i \in I}$, where $I = \{1, \ldots, n\}$, consider a SAT formula defined by

$$\mathcal{F}(\boldsymbol{x}) = \bigwedge_{a \in A} C_a(\boldsymbol{x})$$

where $A$ is an arbitrary finite set (disjoint with $I$) labeling the clauses $C_a$; $C_a(\boldsymbol{x}) = \bigvee_{i \in I(a)} J_{a,i}(x_i)$; any literal $J_{a,i}(x_i)$ is either $x_i$ or $\sim x_i$ ("not" $x_i$); and finally, $I(a) \subset I$ for every $a \in A$. Similarly to $I(a)$, we can define the set $A(i) \subset A$ as $A(i) = \{a : i \in I(a)\}$, that is, the set of clauses containing variable $x_i$ or its negation.

Given a formula $\mathcal{F}$, the problem of finding a variable assignment $s$ such that $\mathcal{F}(s) = 1$, if it exists, can also be written as a spin glass problem as follows: if we consider a set of $n$ Ising spins, $\sigma_i \in \{\pm 1\}$ in place of the Boolean variables ($\sigma_i = -1, 1 \leftrightarrow x_i = 0, 1$) we may write the energy function associated to each clause as follows:

$$E_a = \prod_{r=1}^{K} \frac{(1 + J_{a,i_r}\sigma_{i_r})}{2}$$

where $J_{a,i} = -1$ (resp. $J_{a,i} = 1$) if $x_i$ (resp. $\tilde{x}_i$) appears in clause $a$. The total energy of a configuration $E = \sum_{a=1}^{|A|} E_a$ is nothing but a $K$-spin spin glass model.

Random $K$-SAT is a version of SAT in which each clause is taken to involve exactly $K$ distinct variables, randomly chosen and negated with uniform distribution. Its energy function corresponds to a spin glass system over a finite connectivity (diluted) random graph.

In recent years random $K$-SAT has attracted much interest in computer science and in statistical physics. The interesting limit is the thermodynamic limit $n \to \infty$, $m = |A| \to \infty$ at fixed clause density $\alpha = m/n$.

Its most striking feature is certainly its sharp threshold. It is strongly believed that there exists a phase transition for this problem: numerical and heuristic analytical arguments are in support of the so-called satisfiability threshold conjecture:

**Conjecture** There exists $\alpha_c(K)$ such that with high probability:

- if $\alpha < \alpha_c(K)$, a random instance is satisfiable;
- if $\alpha > \alpha_c(K)$, a random instance is unsatisfiable.

Although this conjecture remains unproven, the existence of a nonuniform sharp threshold has been established by Friedgut (1997). A lot of effort has been devoted to understanding this phase transition. This is interesting both from physics and the computer science points of view, because the random instances with $\alpha$ close to $\alpha_c$ are the hardest to solve. There exist rigorous results that give bounds for the threshold $\alpha_c(K)$: using these bounds, it was shown that $\alpha_c(K)$ scales as $2^K \ln(2)$ when $K \to \infty$.

On the statistical physics side, the cavity method (which is the generalization to disordered systems characterized by ergodicity breaking of the iterative method used to solve exactly physical models on the Bethe lattice), is a powerful tool which is claimed to be able to compute the exact value of the threshold, giving for instance $\alpha_c(3) \simeq 4.2667\ldots$ It is a nonrigorous method but the self-consistency of its results have been checked by a "stability analysis," and it has also led to the development of a new family of algorithms – the so-called "survey propagation" – which can solve efficiently very large instances at clause densities which are very close to the threshold (for technical details see Mézard and Zecchina (2002) and Braunstein *et al.* (2005) and references therein).

The main hypothesis on which the cavity analysis of random $K$-SAT relies is the existence, in a region of clause density $[\alpha_d, \alpha_c]$ close to the threshold, of an intermediate phase called the "hard-SAT" phase; see **Figure 1**. In this phase the set $\mathcal{S}$ of solutions (a subset of the vertices in an $n$-dimensional hypercube) is supposed to split into many disconnected clusters $\mathcal{S} = \mathcal{S}_1 \cup \mathcal{S}_2 \cup \cdots$. If one considers two solutions $X, Y$ in the same cluster $\mathcal{S}_j$, it is

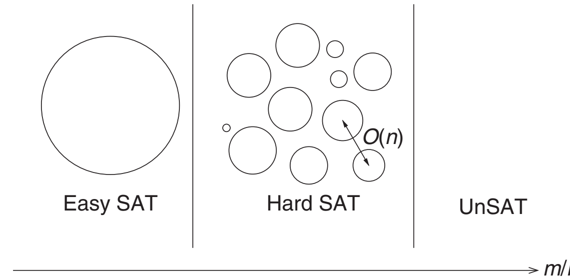

**Figure 1** A pictorial representation of the clustering transition in random $K$-SAT.

possible to walk from $X$ to $Y$ (staying in $\mathcal{S}$) by flipping at each step a finite numbers of variables. If, on the other hand, $X$ and $Y$ are in different clusters, in order to walk from $X$ to $Y$ (staying in $\mathcal{S}$), at least one step will involve an extensive number (i.e., $\propto n$) of flips. This clustered phase is held responsible for entrapping many local-search algorithms into non-optimal metastable states. This phenomenon is not exclusive to random $K$-SAT. It is also predicted to appear in many other hard SAT and optimization problems such as "coloring," and corresponds to the so called "one-step replica symmetry breaking" (1RSB) phase in the language of statistical physics. It is also a crucial limiting feature for decoding algorithms in some error correcting codes.

The only CSP for which the existence of the clustering phase has been established rigorously is the polynomial problem of solving random linear equation in GF (Motwani and Raghavan 2000). For random $K$-SAT, rigorous probabilistic bounds can be used to prove the existence of the clustering phenomenon, for large enough $K$, in some region of $\alpha$ included in the interval $[\alpha_d(K), \alpha_c(K)]$ predicted by the statistical physics analysis.

In the analysis of CSP like $K$-SAT, two main questions are in order. The first is of algorithmic nature and asks for an algorithm which decides whether for a given CSP instance all the constraints can be simultaneously satisfied or not. The second question is more theoretical and deals with large random instances, for which one wants to know the structure of the solution space and predict the typical behavior of classes of algorithms.

#### Message-Passing Algorithms from Statistical Physics

The algorithmic contributions of statistical mechanics to combinatorial optimization are numerous and important (a representative example being the celebrated "simulated annealing algorithm"). For the sake of brevity, here we limit the discussion to the so-called "message-passing algorithms" which are also of great interest in coding theory.

The statistical analysis of the cavity equations allows to study the average properties of ensemble of problems and it is totally equivalent to the replica method in which the average over the ensemble is the first step in any calculation. The survey propagation (SP) equations are a formulation of the cavity equations which is valid for each specific instance and is able to provide information about the statistical behavior of the individual variables in the stable and metastable states of a given energy density (i.e., given fraction of violated constraints).

The single-sample SP equations are nicely described in terms of the factor graph representation used in information theory to characterize error-correcting codes. In the factor graph, the $N$ variables $i, j, k, \ldots$ are represented by circular "variable nodes," whereas the $M$ clauses $a, b, c, \ldots$ are represented by square "function nodes." For random $K$-SAT, the function nodes have connectivity $K$, while the variable nodes have an average Poisson connectivity $K\alpha$.

The iterative SP equations are examples of message-passing procedures. In message-passing algorithms such as the so-called "belief propagation (BP) algorithm" used in error-correcting codes and statistical inference problems, the unknowns which are self-consistently evaluated by iteration are the marginals over the solution space of the variables characterizing the combinatorial problem (the probability space is the set of all solutions sampled with uniform measure). According to the physical interpretation, the quantities that are evaluated by SP are the probability distributions of local fields over the set of clusters. That is, while BP performs a "white" average over solutions, SP takes care of cluster-to-cluster fluctuations, telling us which is the probability of picking up a cluster at random and finding a given variable biased in a certain direction (or unfrozen if it is paramagnetic in the cluster). SP computes quantities which are probabilities over different pure states: the order parameter which is evaluated as fixed point of the SP equations is a probability measure in a space of functions, or for finite $n$, the full list of probability densities describing the cluster-to-cluster fluctuations of the variables.

In both SP and BP one assumes knowledge of the marginals of all variables in the temporary absence of one of them and then writes the marginal probability induced on this "cavity" variable in absence of another third variable interacting with it (i.e., the so-called Bethe lattice approximation for the problem). These relations define a closed set of equations for such cavity marginals that can be solved iteratively (this fact is known as message-passing technique). The equations become exact if the cavity variables acting as inputs are uncorrelated. They are conjectured to be an asymptotically exact approximation over random locally tree–like structures such as, for instance, the random $K$-SAT factor graph. Both BP and SP can be derived in a variational framework.

### Complexity of Counting Problems

In order to describe the nature of computational complexity of counting in physical models, it is enough to consider the classical Ising problem. The

computation of the Ising partition function or, more in general, of the weighted matching polynomial, is the root problem of lattice statistics.

For planar graphs like, for example, two-dimensional regular lattices, counting problems can often be solved by a variety of different methods, for example, transfer matrices and Pfaffians, which require a number of operations which are polynomial in the number of vertices.

The complexity of the counting problems changes if one considers nonplanar graphs, that is, graphs with a nontrivial topological genus. In discrete mathematics, such problems are classified as #P-complete, meaning that the existence of an exact polynomial algorithm for the evaluation of the generating functions would imply the polynomial solvability of many known counting combinatorial problems, the most famous one being the evaluation of the permanent of 0–1 matrices. In statistical mechanics and mathematical chemistry, the interest in nonplanar lattices is obviously related to their $D > 2$ character: the three-dimensional cubic lattice is nothing but a nonplanar graph of topological genus $g = 1 + N/4$, where $N$ is the number of sites.

The planar two-dimensional Ising model was solved in 1944 by Onsager using the algebraic transfer matrix method. Successively, alternative exact solutions have been proposed which resorted to simple combinatorial and geometrical reasoning. As is well known, the underlying idea of the combinatorial methods consists in recasting the sum over spin configurations of the Boltzmann weights as a sum over closed curves (loops) weighted by the activity of their bonds. Double counting is avoided by a proper cancellation mechanism which takes care of the different intrinsic topologies of loops which give rise to the same contribution in the partition function. Such an approach has been developed first by Kac and Ward (1952) and provides a direct way of taking the field theoretic continuum limit. In $D > 2$, the generalization of the above method encounters enormous difficulties due to the variety of intrinsic topologies of surfaces immersed in $D > 2$ lattices.

Another combinatorial method proposed in the 1960s by Kasteleyn is the so-called Pfaffian method. It consists in writing the weighted sum over loops as a dimer covering or prefect matching generating function. Once the relationship between loop counting and dimer coverings (or perfect matchings) over a suitably decorated and properly oriented lattice is established, the Pfaffian method turns out to be a simple technique for the derivation of exact solutions or for the definition of polynomial algorithms over planar lattices which are applicable also to the two-dimensional Ising spin glass.

The generalization of the Pfaffian construction to the nonplanar case must deal with the ambiguity of orienting the homology cycles of the graph. Such a problem can be formally solved in full generality for any orientable lattice and leads to an expression of the Ising partition function or the dimer coverings generating function given as a sum over all possible inequivalent orientations of the lattice (or its embedding surface): for a graph of genus $g$, the homology basis is composed of $2g$ cycles and, therefore, there are $2^{2g}$ inequivalent orientations. It is only for graphs of logarithmic genus that the generalized Pfaffian formalism provides a polynomial algorithm.

Counting perfect matchings can be thought of as the problem of evaluating the permanent of 0–1 matrices over properly constructed bipartite graphs, which is among the oldest and most famous #P-complete problems.

The Pfaffian formalism when applied to the permanent problem leads to a simple general result, that is, it provides a general formula for writing the permanent of a matrix in terms of a number of determinants which is exponential in the genus of the underlying graph.

# Statistical Mechanics of Interfaces

**S Miracle-Solé**, Centre de Physique Théorique, CNRS, Marseille, France

## Introduction

When a fluid is in contact with another fluid, or with a gas, a portion of the total free energy of the system is proportional to the area of the surface of contact, and to a coefficient, the surface tension, which is specific for each pair of substances. Equilibrium will accordingly be obtained when the free energy of the surfaces in contact is a minimum.

Suppose that we have a drop of some fluid, $b$, over a flat substrate, $w$, while both are exposed to air, $a$. We have then three different surfaces of contact, and the total free energy of the system consists of three parts, associated to these three surfaces. A drop of fluid $b$ will exist provided its own two surface tensions exceed the surface tension between the substrate $w$ and the air, that is, provided that

$$\tau^{wb} + \tau^{ba} > \tau^{wa}$$

If equality is attained, then a film of fluid $b$ is formed, a situation which is known as perfect, or complete wetting (see Figure 1).

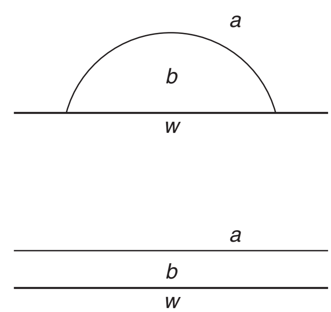

**Figure 1** Partial and complete wetting.

When one of the substances involved is anisotropic, such as a crystal, the contribution to the total free energy of each element of area depends on its orientation. The minimum surface free energy for a given volume then determines the ideal form of the crystal in equilibrium.

It is only in recent times that equilibrium crystals have been produced in the laboratory, first, in negative crystals (vapor bubbles) of organic substances. Most crystals grow under nonequilibrium conditions and it is a subsequent relaxation of the macroscopic crystal that restores the equilibrium.

An interesting phenomenon that can be observed on these crystals is the roughening transition, characterized by the disappearance of the facets of a given orientation, when the temperature attains a certain particular value. The best observations have been made on helium crystals, in equilibrium with superfluid helium, since the transport of matter and heat is then extremely fast. Crystals grow to sizes of 1–5 mm and relaxation times vary from milliseconds to minutes. Roughening transitions for three different types of facets have been observed (see, e.g., Wolf *et al.* (1983)).

These are some classical examples among a variety of interesting phenomena connected with the behavior of the interface between two phases in a physical system. The study of the nature and properties of the interfaces, at least for some simple systems in statistical mechanics, is also an interesting subject of mathematical physics. Some aspects of this study will be discussed in the present article.

We assume that the interatomic forces can be modeled by a lattice gas, and consider, as a simple example, the ferromagnetic Ising model. In a typical two-phase equilibrium state, there is a dense

component, which can be interpreted as a solid or liquid phase, and a dilute phase, which can be interpreted as the vapor phase. Considering certain particular cases of such situations, we first introduce a precise definition of the surface tension and then proceed on the mathematical analysis of some preliminary properties of the corresponding interfaces. The next topic concerns the wetting properties of the system, and the final section is devoted to the associated equilibrium crystal.

## Pure Phases and Surface Tension

The Ising model is defined on the cubic lattice $\mathcal{L} = \boldsymbol{Z}^3$, with configuration space $\Omega = \{-1, 1\}^{\mathcal{L}}$. If $\sigma \in \Omega$, the value $\sigma(i) = -1$ or 1 is the spin at the site $i = (i_1, i_2, i_3) \in \mathcal{L}$, and corresponds to an empty or an occupied site in the lattice gas version of the model. The system is first considered in a finite box $\Lambda \subset \mathcal{L}$, with fixed values of the spins outside.

In order to simplify the exposition, we shall mainly consider the three-dimensional Ising model, though some of the results to be discussed hold in any dimension $d \geq 2$. We shall also, sometimes, refer to the two-dimensional model, it being understood that the definitions have been adapted in the obvious way. We assume that the box $\Lambda$ is a parallelepiped, centered at the origin of $\mathcal{L}$, of sides $L_1, L_2, L_3$, parallel to the axes.

A configuration of spins on $\Lambda(\sigma(i), i \in \Lambda)$, denoted $\sigma_\Lambda$, has an energy defined by the Hamiltonian

$$H_\Lambda(\sigma_\Lambda|\bar{\sigma}) = -J \sum_{\langle i,j\rangle \cap \Lambda \neq \emptyset} \sigma(i)\sigma(j) \qquad [1]$$

where $J$ is a positive constant (ferromagnetic or attractive interaction). The sum runs over all nearest-neighbor pairs $\langle i,j\rangle \subset \mathcal{L}$, such that at least one of the sites belongs to $\Lambda$, and one takes $\sigma(i) = \bar{\sigma}(i)$ when $i \notin \Lambda$, the configuration $\bar{\sigma} \in \Omega$ being the given boundary condition. The probability of the configuration $\sigma_\Lambda$, at the inverse temperature $\beta = 1/kT$, is given by the Gibbs measure

$$\mu_\Lambda(\sigma_\Lambda|\bar{\sigma}) = Z^{\bar{\sigma}}(\Lambda)^{-1} \exp(-\beta H_\Lambda(\sigma_\Lambda|\bar{\sigma})) \qquad [2]$$

where $Z^{\bar{\sigma}}(\Lambda)$ is the partition function

$$Z^{\bar{\sigma}}(\Lambda) = \sum_{\sigma_\Lambda} \exp(-\beta H_\Lambda(\sigma_\Lambda|\bar{\sigma})) \qquad [3]$$

Local properties at equilibrium can be described by the correlation functions between the spins on finite sets of sites,

$$\mu_\Lambda^{\bar{\sigma}}(\sigma(A)) = \sum_{\sigma_\Lambda} \mu_\Lambda(\sigma_\Lambda|\bar{\sigma}) \prod_{i \in A} \sigma(i) \qquad [4]$$

The measures [2] determine (by the Dobrushin–Lanford–Ruelle equations) the set of Gibbs states of the infinite system, as measures on the set $\Omega$ of all configurations. If a Gibbs state happens to be equal to $\lim \mu_\Lambda(\cdot|\bar{\sigma})$, when $L_1, L_2, L_3 \to \infty$, under a fixed boundary condition $\bar{\sigma}$, we shall call it the Gibbs state associated to the boundary condition $\bar{\sigma}$. One also says that this state exists in the thermodynamic limit. Then, equivalently, the correlation functions [4] converge to the corresponding expectation values in this state.

This model presents, at low temperatures (i.e., for $\beta > \beta_c$, where $\beta_c$ is the critical inverse temperature), two different thermodynamic pure phases, a dense and a dilute phase in the lattice gas language (called here the positive and the negative phase). This means two extremal translation-invariant Gibbs states, $\mu^+$ and $\mu^-$, obtained as the Gibbs states associated with the boundary conditions $\bar{\sigma}$, respectively equal to the ground configurations $\bar{\sigma}(i) = 1$ and $\bar{\sigma}(i) = -1$, for all $i \in \mathcal{L}$. The spontaneous magnetization

$$m^*(\beta) = \mu^+(\sigma(i)) = -\mu^-(\sigma(i)) \qquad [5]$$

is then strictly positive. On the other hand, if $\beta \leq \beta_c$, then the Gibbs state is unique and $m^* = 0$.

Each configuration inside $\Lambda$ can be described in a geometric way by specifying the set of Peierls contours which indicate the boundaries between the regions of spin 1 and the regions of spin –1. Unit-square faces are placed midway between the pairs of nearest-neighbor sites $i$ and $j$, perpendicularly to these bonds, whenever $\sigma(i)\sigma(j) = -1$. The connected components of this set of faces are the Peierls contours. Under the boundary conditions (+) and (–), the contours form a set of closed surfaces. They describe the defects of the considered configuration with respect to the ground states of the system (the constant configurations 1 and –1), and are a basic tool for the investigation of the model at low temperatures.

In order to study the interface between the two pure phases, one needs to construct a state describing the coexistence of these phases. This can be done by means of a new boundary condition. Let $\boldsymbol{n} = (n_1, n_2, n_3)$ be a unit vector in $\boldsymbol{R}^3$, such that $n_3 > 0$, and introduce the mixed boundary condition $(\pm, \boldsymbol{n})$, for which

$$\bar{\sigma}(i) = \begin{cases} 1 & \text{if } i \cdot \boldsymbol{n} \geq 0 \\ -1 & \text{if } i \cdot \boldsymbol{n} < 0 \end{cases} \qquad [6]$$

This boundary condition forces the system to produce a defect going transversally through the box $\Lambda$, a large Peierls contour that can be

interpreted as the microscopic interface (also called a domain wall). The other defects that appear above and below the interface can be described by closed contours inside the pure phases.

The free energy per unit area due to the presence of the interface is the surface tension. It is defined by

$$\tau(\boldsymbol{n}) = \lim_{L_1,L_2\to\infty} \lim_{L_3\to\infty} -\frac{n_3}{\beta L_1 L_2} \ln \frac{Z^{\pm,\boldsymbol{n}}(\Lambda)}{Z^{+}(\Lambda)} \qquad [7]$$

In this expression the volume contributions proportional to the free energy of the coexisting phases, as well as the boundary effects, cancel, and only the contributions to the free energy due to the interface are left. The existence of such a quantity indicates that the macroscopic interface, separating the regions occupied by the pure phases in a large volume $\Lambda$, has a microscopic thickness and can therefore be regarded as a surface in a thermodynamic approach.

**Theorem 1** *The interfacial free energy per unit area*, $\tau(\boldsymbol{n})$, *exists*, *is bounded*, *and its extension by positive homogeneity*, $f(\boldsymbol{x}) = |\boldsymbol{x}|\,\tau(\boldsymbol{x}/|\boldsymbol{x}|)$, *is a convex function on* $\boldsymbol{R}^3$. *Moreover*, $\tau(\boldsymbol{n})$ *is strictly positive for* $\beta > \beta_c$, *and vanishes if* $\beta \le \beta_c$.

The existence of $\tau(\boldsymbol{n})$ and also the last statement were proved by Lebowitz and Pfister (1981), in the particular case $\boldsymbol{n} = (0,0,1)$, with the help of correlation inequalities. A complete proof of the theorem was given later with similar arguments. The convexity of $f$ is equivalent to the fact that the surface tension $\tau$ satisfies a thermodynamic stability condition known as the pyramidal inequality (see Messager *et al.* (1992)).

## Gibbs States and Interfaces

In this section we consider the $(\pm, \boldsymbol{n}_0)$ boundary condition, also simply denoted $(\pm)$, associated to the vertical direction $\boldsymbol{n}_0 = (0,0,1)$,

$$\bar{\sigma}(i) = 1 \text{ if } i_3 \ge 0, \quad \bar{\sigma}(i) = -1 \text{ if } i_3 < 0 \qquad [8]$$

The corresponding surface tension is $\tau^{\pm} = \tau(\boldsymbol{n}_0)$. We shall first recall some classical results which concern the Gibbs states and interfaces at low temperatures.

According to the geometrical description of the configurations introduced in the last section, we observe that

$$Z^{\pm,\boldsymbol{n}}(\Lambda)/Z^{+}(\Lambda) = \sum_{\lambda} \exp(-2\beta J|\lambda| - U_\Lambda(\lambda)) \qquad [9]$$

where the sum runs over all microscopic interfaces $\lambda$ compatible with the boundary condition and $|\lambda|$ is the number of faces of $\lambda$ (inside $\Lambda$). The term $U_\Lambda(\lambda)$ equals $-\ln Z^{+}(\lambda,\Lambda)/Z^{+}(\Lambda)$, the sum in the partition function $Z^{+}(\lambda,\Lambda)$ being extended to all configurations whose associated contours do not intersect $\lambda$. Each term in sum [9] gives a weight proportional to the probability of the corresponding microscopic interface.

At low (positive) temperatures, we expect the microscopic interface corresponding to this boundary condition, which at zero temperature coincides with the plane $i_3 = -1/2$, to be modified by small deformations. Each microscopic interface $\lambda$ can then be described by its defects, with respect to the interface at $\beta = \infty$. To this end, one introduces some objects, called walls, which form the boundaries between the horizontal plane portions of the microscopic interface, also called the ceilings of the interface.

More precisely, one says that a face of $\lambda$ is a ceiling face if it is horizontal and such that the vertical line passing through its center does not have other intersections with $\lambda$. Otherwise, one says that it is a wall face. The set of wall faces splits into maximal connected components. The set of walls, associated to $\lambda$, is the set of these components, each component being identified by its geometric form and its projection on the plane $i_3 = -1/2$. Every wall $\omega$, with projection $\pi(\omega)$, increases the energy of the interface by a quantity $2J\|\omega\|$, where $\|\omega\| = |\omega| - |\pi(\omega)|$, and two walls are compatible if their projections do not intersect. In this way, the microscopic interfaces may be interpreted as a "gas of walls" on the two-dimensional lattice.

Dobrushin, who developed the above analysis, also proved the dilute character of this "gas" at low temperatures. This implies that the microscopic interface is essentially flat, or rigid. One can understand this fact by noticing first that the probability of a wall is less than $\exp(-2\beta J\|\omega\|)$ and, second, that in order to create a ceiling in $\lambda$, which is not in the plane $i_3 = -1/2$, one needs to surround it by a wall, that one has to grow when the ceiling is made over a larger area.

Using correlation inequalities one proves that the Gibbs state $\mu^{\pm}$, associated to the $(\pm)$ boundary conditions, always exists, and that it is invariant under horizontal translations of the lattice, that is, $\mu^{\pm}(\sigma(A+a)) = \mu^{\pm}(\sigma(A))$ for all $a = (a_1, a_2, 0)$. It is also an extremal Gibbs state. Let $m(z)$ be the magnetization $\mu^{\pm}((\sigma(z))$ at the site $z = (0,0,z)$. The function $m(z)$ is monotone increasing and satisfies the symmetry property $m(-z) = -m(z+1)$. Some consequences of Dobrushin's work are the following properties.

**Theorem 2** *If the temperature is low enough, that is, if $\beta J \geq c_1$, where $c_1$ is a given constant, then*

$$m^{\pm}(0) \text{ is strictly positive} \qquad [10]$$

$$m^{\pm}(z) \to m^*, \text{ when } z \to \infty, \text{ exponentially fast} \qquad [11]$$

Equation [10] is just another way of saying that the interface is rigid and that the state $\mu^{\pm}$ is non-translation invariant (in the vertical direction). Then, the correlation functions $\mu^{\pm}(\sigma(A))$ describe the local properties, or local structure, of the macroscopic interface. In particular, the function $m(z)$ represents the magnetization profile. Then statement [11], together with the symmetry property, tells us that the thickness of this interface is finite, with respect to the unit lattice spacing.

The statistics of interfaces has been rewritten in terms of a gas of walls and this system may further be studied by cluster expansion techniques. There is an interaction between the walls, coming from the term $U_\Lambda(\lambda)$ in eqn [9], but a convenient mathematical description of this interaction can be obtained by applying the standard low-temperature cluster expansion, in terms of contours, to the regions above and below the interface.

This method was introduced by Gallavotti in his study (mentioned below) of the two-dimensional Ising model. It has been applied by Bricmont and co-workers to examine the interface structure in the present case. As a consequence, it follows that the surface tension, more exactly $\beta\tau^{\pm}(\beta)$, and also the correlation functions, are analytic functions at low temperatures. They can be obtained as explicit convergent series in the variable $\zeta = e^{-2\beta J}$.

The same analysis applied to the two-dimensional model shows a very different behavior at low temperatures. In this case, the microscopic interface $\lambda$ is a polygonal line and the walls belong to the one-dimensional lattice. One can then increase the size of a ceiling without modifying the walls attached to it.

Indeed, Gallavotti turned this observation into a proof that the Gibbs state $\mu^{\pm}$ is now translation invariant. The line $\lambda$ undergoes large fluctuations of order $\sqrt{L_1}$, and disappears from any finite region of the lattice, in the thermodynamic limit. In particular, we have then $\mu^{\pm} = (1/2)(\mu^+ + \mu^-)$, a result that extends to all boundary conditions $(\pm, \boldsymbol{n})$.

Using these results Bricmont and co-workers also studied the local structure of the interface at low temperatures and showed that its intrinsic thickness is finite. To study the global fluctuations, one can compute the magnetization profile by introducing, before taking the thermodynamic limit, a change of scale: $\mu_\Lambda^{\pm}(\sigma(zL_1^{\delta}))$, with $\delta = 1/2$ or near to this value. This is an exact computation that has been done by Abraham and Reed.

Let us come back to the three-dimensional Ising model where we know that the interface orthogonal to a lattice axis is rigid at low temperatures.

**Question 1** At higher temperatures, but before reaching the critical temperature, do the fluctuations of this interface become unbounded, in the thermodynamic limit, so that the corresponding Gibbs state is translation invariant?

One says then that the interface is rough, and it is believed that, effectively, the interface becomes rough when the temperature is raised, undergoing a roughening transition at an inverse temperature $\beta_R > \beta_c$.

It is known that $\beta_R \leq \beta_c^{d=2}$, the critical inverse temperature of the two-dimensional Ising model, since van Beijeren proved, using correlation inequalities, that above this value, the state $\mu^{\pm}$ is not translation invariant. Recalling that the rigid interface may be viewed as a two-dimensional system, the system of walls, a representation that would become inappropriate for a rough interface, one might think that the phase transition of the two-dimensional Ising model is relevant for the roughening transition, and that $\beta_R$ is somewhere near $\beta_c^{d=2}$. Indeed, approximate methods, used by Weeks and co-workers give some evidence for the existence of such a $\beta_R$ and suggest a value slightly smaller than $\beta_c^{d=2}$, as shown in **Table 1**. To this day, however, there appears to be no proof of the fact that $\beta_R > \beta_c$, that is, that the roughening transition for the three-dimensional Ising model really occurs.

At present one is able to study the roughening transition rigorously only for some simplified models with a restricted set of admissible microscopic interfaces. Moreover, the closed contours, describing the defects above and below $\lambda$, are neglected, so that these two regions have the constant configurations 1 or –1, and one has $U_\Lambda(\lambda) = 0$ in eqn [9].

The best known of these models is the classic SOS (solid-on-solid) model in which the interfaces $\lambda$ have the property of being cut only once by all vertical lines of the lattice. This means that $\lambda$ is the graph of a function that can equivalently be used to define the possible configurations of $\lambda$. If $\lambda$ contains the horizontal face with center $(i_1, i_2, i_3 - 1/2)$, then

**Table 1** Some temperature values

| | | |
|---|---|---|
| $d = 3$ | $\beta_c J \sim 0.22$ | approximate critical temperature |
| $d = 3$ | $\beta_R J \sim 0.41$ | conjectured roughening temperature |
| $d = 2$ | $\beta_c J = 0.44$ | exact critical temperature |

the value at $(i_1, i_2)$ of the associated function is $\phi(i_1, i_2) = i_3$.

The proof that the SOS model with the boundary condition (±) has a roughening transition is a highly nontrivial result due to Fröhlich and Spencer. When $\beta$ is small enough, the fluctuations of $\lambda$ are of order $\sqrt{\ln L}$ (in a cubic box of side $L$).

Moreover, other interface models, with additional conditions on the allowed microscopic interfaces, are exactly solvable. The BCSOS (body-centered SOS) model, introduced by van Beijeren, belongs to this class. It is, in fact, the first model for which the existence of a roughening transition has been proved. More recently, also the TISOS (triangular Ising SOS) model, introduced by Blöte and Hilhorst and further studied by Nienhuis and co-workers, has been considered in this context.

The interested reader can find more information and references, concerning the subject of this section, in the review article by Abraham (1986).

## Wetting Phenomena

Next we consider the Ising model over a plane horizontal substrate (also called a wall) and study the difference of surface tensions which governs the wetting properties of this system.

We first describe the approach developed by Fröhlich and Pfister (1987) and briefly report some results of their study. We consider the model on the semi-infinite lattice

$$\mathcal{L}' = \{i \in \mathbf{Z}^3 : i_3 \geq 0\} \quad [12]$$

A magnetic field, $K \geq 0$, is added on the boundary sites, $i_3 = 0$, which describes the interaction with the substrate, supposed to occupy the complementary region $\mathcal{L} \setminus \mathcal{L}'$.

We constrain the model in the finite box $\Lambda' = \Lambda \cap \mathcal{L}'$, with $\Lambda$ as above, and impose the value of the spins outside. The Hamiltonian becomes

$$H^w_{\Lambda'}(\sigma_{\Lambda'}|\bar{\sigma}) = -J \sum_{\langle i,j\rangle \cap \Lambda' \neq \emptyset} \sigma(i)\sigma(j) - K \sum_{i \in \Lambda', i_3 = 0} \sigma(i) \quad [13]$$

Here $\sigma_{\Lambda'}$ represents the configuration inside $\Lambda'$, the pairs $\langle i,j \rangle$ are contained in $\mathcal{L}'$, and $\sigma(i) = \bar{\sigma}(i)$ when $i \notin \Lambda'$, the configuration $\bar{\sigma}$ being the given boundary condition (see **Figure 2**). The corresponding partition function is denoted by $Z^{w\bar{\sigma}}(\Lambda')$.

Since there are two pure phases in the model, we must consider two surface free energies, or surfaces tensions, $\tau^{w+}$ and $\tau^{w-}$, between the wall and the positive or negative phase present in the bulk. They are defined through the choice of the boundary condition, $\bar{\sigma}(i) = 1$ or $\bar{\sigma}(i) = -1$, for all $i \in \mathcal{L}'$. Let us consider first the case of the (−) boundary condition.

The surface free energy contribution per unit area due to the presence of the wall, when we have the negative phase in the bulk, is

$$\tau^{w-}(\beta, K) = \lim_{L_1, L_2 \to \infty} \lim_{L_3 \to \infty} -\frac{1}{\beta L_1 L_2} \ln \frac{Z^{w-}(\Lambda')}{Z^-(\Lambda)^{1/2}} \quad [14]$$

The division by $Z^-(\Lambda)^{1/2}$ allows us to subtract from the total free energy, $\ln Z^{w-}(\Lambda')$, the bulk term and all boundary terms which are not related to the presence of the wall. The existence of limit [14] follows from correlation inequalities, and we have $\tau^{w-} \geq 0$.

One can prove, as well, the existence of the Gibbs state $\mu^{w-}$ of the semi-infinite system, associated to the (−) boundary condition. This state is the limit of the finite volume Gibbs measures $\mu_{\Lambda'}(\sigma_{\Lambda'}|(-))$ defined by the Hamiltonian [13]. It describes the local equilibrium properties of the system near the wall, when deep inside the bulk the system is in the negative phase. Similar definitions give the surface tension $\tau^{w+}$ and the Gibbs state $\mu^{w+}$, corresponding to the boundary condition $\bar{\sigma}(i) = 1$, for all $i \in \Lambda'$.

We remark that the states $\mu^{w+}$ and $\mu^{w-}$ are invariant by translations parallel to the plane $i_3 = 0$, and introduce the magnetizations, $m^{w-}(z) = \mu^{w-}(\sigma(z))$, where $z$ denotes the site $(0, 0, z)$, $m^{w-} = m^{w-}(0)$, and

similarly $m^{w+}(z)$ and $m^{w+}$. Their connection with the surface free energies is given by the formula

$$\tau^{w-}(\beta,K) - \tau^{w+}(\beta,K) = \int_0^K (m^{w+}(\beta,s) - m^{w-}(\beta,s))\,ds \qquad [15]$$

We mention in the following theorem some results of Fröhlich and Pfister's study. Here $\tau^{\pm}$ is, as before, the usual surface tension between the two pure phases of the system, for a horizontal interface.

**Theorem 3** *With the above definitions, we have*

$$\tau^{w-}(\beta,K) - \tau^{w+}(\beta,K) \le \tau^{\pm}(\beta) \qquad [16]$$

$$m^{w+}(\beta,K) - m^{w-}(\beta,K) \ge 0 \qquad [17]$$

*and the difference in [17] is a monotone decreasing function of the parameter K. Moreover, if $m^{w+} = m^{w-}$, then the Gibbs states $\mu^{w+}$ and $\mu^{w-}$ coincide.*

The proof is a subtle application of correlation inequalities. Since, from Theorem 3, the integrand in eqn [15] is a positive and decreasing function, the difference $\Delta\tau = \tau^{w-} - \tau^{w+}$ is a monotone increasing and concave (and hence continuous) function of the parameter $K$. On the other hand, one can prove that $\Delta\tau = \tau^{\pm}$, if $K \ge J$. This justifies the following definition:

$$K_w(\beta) = \min\{K\colon \Delta\tau(\beta,K) = \tau^{+-}(\beta)\} \qquad [18]$$

In the thermodynamic description of wetting, the partial-wetting regime is characterized by the strict inequality in [16]. Equivalently, by $K < K_w(\beta)$. We must have then $m^{w+} \neq m^{w-}$, because of eqn [15]. This shows that, in the case of partial wetting, $\mu^{w+}$ and $\mu^{w-}$ are different Gibbs states.

The complete-wetting regime is characterized by the equality in [16], that is, by $K \ge K_w(\beta)$. Then, we have $m^{w+} = m^{w-}$, and taking into account the last statement in Theorem 3, also $\mu^{w+} = \mu^{w-}$. This last result implies that there is only one Gibbs state. Thus, complete wetting corresponds to unicity of the Gibbs state.

In this case, we also have $\lim m^{w-}(z) = m^*$, when $z \to \infty$, because this is always true for $m^{w+}(z)$. This indicates that we are in the positive phase of the system although we have used the (–) boundary condition, so that the bulk negative phase cannot reach the wall anymore. The film of positive phase, which wets the wall completely, has an infinite thickness with respect to the unit lattice spacing, in the thermodynamic limit.

When $\beta = \infty$, only a few particular ground configurations contribute to the partition functions, such as the configuration $\sigma(i) = -1$ for the partition function $Z^{w-}$, etc., and we obtain $\Delta\tau = 2K$ and $\tau^{\pm} = 2J$. For nonzero but low temperatures, the small perturbations of these ground states have to be considered, a problem that can be treated by the method of cluster expansions. In fact, the corresponding defects can be described by closed contours as in the case of pure phases.

**Theorem 4** *For $K < J$, the functions $\beta\tau^{w-}(\beta,K)$ and $\beta\tau^{w+}(\beta,K)$ are analytic at low temperatures, that is, provided that $\beta(J-K) \ge c_2$, where $c_2$ is a given constant. Moreover, $m^{w+}(z)$ and $m^{w-}(z)$ tend, respectively, to $m^*$ and to $-m^*$, when $z \to \infty$, exponentially fast.*

The last statement in Theorem 4 tells us that the wall affects only a layer of finite thickness (with respect to the lattice spacing). From a macroscopic point of view, the negative phase reaches the wall, and we are in the partial-wetting regime. Indeed, a strict inequality holds in [16].

Thus, for $K < J$ there is always partial wetting at low temperatures. Then the following question arises:

**Question 2** Is there a situation of complete wetting at higher temperatures? It is understood here that $K$ takes a fixed value, characteristic of the substrate, such that $0 < K < J$.

This is known to be the case in dimension $d = 2$, where the exact value of $K_w(\beta)$ can be obtained from Abraham's solution of the model:

$$\cosh 2\beta K_w = \cosh 2\beta J - e^{-2\beta J}\sinh 2\beta J$$

Then complete wetting occurs for $\beta$ in the interval $\beta_c < \beta \le \beta_w(K)$, where $\beta_c$ is the critical inverse temperature and $\beta_w(K)$ is the solution of $K_w(\beta) = K$. The case $d = 2$ has been reviewed in Abraham (1986).
